The pointed-to type, of a pointer type, is useful information. It can be used by a translator to perform type checking and it tells readers of the source something about the pointed-to object. Converting a pointer type to pointer to **void** throws away this information, while converting a pointer to **void** to another pointer type adds information. Should this conversion process be signaled by an explicit cast, or is an implicit conversion acceptable? This issue is discussed elsewhere. The main difference between conversions involving pointer to **void** and other conversions is that they are primarily about a change of information content, not a change of value.

653 operand convert automatically

Example

```
1  extern int ei;
2  extern unsigned char euc;
3
4  void f(void *p)
5  {
6  (*(char *)p)++;
7  }
8
9  void q(void)
10 {
11 unsigned char *p_uc = &euc;
12 int *p_i = &ei;
13
14 f(p_uc);
15 f((void *)p_uc);
16
17 f(p_i);
18 f((void *)p_i);
19 }
```

---

744 A pointer to any incomplete or object type may be converted to a pointer to **void** and back again;

pointer converted to pointer to void

Commentary

This is actually a requirement on the implementation that is worded as a permission for the language user. It implies that any pointer can be converted to pointer to **void** without loss of information about which storage location is being referred to. There is no requirement that the two pointer representations be the same (except for character types), only that the converted original can be converted back to a value that compares equal to the original (see next C sentence). This sentence is a special case of wording given elsewhere, except that here there are no alignment restrictions.

558 pointer to void same representation and alignment as
758 pointer converted to pointer to different object or type

The purpose of this requirement is to support the passing of different types of pointers as function arguments, allowing a single function to handle multiple types rather than requiring multiple functions each handling a single type. This single function is passed sufficient information to enable it to interpret the pointed-to object in a meaningful way, or at least pass the pointer on to another function that does. Using a union type would be less flexible, since a new member would have to be added to the union type every time a new pointer type was passed to that function (which would be impossible to do in the interface to a third-party library).

C++

5.2.10p7 *Except that converting an rvalue of type "pointer to T1" to the type "pointer to T2" (where T1 and T2 are object types and where the alignment requirements of T2 are no stricter than those of T1) and back to its original type yields the original pointer value, the result of such a pointer conversion is unspecified.*

The C++ wording is more general than that for C. A pointer can be converted to any pointer type and back again, delivering the original value, provided the relative alignments are no stricter.

Source developed using a C++ translator may make use of pointer conversion sequences that are not required to be supported by a C translator.

Coding Guidelines

Developers who want to convert a pointer-to X into a pointer-to Y usually do so directly, using a single cast. A conversion path that goes via pointer to **void** is not seen as providing a more reliable result (it doesn't) or a more *type correct* way of doing things (it isn't).

A pointer converted to pointer to **void** and subsequently converted to a different pointer type is either unintended behavior by the developer or a case of deliberate type punning by the developer. Guideline recommendations are not intended to deal with constructs that are obviously faults, and the issue of type punning is discussed elsewhere.

guidelines 0 not faults
type punning 531 union

---

converted via pointer to void compare equal

the result shall compare equal to the original pointer. 745

Commentary

This is a requirement on the implementation. It is not the same as one specifying that the representation shall be bit-for-bit identical. The standard says nothing about the internal representation of pointers. It is possible for two pointers to compare equal and have different bit representations.

pointer 590 segmented architecture

C++

5.2.9p10 *A value of type pointer to object converted to "pointer to cv **void**" and back to the original pointer type will have its original value.*

In C++ incomplete types, other than *cv* **void**, are included in the set of object types.

Common Implementations

Implementations don't usually change the representation of a pointer value when it is cast to another pointer type. However, when the target processor has a segmented architecture, there may be a library call that checks that the value is in canonical form. On most implementations, it is very likely that when converted back the result will be bit-for-bit identical to the original value.

pointer 590 segmented architecture

---

pointer converting qualified/unqualified

For any qualifier *q*, a pointer to a non-*q*-qualified type may be converted to a pointer to the *q*-qualified version of the type; 746

Commentary

This specification is asymmetric. The specification for when a pointer to a q-qualified type is converted to a pointer to a non-q-qualified version of the type is handled by the general wording on converting object and incomplete types. Converting a pointer to a non-q-qualified type to a pointer to a q-qualified version of the type is going to possibly:

pointer 758 converted to pointer to different object or type

- Limit the operations that will be performed on it (for the **const** qualifier).

- Prevent the translator from optimizing away accesses (for the **volatile** qualifier) and reusing values already held in a register.
- Improve the quality of optimizations performed by a translator (for the **restrict** qualifier) or cause undefined behavior.

1513 restrict undefined behavior

When converting from a pointer-to non-q-qualified to a pointer-to q-qualified type, under what circumstances is it possible to guarantee that the following requirements (sometimes known as *type safe* requirements) are met:

1. A program will not attempt to change the value of an object defined using the **const** qualifier.
2. A program will not access an object defined with the **volatile** in a manner that is not a volatile-qualified access.

For instance, allowing the implicit conversion `char **` $\Rightarrow$ `char const **` would violate one of the above requirements. It could lead to a const-qualified object being modified:

```
1  char const    c  = 'X';
2  char        *pc       ;
3  char const **pcc = &pc; /* Assume this was permitted. */
4  *pcc = &c;
5  *pc = 'Y';              /* Modifies c, a const-qualified object. */
```

This example shows that simply adding the **const** qualifier within a pointer type does not automatically ensure type safety.

Smith[1260] formally proved the necessary conditions that need to hold for the two requirements listed above to be met (provided the type system was not overridden using an explicit cast). Let `T1` and `T2` be the following types, respectively:

$$T cv_{1,n} * \ldots cv_{1,1} * cv_{1,0} \tag{746.1}$$

$$T cv_{2,n} * \ldots cv_{2,1} * cv_{2,0} \tag{746.2}$$

where cv is one of nothing, **const**, **volatile**, or **const volatile**. If $T1$ and $T2$ are different, but similar pointer types, both requirements listed above are met if the following conditions are also met:

1. For every $j > 0$, if **const** is in $cv_{1,j}$, then **const** is in $cv_{2,j}$; and if **volatile** is in $cv_{1,j}$, then **volatile** is in $cv_{2,j}$.
2. If $cv_{1,j}$ and $cv_{2,j}$ are different, then **const** is in every $cv_{2,k}$ for $0 < k < j$.

The first condition requires the converted-to type to contain at least the same qualifiers as the type being converted from for all but the outermost pointer type. For the second case, $cv_{1,j}$ and $cv_{2,j}$ are different when the converted-to type contains any qualifier not contained in $cv_{2,j}$. The requirement on $cv_{2,j}$ including the **const** qualifier ensures that, once converted, a volatile-qualified value cannot be accessed.

```
1  char **    ⇒   char const * const *                  /* Is type safe.     */
2  char **    ⇒   char volatile * volatile *            /* Is not type safe. */
3  char **    ⇒   char const volatile * const volatile *  /* Is type safe.     */
```

There is an important difference of intent between the two qualifiers **const** and **volatile**, and the qualifier **restrict**. The **restrict** qualifier is not subject to some of the constraints on type qualifiers in conversions and assignments of pointers that apply to the other two qualifiers. This is because performing the semantically appropriate checks on uses of the **restrict** qualifier is likely to cause a significant overhead for

restrict 1490 requires all accesses

implementations. The burden of enforcement is placed on developers, to use **restrict** only when they know that the conditions it asserts hold true.

Applying the ideas of type safety, when assigning pointers, to restrict-qualified types leads to the conclusion that it is *safe* to assign to a less **restrict** qualified type (in the formalism used above $j = 0$ rather than $j > 0$) and *unsafe* to assign to a more restrict-qualified type (the opposite usage to that applying to uses of const- or volatile-qualified types). However, it is the *unsafe* conversions that are likely to be of most use in practice (e.g., when passing arguments to functions containing computationally intensive loops).

C++

4.4p1 *An rvalue of type "pointer to* `cv1 T` *" can be converted to an rvalue of type "pointer to* `cv2 T` *" if "* `cv2 T` *" is more cv-qualified than "* `cv1 T` *."*

4.4p2 *An rvalue of type "pointer to member of X of type* `cv1 T` *" can be converted to an rvalue of type "pointer to member of X of type* `cv2 T` *" if "* `cv2 T` *" is more cv-qualified than "* `cv1 T` *."*

Other Languages

The qualifiers available in C do not endow additional access permissions to objects having that type, they only reduce them. This situation is not always true in other languages where specific cases sometimes need to be called out.

Coding Guidelines

This C sentence describes the behavior when a conversion adds qualifiers to a pointer type. The standard does not contain a sentence that specifically discusses the behavior when conversions remove qualifiers from a pointer type. This issue is discussed elsewhere.

pointer 758 converted to pointer to different object or type

---

quali-fied/unqualified pointer compare equal

the values stored in the original and converted pointers shall compare equal. 747

Commentary

This is a requirement on the implementation. Qualifiers provide additional information on the properties of objects, they do not affect the representation of the pointer used.

pointer 559 to quali-fied/unqualified types

C++

3.9.2p3 *Pointers to cv-qualified and cv-unqualified versions (3.9.3) of layout-compatible types shall have the same value representation and alignment requirements (3.9).*

By specifying layout-compatible types, not the same type, the C++ Standard restricts the freedom of implementations more than C99 does.

Common Implementations

Qualifiers provide information that enables translators to optimize, or not, programs. It is very unlikely that the conversion operation itself will result in any machine code being generated. The likely impact (quality of machine code generated by a translator) will be on subsequent accesses using the pointer value, or the pointed-to object.

---

null pointer constant

An integer constant expression with the value 0, or such an expression cast to type **void** `*`, is called a *null pointer constant*.[55] 748

Commentary

This defines the term *null pointer constant*, which is rarely used in its full form by developers. The shortened term *null pointer* is often used to cover this special case (which technically it does do). 749 null pointer 1333 constant null pointer constant

Note that a constant expression is required— a value known at translation time. A value of zero computed during program execution is not a null pointer constant. The reason for this distinction is that the token `0` (and the sequence of tokens that includes a cast operation) is purely an external representation, in the source code, of something called a null pointer constant. The internal, execution-time value can be any sequence of bits. The integer constant expression `(1-1)`, for example, has the value `0` and could be used to denote the null pointer constant (the response to DR #261 confirmed this interpretation). However, while the value of the expression `(x-x)`, where `x` is an initialized integer object, might be known at translation time it does not denote a null pointer constant.

Developers (and implementations) often treat any cast of the value `0` to a pointer type as a null pointer constant. For instance, the expression `(char *)0` is often used to represent a null pointer constant in source code. While it is a null pointer, it is not the null pointer constant. Such usage is often a hangover from the prestandard days, before the type **`void`** was introduced.

C++

A null pointer constant is an integral constant expression (5.19) rvalue of integer type that evaluates to zero. 4.10p1

The C++ Standard only supports the use of an integer constant expression with value `0`, as a null pointer constant. A program that explicitly uses the pointer cast form need not be conforming C++; it depends on the context in which it occurs. Use of the implementation-provided `NULL` macro avoids this compatibility problem by leaving it up to the implementation to use the appropriate value.

The C++ Standard specifies the restriction that a null pointer constant can only be created at translation time.

64) Converting an integral constant expression (5.19) with value zero always yields a null pointer (4.10), but converting other expressions that happen to have value zero need not yield a null pointer. Footnote 64

Other Languages

Many languages use a reserved word, or keyword (**`nil`** is commonly seen), to represent the concept and value of the null pointer.

Common Implementations

Many implementations use an execution-time representation of all bits zero as the value of the null pointer constant. Implementations for processors that use a segmented memory architecture have a number of choices for the representation of the null pointer. The Inmos Transputer[622] has a signed address space with zero in the middle and uses the value 0x80000000 as its execution-time representation; the IBM/390 running CICS also used this value. Non-zero values were also used on Prime and Honeywell/Multics.[179] 590 pointer segmented architecture

Coding Guidelines

Technically there is a distinction between a null pointer constant and a null pointer. In practice implementations rarely make a distinction. It is debatable whether there is a worthwhile benefit in trying to educate developers to distinguish between the two terms. 749 null pointer

As the following two points show attempting to chose between using `0` and `(void *)0` involves trading off many costs and benefits:

- The literal `0` is usually thought about in arithmetic, rather than pointer, terms. A cognitive switch is needed to think of it as a null pointer constant. Casting the integer constant to pointer to **`void`** may remove the need for a cognitive switch, but without a lot of practice (to automate the process) recognizing the token sequence `(void *)0` will need some amount of conscious effort. 0 cognitive switch

- When searching source using automated tools (e.g., `grep`), matches against the literal `0` will not always denote the null pointer constant. Matches against `(void *)0` will always denote the null pointer constant; however, there are alternative character sequences denoting the same quantity (e.g., `(void*)0`).

However, there is a third alternative. The `NULL` macro is defined in a number of standard library headers. Use of this macro has the advantages that the name is suggestive of its purpose; it simplifies searches (although the same sequence of characters can occur in other names) and source remains C++ compatible. It is likely that one of the standard library headers, defining it, has already been **`#include`**d by a translation unit. If not, the cost of adding a **`#include`** preprocessor directive is minimal.

Cg 748.1

The null pointer constant shall only be represented in the visible form of source code by the `NULL` macro.

Casting the value of an object having an integer type to a pointer type makes use of undefined behavior. While the null pointer constant is often represented during program execution, by all bits zero, there is no requirement that any particular representation be used.

Example

```
1  #include <stdio.h>
2
3  extern int glob = 3;
4
5  char *p_c_1 = 0;
6  char *p_c_2 = (void *)0;
7  char *p_c_3 = 9 - 8 - 1;
8  char *p_c_4 = (1 == 2) && (3 == 4);
9  char *p_c_5 = NULL;
10
11 void f(void)
12 {
13 if (NULL != (void *)(glob - glob))
14    printf("Surprising, but possible\n");
15 }
```

---

null pointer

If a null pointer constant is converted to a pointer type, the resulting pointer, called a *null pointer*, is guaranteed to compare unequal to a pointer to any object or function. 749

Commentary

This is a requirement on the implementation. The null pointer constant is often the value used to indicate that a pointer is not pointing at an object; for instance, on a linked list or other data structure, that there are no more objects on the list. Similarly, the null pointer constant is used to indicate that no function is referred to by a pointer-to function.

The `(void *)0` form of representing the null pointer constant already has a pointer type.

C++

4.10p1 *A null pointer constant can be converted to a pointer type; the result is the null pointer value of that type and is distinguishable from every other value of pointer to object or pointer to function type.*

A null pointer constant (4.10) can be converted to a pointer to member type; the result is the null member pointer value of that type and is distinguishable from any pointer to member not created from a null pointer constant.

Presumably *distinguishable* means that the pointers will compare unequal.

Two pointers of the same type compare equal if and only if they are both null, both point to the same object or function, or both point one past the end of the same array. 5.10p1

From which we can deduce that a null pointer constant cannot point one past the end of an object either.

Other Languages

Languages that have a construct similar to the null pointer constant usually allow it to be converted to different pointer types (in Pascal it is a reserved word, **`nil`**).

Common Implementations

All bits zero is a convenient execution-time representation of the null pointer constant for many implementations because it is invariably the lowest address in storage. (The INMOS Transputer[622] had a signed address space, which placed zero in the middle.) Although there may be program bootstrap information at this location, it is unlikely that any objects or functions will be placed here. Many operating systems leave this storage location unused because experience has shown that program faults sometimes cause values to be written into the location specified by the null pointer constant (the more developer-oriented environments try to raise an exception when that location is accessed).

Another implementation technique, when the host environment does not include address zero as part of a processes address space, is to create an object (sometimes called `__null`) as part of the standard library. All references to the null pointer constant refer to this object, whose address will compare unequal to any other object or function.

---

750 Conversion of a null pointer to another pointer type yields a null pointer of that type.

null pointer conversion yields null pointer

Commentary

This is a requirement on the implementation. It is the only situation where the standard guarantees that a pointer to any type may be converted to a pointer to a completely different type, and will deliver a defined result. (Conversion to pointer to **`void`** requires the pointer to be converted back to the original type before the value is defined.)

743 pointer to void converted to/from
744 pointer converted to pointer to void

C90

The C90 Standard was reworded to clarify the intent by the response to DR #158.

Common Implementations

In most implementations this conversion leaves the representation of the null pointer unmodified and is essentially a no-op (at execution time). However, on a segmented architecture, the situation is not always so simple. For instance, in an implementation that supports both near and far pointers, a number of possible representation decisions may be made, including:

590 pointer segmented architecture

- The *near* null pointer constant might have offset zero, while the *far* null pointer constant might use an offset of zero and a segment value equal to the segment value used for all near pointers (which is likely to be nonzero because host environments tend to put their own code and data at low storage locations). When the integer constant zero is converted to a *far* null pointer constant representation, translators can generate code to create the appropriate segment offset. When objects having an integer type are converted to pointers, implementations have to decide whether they are going to treat the value as a meaningless bit pattern, or whether they are going to check for and special-case the value zero. A similar decision on treating pointer values as bit patterns or checking for special values has to be made when generating code to convert pointers to integers.

- The *near* null pointer constant might have offset zero, while the *far* null pointer constant might have both segment and offset values of zero. In this case the representation is always all bits zero; however, there are two addresses in storage that are treated as being the null pointer constant. When two pointers that refer to the same object are subtracted, the result is zero; developers invariably extend this behavior to include the subtraction of two null pointer constants (although this behavior is not guaranteed by the standard because the null pointer constant does not refer to an object). Because the null pointer constant may be represented using two different addresses in storage, implementation either has to generate code to detect when two null pointer constants are being subtracted or be willing to fail to meet developer expectations in some cases.

Debugging implementations that make use of a processor's automatic hardware checking (if available) of address accesses may have a separate representation (e.g., offset zero and a unique segment value) for every null pointer constant in the source. (This enables runtime checks to trace back dereferences of the null pointer constant to the point in the source that created the constant.)

---

null pointer compare equal

Any two null pointers shall compare equal. 751

Commentary

This is a requirement on the implementation. They compare equal using the equality operator (they are not required to have the same, bit-for-bit, representations) irrespective of their original pointer type. (There may be equality operator constraints that effectively require one or the other of the operands to be cast before the equality operation is performed.)

equality operators constraints 1213

C++

4.10p1 *Two null pointer values of the same type shall compare equal.*

4.11p1 *Two null member pointer values of the same type shall compare equal.*

The C wording does not restrict the null pointers from being the same type.

4.10p3 *The null pointer value is converted to the null pointer value of the destination type.*

This handles pointers to class type. The other cases are handled in 5.2.7p4, 5.2.9p8, 5.2.10p8, and 5.2.11p6.

Other Languages

Null pointers are usually considered a special value and compare equal, independent of the pointer type.

---

integer permission to convert to pointer

An integer may be converted to any pointer type. 752

Commentary

This is the one situation where the standard allows a basic type to be converted to a derived type. Prior to the C90 Standard, a pointer value had to be input as an integer value that was then cast to a pointer type. The `%p` qualifier was added to the `scanf` library function to overcome this problem.

Other Languages

Many other languages permit some form of integer-to-pointer type conversion. Although supporting this kind of conversion is frowned on by supporters of strongly typed languages, practical issues (it is essential in some applications) mean that only the more academic languages provide no such conversion path. Java does not permit an integer to be converted to a reference type. Such a conversion would allow the security in the Java execution-time system to be circumvented.

Common Implementations

Most implementations do not generate any machine code for this conversion. The bits in the integer value are simply interpreted as having a pointer value.

Coding Guidelines

The standard may allow this conversion to be made, but why would a developer ever want to do it? Accessing specific (at known addresses) storage locations might be one reason. Some translators include an extension that enables developers to specify an object's storage location in its definition. But this extension is only available in a few translators. Casting an integer value to a pointer delivers predictable results on a wider range of translators. The dangers of converting integer values to pointers tend to be talked about more often than the conversion is performed in practice. When such a conversion is used, it is often essential.

1348 object specifying address

In some development environments (e.g., safety-critical) this conversion is sometimes considered sufficiently dangerous that it is often banned outright. However, while use of the construct might be banned on paper, experience suggests that such usage still occurs. The justifications given to support these usages, where it is necessary to access specific storage locations, can involve lots of impressive-sounding technical terms. Such obfuscation serves no purpose. Clear rationale is in everybody's best interests. Such conversions make use of representation information and, as such, are covered by a guideline recommendation. The following wording is given as a possible deviation to this representation usage guideline recommendation:

569.1 representation information using

Dev 569.1 Values whose integer type has a rank that is less than or equal to that of the type `intptr_t` may be converted to a pointer type.

Dev 569.1 Integer values may be converted to a pointer type provided all such conversions are commented in the source code and accompanied by a rationale document.

Example

```
1   char *p_c = (char *)43;
```

---

753 Except as previously specified, the result is implementation-defined, might not be correctly aligned, might not point to an entity of the referenced type, and might be a trap representation.[56)]

integer-to-pointer implementation-defined

Commentary

This is a complete list of all the issues that need to be considered when relying on such a conversion. The integer constant zero is a special case. C does not provide any mechanisms for checking that a pointer is well-formed in the sense of being correctly aligned or pointing at an object whose lifetime has not terminated.

748 null pointer constant

There is a long-standing developer assumption that a pointer type occupies the same number of value bits as the type **long**. The growing availability of processors using 64-bit addressing support for type **long long** (which often means a 32-bit representation is used for type **long**) means that uncertainty over the minimum rank of the integer type needed to represent a pointer value is likely to grow. The introduction of the typedef name `intptr_t` is intended to solve this problem.

C++

The C++ Standard specifies the following behavior for the **reinterpret_cast**, which is equivalent to the C cast operator in many contexts.

> *A pointer converted to an integer of sufficient size (if any such exists on the implementation) and back to the same pointer type will have its original value; mappings between pointers and integers are otherwise implementation-defined.*

5.2.10p5

The C++ Standard provides a guarantee— a round path conversion via an integer type of sufficient size (provided one exists) delivers the original value. Source developed using a C++ translator may contain constructs whose behavior is implementation-defined in C.

The C++ Standard does not discuss trap representations for anything other than floating-point types.

Other Languages

The above issues are not specific to C, but generic to languages designed to run on a wide range of processors. Anything that could go wrong in one language could go equally wrong in another.

Common Implementations

Most implementations take the pattern of bits in the integer value and interpret them as a pointer value. They do not perform any additional processing on the bit pattern (address representations used by implementations are discussed elsewhere).

byte 54
address unique

Just because the equality `sizeof(char *) == sizeof(int *)` holds does not mean that the same representations are used. For instance, one Data General MV/Eclipse C compiler used different representations, although the sizes of the pointer types were the same. The IAR PICmicro compiler[612] provides access to more than 10 different kinds of banked storage. Pointers to this storage can be 1, 2, or 3 bytes in size. On such a host, the developer needs to be aware of the storage bank referred to by a particular pointer. Converting an integer type to a pointer-to type using the ILE C translator for the IBM AS/400[617] causes the right four bytes of the 16-byte pointer to hold the integer value. This pointer value cannot be dereferenced.

Coding Guidelines

representation information using 569.1

If the guideline recommendation dealing with use of representation information is followed, then this conversion will not occur. If there are deviations to this guideline recommendation, it is the developer's responsibility to ensure that the expected result is obtained. Possible deviations and situations to watch out for are not sufficiently common to enable deviations to be specified here.

---

pointer permission to convert to integer

Any pointer type may be converted to an integer type. 754

Commentary

integer 752
permission to convert to pointer

The inverse operation to the one described in a previous C sentence. Prior to the introduction of the C Standard, C90, pointer values had to be converted to integers before they could be output. The `%p` conversion specifier was added to the `printf` family of functions to overcome this problem. Pointer types are sometimes converted to integers because developers want to perform bit manipulation on the value, often followed by a conversion back to the original pointer type. Application areas that perform this kind of manipulation include garbage collectors, tagged pointers (where unused address bits are used to hold information on the pointed-to object), and other storage management functions.

C++

5.2.10p4 *A pointer can be explicitly converted to any integral type large enough to hold it.*

The C++ wording is more restrictive than C, which has no requirement that the integer type be large enough to hold the pointer.

integer-to-pointer implementation-defined 753

While the specification of the conversion behaviors differ between C++ and C (undefined vs. implementation-defined, respectively), differences in the processor architecture is likely to play a larger role in the value of the converted result.

Other Languages

There are fewer practical reasons for wanting to convert a pointer-to integer type than the reverse conversion, and languages are less likely to support this kind of conversion. Java does not permit a reference type to be converted to an integer. Such a conversion would allow the security in the Java execution-time system to be circumvented.

Common Implementations

Most implementations do not generate any machine code for this conversion. The bits in the integer value are simply interpreted as having a pointer value.

Coding Guidelines

Pointer-to-integer conversions differ from integer-to-pointer conversions in that there are likely to be fewer cases where a developer would need to perform them. The C language supports pointer arithmetic, so it is not necessary to convert the value to an integer type before incrementing or decrementing it. One use (perhaps the only real one) of such a conversion is the need to perform some nonarithmetic operation, for instance a bitwise operation, on the underlying representation. If bit manipulation is to be carried out, then type punning (e.g., a union type) is an alternative implementation strategy.

531 type punning union

Such conversions make use of representation information and as such are covered by a guideline recommendation. The following wording is given as a possible deviation to this representation usage guideline recommendation (it mirrors those suggested for integer-to-pointer conversions):

569.1 representation information using
752 integer permission to convert to pointer

Dev 569.1 A value having a pointer type may only be converted to an integer type whose rank is greater than or equal to that of the type `intptr_t`.

Dev 569.1 A value having a pointer type may only be converted to an integer type provided all such conversions are commented in the source code and accompanied by a rationale document.

Example

```
1  #include <stdint.h>
2
3  extern char *c_p;
4
5  void f(void)
6  {
7  unsigned char l_uc  = (unsigned char)c_p;
8  int           l_i   = (int)          c_p;
9  intptr_t      l_ip  = (intptr_t)     c_p;
10 uintptr_t     l_uip = (uintptr_t)    c_p;
11 long long     l_ll  = (long long)    c_p;
12 }
```

Usage

Usage information on pointer conversions is given elsewhere (see Table 758.1 and Figure 1134.1).

---

755 Except as previously specified, the result is implementation-defined.

Commentary

There is both implementation-defined and undefined behavior involved here. By specifying implementation-defined behavior, if the result can be represented, the Committee is requiring that the developer have access to information on the converted representation (in the accompanying documentation).

756 pointer conversion undefined behavior
42 implementation-defined behavior

Other Languages

Like integer-to-pointer conversions the issues tend to be generic to all languages. In many cases language specification tends to be closer to the C term *undefined behavior* rather than implementation-defined behavior.

753 integer-to-pointer implementation-defined

Common Implementations

Like integer-to-pointer conversions, most implementations simply take the value representation of a pointer and interpret the bits (usually the least significant ones if the integer type contains fewer value bits) as the appropriate integer type. Choosing a mapping such that the round trip of pointer-to-integer conversion,

integer-753 to-pointer implementation-defined

followed by integer-to-pointer conversion returns a pointer that refers to the same storage location is an objective for some implementations.

Some pointer representations contain status information, such as supervisor bits, as well as storage location information. The extent to which this information is included in the integer value can depend on the number of bits available in the value representation. Converting a pointer-to function type to an integer type using the ILE C translator for the IBM AS/400[617] always produces the result 0.

---

pointer conversion undefined behavior

If the result cannot be represented in the integer type, the behavior is undefined. 756

Commentary

The first requirement is that the integer type have enough bits to enable it to represent all of the information present in the pointer value. There then needs to be a mapping from pointer type values to the integer type.

C90

If the space provided is not long enough, the behavior is undefined.

The C99 specification has moved away from basing the specification on storage to a more general one based on representation.

C++

The C++ Standard does not explicitly specify any behavior when the result cannot be represented in the integer type. (The wording in 5.2.10p4 applies to "any integral type large enough to hold it.")

Common Implementations

Most implementations exhibit no special behavior if the result cannot be represented. In most cases a selection of bits (usually the least significant) from the pointer value is returned as the result.

The result need not be in the range of values of any integer type. 757

Commentary

This statement means that there is no requirement on the implementation to provide either an integer type capable of representing all the information in a pointer value, or a mapping if such an integer type is available

C90

The C90 requirement was based on sufficient bits being available, not representable ranges.

C++

There is no equivalent permission given in the C++ Standard.

Common Implementations

Implementation vendors invariably do their best to ensure that such a mapping is supported by their implementations. The IBM AS/400[616] uses 16 bytes to represent a pointer value (the option `datamodel` can be used to change this to 8 bytes), much larger than can be represented in any of the integer types available on that host.

Coding Guidelines

While the typedef names `intptr_t` and `uintptr_t` (specified in the library subsection) provide a mechanism for portably representing pointer values in an integer type, support for them is optional. An implementation is not required to provide definitions for them in the **<stdint.h>** header.

---

pointer converted to pointer to different object or type

pointer 743 to void converted to/from

A pointer to an object or incomplete type may be converted to a pointer to a different object or incomplete type. 758

Commentary

This is a more general case of the permission given for pointer to **void** conversions.

C++

The C++ Standard states this in 5.2.9p5, 5.2.9p8, 5.2.10p7 (where the wording is very similar to the C wording), and 5.2.11p10.

Other Languages

Many languages that support pointer types and a cast operator also support some form of conversion between different pointers.

Coding Guidelines

Experience suggests that there are two main reasons for developers wanting to convert a pointer-to object type to point at different object types:

1. Pointer-to object types are often converted to pointer-to character type. A pointer to **unsigned char** is commonly used as a method of accessing all of the bytes in an object's representation (e.g., so they can be read or written to a different object, file, or communications link). The standard specifies requirements on the representation of the type **unsigned char** in order to support this common usage. The definition of effective type also recognizes this usage,

571 unsigned char pure binary
948 effective type

2. Pointers to different structure types are sometimes cast to each other's types. This usage is discussed in detail elsewhere.

1037 union special guarantee

Pointer conversions themselves are rarely a cause of faults; it is the subsequent accesses to the referenced storage that is the source of the problems. Pointer conversion can be looked on as a method of accessing objects using different representations. As such, it is implicitly making use of representation information, something which is already covered by a guideline recommendation. Recognizing that developers do sometimes need to make use of representation information, the following wording is given as a possible deviation to this representation usage guideline recommendation:

569.1 representation information using

Dev 569.1 A pointer-to character type may be converted to a pointer-to another type having all of the qualifiers of the original pointed-to type.

Dev 569.1 A pointer may be converted to a pointer-to character type having all of the qualifiers of the original pointed-to type.

Dev 569.1 A pointer-to structure type may be converted to a different pointer-to structure type provided they share a common initial sequence.

Example

```
1  extern int *p_i;
2  extern const float *p_f;
3  extern unsigned char *p_uc;
4
5  void f(void)
6  {
7  p_uc = (unsigned char *)p_i;
8  /* ... */
9  p_uc = (unsigned char *)p_uc;
10 p_uc = (unsigned char const *)p_uc;
11 }
```

Table 758.1: Occurrence of implicit conversions that involve pointer types (as a percentage of all implicit conversions that involve pointer types). Based on the translated form of this book's benchmark programs.

To Type	From Type	%	To Type	From Type	%
`( struct * )`	`int`	44.0	`( void * )`	`int`	4.2
(function *)	`int`	18.4	`( unsigned char * )`	`int`	3.4
`( char * )`	`int`	7.9	(ptr-to *)	`int`	2.0
`( const char * )`	`int`	6.9	`( int * )`	`int`	1.9
`( union * )`	`int`	5.5	`( long * )`	`int`	1.1
(other-types *)	other-types *	4.7			

If the resulting pointer is not correctly aligned[57)] for the pointed-to type, the behavior is undefined. 759

Commentary

alignment 39

It is the pointed-to object whose alignment is being discussed here. Object types may have different alignment requirements, although the standard guarantees certain alignments. It is guaranteed that converting a pointer value pointer to **`void`** and back to the original type will produce a result that compares equal to the original value.

pointer 744 converted to pointer to void

alignment 39

What does the term *correctly* mean here? Both C implementations and processors may specify alignment requirements, but the C Standard deals with implementations (which usually take processor requirements into account). It needs to be the implementation's alignment requirements that are considered correct, if they are met. Different processors handle misaligned accesses to storage in different ways. The overhead of checking each access, via a pointer value, before it occurred would be excessive. The Committee traded off performance for undefined behavior.

C++

5.2.10p7 *Except that converting an rvalue of type "pointer to `T1`" to the type "pointer to `T2`" (where `T1` and `T2` are object types and where the alignment requirements of `T2` are no stricter than those of `T1`) and back to its original type yields the original pointer value, the result of such a pointer conversion is unspecified.*

The unspecified behavior occurs if the pointer is not cast back to its original type, or the relative alignments are stricter.

Source developed using a C++ translator may contain a conversion of a pointer value that makes use of unspecified behavior, but causes undefined behavior when processed by a C translator.

Other Languages

storage layout 1354

Alignment is an issue resulting from processor storage-layout requirements. As such the resulting undefined behavior could almost be said to be language-independent.

Common Implementations

Most implementations treat a pointer-to-pointer conversion as a no-op in the generated machine code; that is, no conversion code is actually generated. The original bit pattern is returned. The effects of alignment usually become apparent later when the object referenced by the converted pointer value is accessed. An incorrectly aligned pointer value can cause a variety of different execution-time behaviors, including raising a signal.

The Unisys A Series[1390] uses byte addresses to represent pointer-to character types and word addresses (six bytes per word) to represent pointers to other integer types. Converting a pointer to **`char`** to a pointer to **`int`** requires that the pointer value be divided by six. Unless the **`char`** object pointed to is on a 6-byte address boundary, the converted pointer will no longer point at it.

Coding Guidelines

Converting pointer type requires developers to consider a representation issue other than that of the pointed-to types alignment. The guideline recommendation dealing with use of representation information is applicable here.

39 alignment
569.1 representation information using

What if a deviation from the guideline recommendation dealing with use of representation information is made? In source code that converts values having pointer types, alignment-related issues are likely to be encountered quickly during program testing. However, pointer conversions that are correctly aligned on one processor may not be correctly aligned for another processor. (This problem is often encountered when porting a program from an Intel x86-based host, few alignment restrictions, to a RISC-based host, which usually has different alignment requirements for the different integer types.) Alignment of types, as well as representation, thus needs to be considered when creating a deviation for conversion of pointer types.

---

760 Otherwise, when converted back again, the result shall compare equal to the original pointer.

pointer converted back to pointer
745 converted via pointer to void compare equal

Commentary

This is a requirement on the implementation. It mirrors the requirement given for pointer to **void**, except that in this case there is an issue associated with the relative alignments of the two pointer types.

C++

Except that converting an rvalue of type "pointer to T1" to the type "pointer to T2" (where T1 and T2 are object types and where the alignment requirements of T2 are no stricter than those of T1) and back to its original type yields the original pointer value, the result of such a pointer conversion is unspecified.

5.2.10p7

The C++ Standard does not specify what *original pointer value* means (e.g., it could be interpreted as bit-for-bit equality, or simply that the two values compare equal).

Common Implementations

For most implementations the converted and original values are bit for bit identical, even when the target processor uses a segmented architecture. (On such processors, it is usually only the result of arithmetic operations that need to be checked for being in canonical form.)

590 pointer segmented architecture

---

761 When a pointer to an object is converted to a pointer to a character type, the result points to the lowest addressed byte of the object.

pointer converted to pointer to character object lowest addressed byte
570 object contiguous sequence of bytes

Commentary

This is a requirement on the implementation. By specifying an address, the standard makes it possible to predictably walk a pointer over the entire storage space allocated to the object (using **sizeof** to determine how many bytes it contains). The standard could equally have chosen the highest address. But common developer thinking is for addresses to refer to the beginning of an object, which is the lowest address when storage starts at zero and increases. The vast majority of processors have an address space that starts at zero (the INMOS Transputer[622] has a signed address space). Instructions for loading scalars from a given address invariably assume that successive bytes are at greater addresses.

The lowest address of an object is not required to correspond to the least significant byte of that object, if it represents a scalar type.

C90

The C90 Standard does not explicitly specify this requirement.

C++

4.10p2

The result of converting a "pointer to `cv` *T" to a "pointer to* `cv void`*" points to the start of the storage location where the object of type T resides, . . .*

However, the C wording is for pointer-to character type, not pointer to **`void`**.

3.9.2p4 *A cv-qualified or cv-unqualified (3.9.3)* `void*` *shall have the same representation and alignment requirements as a cv-qualified or cv-unqualified* `char*`.

5.2.10p7 *A pointer to an object can be explicitly converted to a pointer to an object of different type[65]. Except that converting an rvalue of type "pointer to T1" to the type "pointer to T2" (where T1 and T2 are object types and where the alignment requirements of T2 are no stricter than those of T1) and back to its original type yields the original pointer value, the result of such a pointer conversion is unspecified.*

The C++ Standard does not require the result of the conversion to be a pointer to the lowest addressed byte of the object. However, it is very likely that C++ implementations will meet the C requirement.

Other Languages

Most languages do not get involved in specifying this level of detail.

Coding Guidelines

representation information using 569.1

Needing to know that an address refers to the lowest addressed byte of an object suggests that operations are performed at this level of implementation detail (which violates the guideline recommendation dealing with use of representation information). However, there are situations where the specification of different functionality, in the standard, is interconnected. For instance, the specification of the `memcpy` library function needs to know whether the addresses passed to it points at the lowest or highest byte.

Dev 569.1

A program may depend on the lowest address of a byte being returned by the address-of operator (after conversion to pointer-to character type) when the result is either passed as an argument to a standard library function defined to accept such a value, or assigned to another object that is used for that purpose.

---

footnote 55

55) The macro **`NULL`** is defined in **`<stddef.h>`** (and other headers) as a null pointer constant; see 7.17. 762

Commentary

It is also defined in the headers **`<locale.h>`**, **`<stdio.h>`**, **`<stdlib.h>`**, **`<string.h>`**, **`<time.h>`**, and **`<wchar.h>`**.

Other Languages

Many languages defined a reserved word to represent the null pointer constant. The word **`nil`** is often used.

Coding Guidelines

null pointer constant 748

Some existing source code provides its own definition of this macro rather than **`#include`**ing the appropriate header. Given that the value of the null pointer constant is defined by the standard this usage would appear to be harmless.

---

footnote 56 pointer/integer consistent mapping

56) The mapping functions for converting a pointer to an integer or an integer to a pointer are intended to be consistent with the addressing structure of the execution environment. 763

Commentary

Allowing conversions between pointers and integers is of no practical use unless implementations are willing to go along with developers' expectations of being able to convert pointers in some meaningful way. One, formally validated, C90 implementation[681] represents pointers as an index into an array (the array holding the base address of the actual object and the offset within it). In this implementation a pointer-to integer conversion yielded the value of the array index, not the actual address of the object. While presence of this footnote does not prevent such an implementation from conforming to C99, its behavior might limit the number of product sales made.

C++

[Note: it is intended to be unsurprising to those who know the addressing structure of the underlying machine.] 5.2.10p4

Is an unsurprising mapping the same as a consistent one? Perhaps an unsurprising mapping is what C does. :-)

Other Languages

While languages do not get involved in this level of detail, their implementations often pander to developer expectations.

Common Implementations

The intended execution environments addressing structure is the one visible to an executing program. The extent to which the underlying hardware addressing is visible to programs varies between target processors. A processor may have a linear address space at the physical level, but at the logical level the addressing structure could be segmented. It is likely to be in vendors' commercial interest for their implementations to support some form of meaningful mapping. 590 pointer segmented architecture

Some of the issues involved in representing the null point constant in a consistent manner are discussed elsewhere. 748 null pointer constant

Coding Guidelines

This footnote expresses the assumption that C developers might want to convert between integer and pointer types in some meaningful way. Such usage is making use of representation information and is covered by a guideline recommendation. 569.1 representation information using

---

764 57) In general, the concept "correctly aligned" is transitive: if a pointer to type A is correctly aligned for a pointer to type B, which in turn is correctly aligned for a pointer to type C, then a pointer to type A is correctly aligned for a pointer to type C. footnote 57

Commentary

Your author knows of no implementations where the concept *correctly aligned* is not transitive.

C90

This observation was not explicitly specified in the C90 Standard.

C++

The C++ Standard does not point out that alignment is a transitive property.

---

765 Successive increments of the result, up to the size of the object, yield pointers to the remaining bytes of the object. object point at each bytes of

Commentary

Here the standard is specifying the second of the two requirements needed to allow strictly conforming C code to handle objects as a sequence of bytes, via a pointer-to character type (the other is that the address of

byte 54 address unique
sizeof char 1124 defined to be 1
object 570 contiguous sequence of bytes
array 526 contiguously allocated set of objects
value 573 copied using unsigned char
pointer 1169 one past end of object

individual bytes is unique). The increment value here being `sizeof(unsigned char)`, which is defined to be 1.

The standard specifies elsewhere that the bytes making up an object are contiguously allocated. There is also a guarantee to be able to increment the result one past the end of the object.

C90

The C90 Standard does not explicitly specify this requirement.

C++

The equivalent C++ requirement is only guaranteed to apply to pointer to **`void`** and it is not possible to perform arithmetic on this pointer type. However, in practice C++ implementations are likely to meet this C requirement.

Other Languages

Most languages do not support the concept of converting a pointer-to character type for the purpose of accessing the bytes of the pointed-to object. However, this concept is sometimes used by developers in other languages (they have to make use of particular implementation details that are not given any language standard's blessing).

Coding Guidelines

Pointing at the individual bytes making up an object is one of the steps involved in making use of representation information. The applicable coding guideline discussion is the one dealing with the overall general issue of using representation information complete process, not the individual steps involved.

types 569 representation

---

pointer to function converted

A pointer to a function of one type may be converted to a pointer to a function of another type and back again; 766

Commentary

pointer 758 converted to pointer to different object or type

This is a requirement on the implementation. It mimics the one specified for pointer-to object conversions. The standard is silent on the issue of converting a pointer-to function type to a pointer-to object type. As such the behavior is implicitly undefined.

Other Languages

Few languages support pointers to functions. Some languages allow objects to have a function type, they can be assigned references to functions but are not treated as pointers. Those languages that do support some form of indirect function call via objects do not always support casting of function types.

Common Implementations

Most implementations use the same representation for pointers to objects and pointers to functions (the pointer value being the address of the function in the program's address space). The C compiler for the Unisys e-@ction Application Development Solutions[1391] returns the value 32 when **`sizeof`** is applied to a pointer-to function and 8 when it is applied to a pointer-to object.

call function 768 via converted pointer

Although pointers to different function types usually have the same representation and alignment requirements, the same cannot be said for their argument-passing conventions. Some implementations represent a pointer-to function type as an index into a table. This approach is sometimes used to provide a form of memory management, in software, when this is not provided by the target host hardware. Accessing functions via an index into a table, rather than jumping directly to their address in memory, provides the hook for a memory manager to check if the machine code for a function needs to be swapped into memory because it has been called (and potentially another function machine code swapped out).

The IAR PICmicro compiler[612] offers four different storage banks that pointers to functions can refer to. Part of the information needed to deduce the address of a function is the storage bank that contains it (the translator obtains this information from the declaration of each pointer type). The value of a pointer-to function may be assigned to another object having a pointer-to function type, but information on the bank it refers to is not part of the value representation. If two pointers to function refer to different storage banks, it

is not possible to call a function referred to by one via the other. This compiler also provides a mechanism for specifying which storage bank is to be used to pass the arguments in a call to a particular function.

Coding Guidelines

Pointers to functions are usually converted to another pointer type for the same reasons as pointer-to object types are converted to pointer to **void**; the desire for a single function accepting arguments that have different pointer-to function types. Manipulation of functions as pointer values is not commonly seen in code and developers are likely to have had little practice in reading or writing the types involved. The abstract declarator that is the pointer-to function type used in the conversion tends to be more complex than most other types, comprising both the return type and the parameter information. This type also needs to be read from the inside out, not left-to-right.

744 pointer converted to pointer to void

1624 abstract declarator syntax

Is there a pointer-to function type equivalent to the pointer to **void** type for pointer-to function conversions? The keyword **void** is an explicit indicator that no information is available. In the case of pointer-to function conversions either the return type, or the parameter type, or both could be unknown.

Example

```
1   extern int f_1(int (*)(void));
2   extern int f_2(void (*)(int, char));
3
4   extern int g_1a(int);
5   extern int g_1b(long);
6   extern long g_2a(int, char);
7   extern float g_2b(int, char);
8
9   void h(void)
10  {
11  f_1((int (*)(void))g_1a);
12  f_1((int (*)(void))g_1b);
13
14  f_2((void (*)(int, char))g_2a);
15  f_2((void (*)(int, char))g_2b);
16  }
```

---

767 the result shall compare equal to the original pointer.

Commentary

This is a requirement on the implementation. This is the only guarantee on the properties of pointer-to function conversion. It mimics that given for pointer-to object conversions.

760 pointer converted back to pointer

Other Languages

Those languages that do support some form of indirect function call, via values held in objects, often support equality comparisons on the values of such objects, even if they do not support conversions on these types.

Example

```
1   extern int f(void);
2
3   void g(void)
4   {
5   if ((int (*)(void))(int (*)(float, long long))f != f)
6      ; /* Complain. */
7   }
```

call function via converted pointer

If a converted pointer is used to call a function whose type is not compatible with the pointed-to type, the behavior is undefined. 768

Commentary

In practice the representation of pointers to functions is rarely dependent on the type of the function (although it may be different from the representation used for pointers to objects). The practical issue is one of argument-passing. It is common practice for translators to use different argument passing conventions for functions declared with different parameters. (It may depend on the number and types of the parameters, or whether a prototype is visible or not.) For instance, an implementation may pass the first two arguments in registers if they have integer type; but on the stack if they have any other type. The code generated by a translator for the function definition and calls to it are aware of this convention. If a pointer to a function whose first parameter has a structure type (whose first member is an integer) is cast to a pointer to a function whose first parameter is the same integer type (followed by an ellipsis), a call via the converted pointer will not pass the parameters in the form expected by the definition (the first member of the structure will not be passed in a register, but on the stack with all the other members).

C++

5.2.10p6 *The effect of calling a function through a pointer to a function type (8.3.5) that is not the same as the type used in the definition of the function is undefined.*

compatible type if 631

C++ requires the parameter and return types to be the same, while C only requires that these types be compatible. However, the only difference occurs when an enumerated type and its compatible integer type are intermixed.

Common Implementations

In the majority of implementations a function call causes a jump to a given address. The execution of the machine instructions following that address will cause accesses to the storage locations or registers, where the argument values are expected to have been assigned to. Thus the common undefined behavior will be to access these locations irrespective of whether anything has been assigned to them (potentially leading to other undefined behaviors).

Coding Guidelines

Conversions involving pointer-to function types occur for a variety of reasons. For instance, use of callback functions, executing machine code that is known to exist at a given storage location (by converting an integer value to pointer-to function), an array of pointer-to function (an indirect call via an array index being deemed more efficient, in time and/or space, than a **switch** statement). While indirect function calls are generally rare, they do occur relatively often in certain kinds of applications (e.g., callbacks in GUI interface code, dispatchers in realtime controllers).

Example

```
1  extern void f(void);
2
3  extern int (*p_f_1)(void);
4  extern int (*p_f_2)(int);
5  extern int (*p_f_3)(char, float);
6  extern int (*p_f_4)();
7
8  int (*p_f_10)(void) = (int (*)(void))f;
9  long (*p_f_11)(int) = (long (*)(int))f;
10 int (*p_f_12)(char, float) = (int (*)(char, float))f;
11 int (*p_f_13)() = (int (*)())f;
```

```
12
13  void f(void)
14  {
15  ((int (*)())p_f_1)();
16  ((int (*)(int))p_f_1)(2);
17  ((void (*)(void))p_f_1)();
18  ((int (*)())p_f_2)();
19  ((int (*)(float, char))p_f_3)(1.2, 'q');
20  ((int (*)(void))p_f_4)();
21  }
```

769 **Forward references:** cast operators (6.5.4), equality operators (6.5.9), integer types capable of holding object pointers (7.18.1.4), simple assignment (6.5.16.1).

6.4 Lexical elements

token syntax preprocessing token syntax

770

token:
keyword
identifier
constant
string-literal
punctuator

preprocessing-token:
header-name
identifier
pp-number
character-constant
string-literal
punctuator
each non-white-space character that cannot be one of the above

Commentary

Tokens (preprocessor or otherwise) are the atoms from which the substance of programs are built. Preprocessing tokens are created in translation phase 3 and are turned into tokens in translation phase 7.

124 translation phase 3
136 translation phase

All characters in the basic source character set can be used to form some kind of preprocessing token that is defined by the standard. When creating preprocessing tokens the first non-white-space character is sufficient, in all but one case, to determine the kind of preprocessing token being created.

punctuator 912 syntax
header name 918 syntax

The two characters, double-quote and single-quote, must occur with their respective matching character if they are to form a defined preprocessor-token. The special case of them occurring singly, which matches against "non-white-space character that cannot be one of the above," is dealt with below. The other cases that match against *non-white-space character that cannot be one of the above* involve characters that are outside of the basic source character set. A program containing such extended characters need not result in a constraint violation, provided the implementation supports such characters. For instance, they could be stringized prior to translation phase 7, or they could be part of a preprocessor-token sequence being skipped as part of a conditional compilation directive.

character 776 ' or " matches
basic source character set 221
extended characters 215
preprocessing token 771 shall have lexical form
1950 operator

The header-name preprocessing token is context-dependent and only occurs in the **#include** preprocessing directive. It never occurs after translation phase 4.

#include 1897 h-char-sequence

C90

The *non-terminal* operator was included as both a *token* and *preprocessing-token* in the C90 Standard. Tokens that were operators in C90 have been added to the list of punctuators in C99.

C++

C++ maintains the C90 distinction between operators and punctuators. C++ also classifies what C calls a constant as a literal, a string-literal as a literal and a C character-constant is known as a character-literal.

Other Languages

Few other language definitions include a preprocessor. The PL/1 preprocessor includes syntax that supports some statements having the same syntax as the language to be executed during translation.

Some languages (e.g., PL/1) do not distinguish between keywords and identifiers. The context in which a name occurs is used to select the usage to which it is put. Other languages (e.g., Algol 60) use, conceptually, one character set for keywords and another for other tokens. In practice only one character set is available. In books and papers the convention of printing keywords in bold was adopted. A variety of conventions were used for writing Algol keywords in source, including using an underline facility in the character encodings, using matching single-quote characters, or simply all uppercase letters.

Common Implementations

The handling of "each non-white-space character that cannot be one of the above" varies between implementations. In most cases an occurrence of such a preprocessing token leads to a syntax or constraint violation.

Coding Guidelines

Most developers are not aware of that preprocessing-tokens exist. They think in terms of a single classification of tokens— the token. The distinction only really becomes noticeable when preprocessing-tokens that are not also tokens occur in the source. This can occur for pp-number and the "each non-white-space character that cannot be one of the above" and is discussed elsewhere. There does not appear to be a worthwhile benefit in educating developers about preprocessing-tokens.

pp-number 927 syntax

Summary

The following two sections provide background on those low-level visual processing operations that might be applicable to source code. The first section covers what is sometimes called *early vision*. This phase of vision is carried out without apparent effort. The possibilities for organizing the visual appearance of source code to enable it to be visually processed with no apparent effort are discussed. At this level the impact of individual characters is not considered, only the outline image formed by sequences (either vertically or horizontally) of characters. The second section covers eye movement in reading. This deals with the processing of individual, horizontal sequences of characters. To some extent the form of these sequences is under the control of the developer. Identifiers (whose spelling is under developer-control) and space characters make up a large percentage of the characters on a line.

The early vision factors that appear applicable to C source code are proximity, edge detection, and distinguishing features. The factors affecting eye movement in reading are practice related. More frequently encountered words are processed more quickly and knowledge of the frequency of letter sequences is used to decide where to move the eyes next.

770 reading practice
770 letter detection

The discussion assumes a 2-D visual representation; although 3-D visualization systems have been developed[1285] they are still in their infancy.

1 Early vision

One of the methods used by these coding guidelines to achieve their stated purpose is to make recommendations that reduce the cognitive load needed to read source code. This section provides an overview of some of the operations the human visual system can perform without requiring any apparent effort. The experimental evidence[1130] suggests that the reason these operations do not create a cognitive load is that they occur before the visual stimulus is processed by the human cognitive system. The operations occur in what is known as *early vision*. Knowledge of these operations may be of use in deciding how to organize the visible appearance of token sequences (source code layout).

vision early

0 coding guidelines introduction

The display source code uses a subset of the possible visual operations that occur in nature. It is nonmoving, two-dimensional, generally uses only two colors, items are fully visible (they are not overlayed), and edges are rarely curved. The texture of the display is provided by the 96 characters of the source character set (in many cases a limited number of additional characters are also used). Given that human visual processing is tuned to extract important information from natural scenes,[580] it is to be expected that many optimized visual processes will not be applicable to viewing source code.

214 source character set

1.1 Preattentive processing

Some inputs to the human visual system appear to *pop-out* from their surroundings. Preattentive processing, so called because it occurs before conscious attention, is automatic and apparently effortless. The examples in Figure 770.1 show some examples of features that *pop-out* at the reader.

vision preattentive

Preattentive processing is independent of the number of distractors; a search for the feature takes the same amount of time whether it occurs with one, five, ten, or more other distractors. However, the disadvantage is that it is only effective when the features being searched for are relatively rare. When a display contains many different, distinct features (the mixed category in Figure 770.1), the *pop-out* effect does not occur. The processing abilities demonstrated in Figure 770.1 are not generally applicable to C source code for a number of reasons.

221 basic source character set

- C source code is represented using a fixed set of characters. Opportunities for introducing *graphical effects* into source code are limited. The only, universally available technique for controlling the visual appearance of source code is white space.
- While there are circumstances when a developer might want to attend to a particular identifier, or declaration, in general there are no constructs that need to *pop-out* to all readers of the source. Program development environments may highlight (using different colors) searched for constructs, dependencies between constructs, or alternative representations (for instance, call graphs), but these are temporary requirements that change over short periods of time, as the developer attempts to comprehend source code.

1.2 Gestalt principles

Founded in 1912 the Gestalt school of psychology proposed what has become known as the *Gestalt laws of perception* (*gestalt* means *pattern* in German); they are also known as the *laws of perceptual organization*. The underlying idea is that the whole is different from the sum of its parts. These so-called *laws* do not have the rigour expected of a scientific law, and really ought to be called by some other term (e.g., principle). The following are some of the more commonly occurring principles

gestalt principles

- **Proximity**: Elements that are close together are perceptually grouped together (see Figure 770.2).

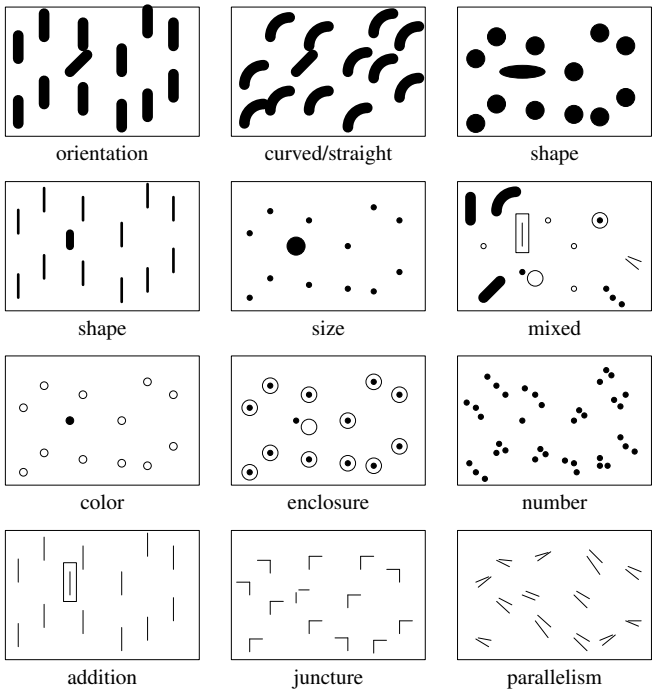

Figure 770.1: Examples of features that may be preattentively processed (parallel lines and the junction of two lines are the odd ones out). Adapted from Ware.[1441]

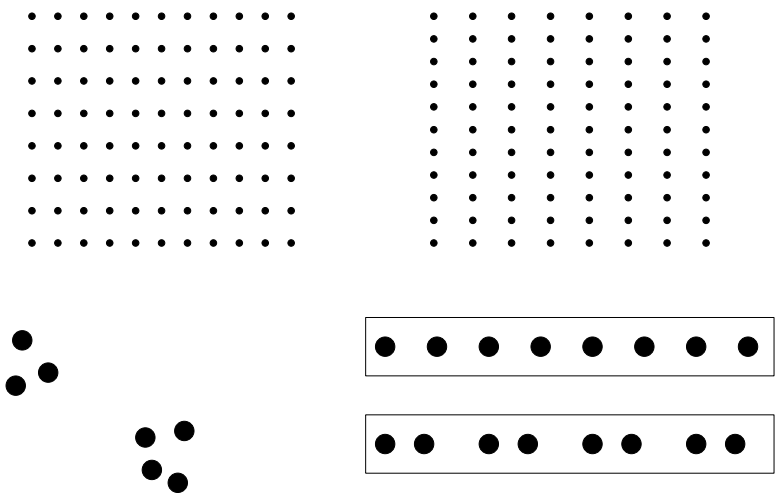

Figure 770.2: Proximity— the horizontal distance between the dots in the upper left image is less than the vertical distance, causing them to be perceptually grouped into lines (the relative distances are reversed in the upper right image).

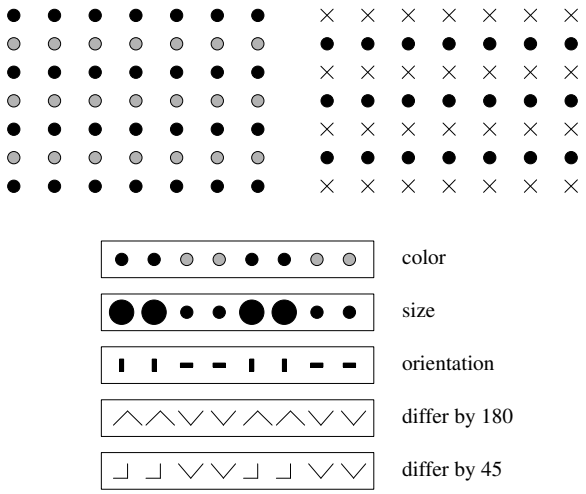

Figure 770.3: Similarity— a variety of dimensions along which visual items can differ sufficiently to cause them to be perceived as being distinct; rotating two line segments by 180° does not create as big a perceived difference as rotating them by 45°.

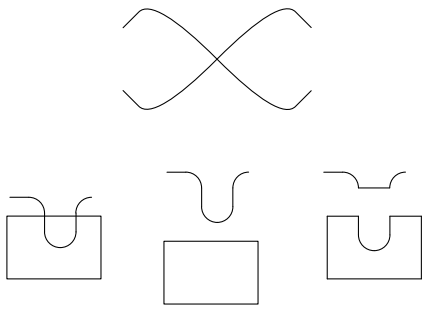

Figure 770.4: Continuity— upper image is perceived as two curved lines; the lower-left image is perceived as a curved line overlapping a rectangle rather than an angular line overlapping a rectangle having a piece missing (lower-right image).

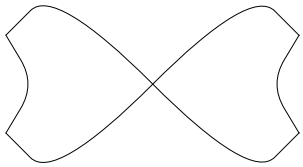

Figure 770.5: Closure— when the two perceived lines in the upper image of Figure 770.4 are joined at their end, the perception changes to one of two cone-shaped objects.

- **Similarity**: Elements that share a common attribute can be perceptually grouped together (see Figure 770.3).
- **Continuity**, also known as **Good continuation**: Lines and edges that can be seen as smooth and continuous are perceptually grouped together (see Figure 770.4). continuation gestalt principle of
- **Closure**: Elements that form a closed figure are perceptually grouped together (see Figure 770.5).
- **Symmetry**: Treating two, mirror image lines as though they form the outline of an object (see Figure 770.6). This effect can also occur for parallel lines.
- **Other** principles include grouping by connectedness, grouping by common region, and synchrony.[1047]

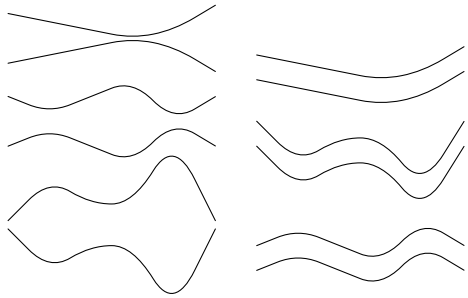

Figure 770.6: Symmetry and parallelism— where the direction taken by one line follows the same pattern of behavior as another line.

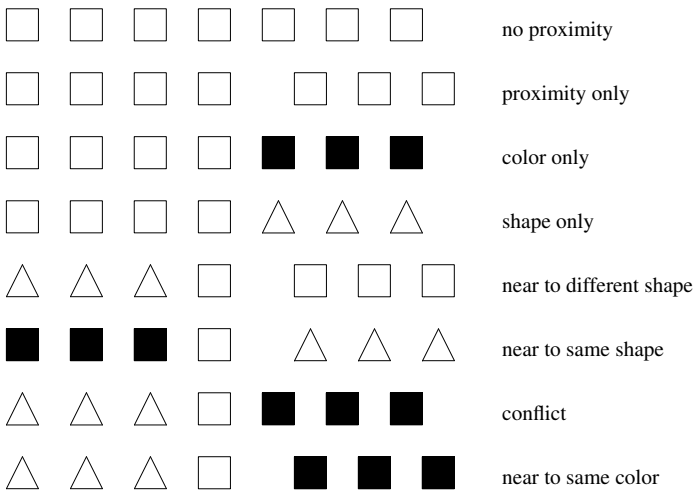

Figure 770.7: Conflict between proximity, color, and shape. Based on Quinlan.[1132]

The organization of visual grouping of elements in a display, using these principles, is a common human trait. However, when the elements in a display contain instances of more than one of these perceptual organization principles, people differ in their implicit selection of principle used. A study by Quinlan and Wilton[1132] found that 50% of subjects grouped the elements in Figure 770.7 by proximity and 50% by similarity. They proposed the following, rather incomplete, algorithm for deciding how to group elements:

1. Proximity is used to initially group elements.
2. If there is a within-group attribute mismatch, but a match between groups, people select between either a proximity or a similarity grouping (near to different shape in Figure 770.7).
3. If there is a within-group and between-group attribute mismatch, then proximity is ignored. Grouping is then often based on color rather than shape (near to same color and near to same shape in Figure 770.7).

Recent work by Kubovy and Gepshtein[779] has tried to formulate an equation for predicting the grouping of rows of dots. Will the grouping be based on proximity or similarity? They found a logarithmic relationship between dot distance and brightness that is a good predictor of which grouping will be used.

The symbols available to developers writing C source provide some degree of flexibility in the control of its visual appearance. The appearance is also affected by parameters outside of the developers' control—for instance, line and intercharacter spacing. While developers may attempt to delineate sections of source

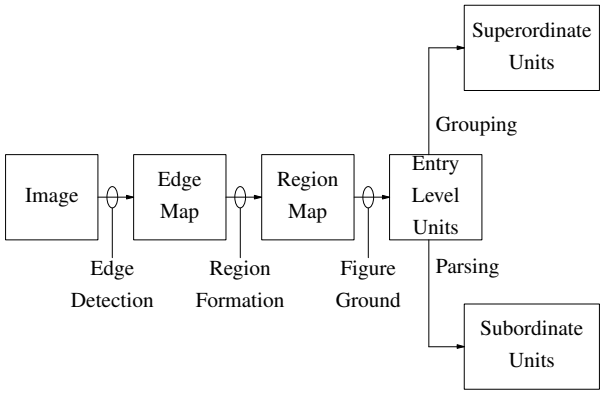

Figure 770.8: A flowchart of Palmer and Rock's[1047] theory of perceptual organization.

using white space and comments, the visual impact of the results do not usually match what is immediately apparent in the examples of the Gestalt principles given above. While instances of these principles may be used in laying out particular sequences of code, there is no obvious way of using them to create generalized layout rules. The alleged benefits of particular source layout schemes invariably depend on practice (a cost). The Gestalt principles are preprogrammed (i.e., there is no conscious cognitive cost). These coding guidelines cannot perform a cost/benefit analysis of the various code layout rules because your author knows of no studies, using experienced developers, investigating this topic.

770 reading practice

1.3 Edge detection

The striate cortex is the visual receiving area of the brain. Neurons within this area respond selectively to the orientation of edges, the direction of stimulus movement, color along several directions, and other visual stimuli. In Palmer and Rock's[1047] theory of perceptual organization, edge detection is the first operation performed on the signal that appears as input to the human visual system. After edges are detected, regions are formed, and then figure–ground principles operate to form entry-level units (see Figure 770.8).

C source is read from left to right, top to bottom. It is common practice to precede the first non-white-space character on a sequence of lines to start at the same horizontal position. This usage has been found to reduce the effort needed to visually process lines of code that share something in common; for instance, statement indentation is usually used to indicate block nesting.

Edge detection would appear to be an operation that people can perform with no apparent effort. An edge can also be used to speed up the search for an item if it occurs along an edge. In the following sequences of declarations, less effort is required to find a particular identifier in the second two blocks of declarations. In the first block the reader first has to scan a sequence of tokens to locate the identifier being declared. In the other two blocks the locations of the identifiers are readily apparent. Use of edges is only part of the analysis that needs to be carried out when deciding what layout is likely to minimize cognitive effort. These analyses are given for various constructs elsewhere.

reading kinds of 770

Searching is only one of the visual operations performed on source. Systematic line-by-line, token-by-token reading is another. The extent to which the potentially large quantities of white space introduced to create edges increases the effort required for systematic reading is unknown. For instance, the second block (previous code example) maintains the edge at the start of the lines at which systematic reading would start, but at the cost of requiring a large saccade to the identifier. The third block only requires a small saccade to the identifier, but there is no edge to aid in the location of the start of a line.

Saccade 770

1.4 Reading practice

reading practice

expertise 0

A study by Kolers and Perkins[761] offers some insight into the power of extended practice. In this study subjects were asked to read pages of text written in various ways; pages contained, normal, reversed, inverted, or mirrored text.

```
Expectations can also mislead us; the unexpected is always hard to
perceive clearly.  Sometimes we fail to recognize an object because we

power law of learning 0

The time taken for subjects to read a page of text in a particular orientation was measured. The more pages subjects read, the faster they became. This is an example of the power law of learning. A year later Kolers[760] measured the performance of the same subjects, as they read more pages. Performance improved with practice, but this time the subjects had past experience and their performance started out better and improved more quickly (see Figure 770.9). These results are similar to those obtained in the letter-detection task.

letter detection 770

Just as people can learn to read text written in various ways, developers can learn to read source code laid out in various ways. The important issue is not developers' performance with a source code layout they have extensive experience reading, but their performance on a layout they have little experience reading. For instance, how quickly can they achieve a reading performance comparable to that achieved with a familiar layout (based on reading and error rate). The ideal source code layout is one that can be quickly learned and has a low error rate (compared with other layouts).

reading practice 770

Unfortunately there are no studies, using experienced developers, that compare the effects of different source code layout on reading performance. Becoming an experienced developer can be said to involve learning to read source that has been laid out in a number of different ways. The visually based guidelines in this book do not attempt to achieve an optimum layout, rather they attempt to steer developers away from layouts that are likely to be have high error rates.

Many developers believe that the layout used for their own source code is optimal for reading by themselves, and others. It may be true that the layout used is optimal for the developer who uses it, but the reason for this

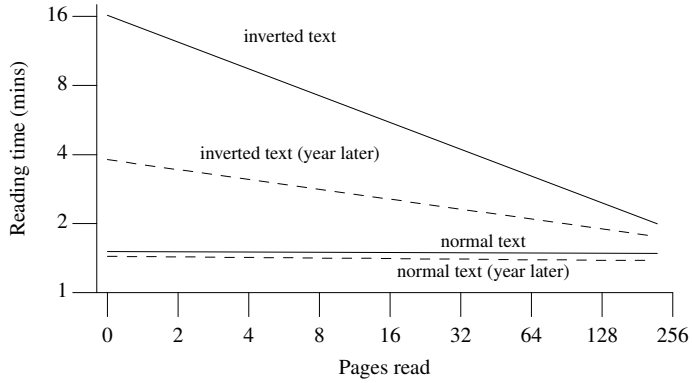

Figure 770.9: The time taken for subjects to read a page of text in a particular orientation, as they read more pages. Results are for the same six subjects in two tests more than a year apart. Based on Kolers.[760]

is likely to be practice-based rather than any intrinsic visual properties of the source layout. Other issues associated with visual code layout are discussed in more detail elsewhere.

1348 declaration visual layout
1707 statement visual layout

1.5 Distinguishing features

distinguishing features

A number of studies have found that people are more likely to notice the presence of a distinguishing feature than the absence of a distinguishing feature. This characteristic affects performance when searching for an item when it occurs among visually similar items. It can also affect reading performance— for instance, substituting an *e* for a *c* is more likely to be noticed than substituting a *c* for an *e*.

A study by Treisman and Souther[1363] found that visual searches were performed in parallel when the target included a unique feature (search time was not affected by the number of background items), and searches were serial when the target had a unique feature missing (search time was proportional to the number of background items). These results were consistent with Treisman and Gelade's[1364] feature-integration theory.

What is a unique feature? Treisman and Souther investigated this issue by having subjects search for circles that differed in the presence or absence of a gap (see Figure 770.10). The results showed that subjects were able to locate a circle containing a gap, in the presence of complete circles, in parallel. However, searching for a complete circle, in the presence of circles with gaps, was carried out serially. In this case the gap was the unique feature. Performance also depended on the proportion of the circle taken up by the gap.

As discussed in previous subsections, C source code is made up of a fixed number of different characters. This restricts the opportunities for organizing source to take advantage of the search asymmetry of preattentive processing. It is important to remember the preattentive nature of parallel searching; for instance, comments are sometimes used to signal the presence of some construct. Reading the contents of these comments would require attention. It is only their visual presence that can be a distinguishing feature from the point of view of preattentive processing. The same consideration applies to any organizational layout using space characters. It is the visual appearance, not the semantic content that is important.

1.6 Visual capacity limits

A number of studies have looked at the capacity limits of visual processing.[426, 1419] Source code is visually static, that is it does not move under the influence of external factors (such as the output of a dynamic trace of an executing program might). These coding guidelines make the assumption that the developer-capacity bottleneck occurs at the semantic level, not the visual processing stage.

2 Reading (eye movement)

Reading eye movement

While C source code is defined in terms of a sequence of ordered lines containing an ordered sequence of characters, it is rarely read that way by developers. There is no generally accepted theory for how developers read source code, at the token level, so the following discussion is necessarily broad and lacking in detail. Are

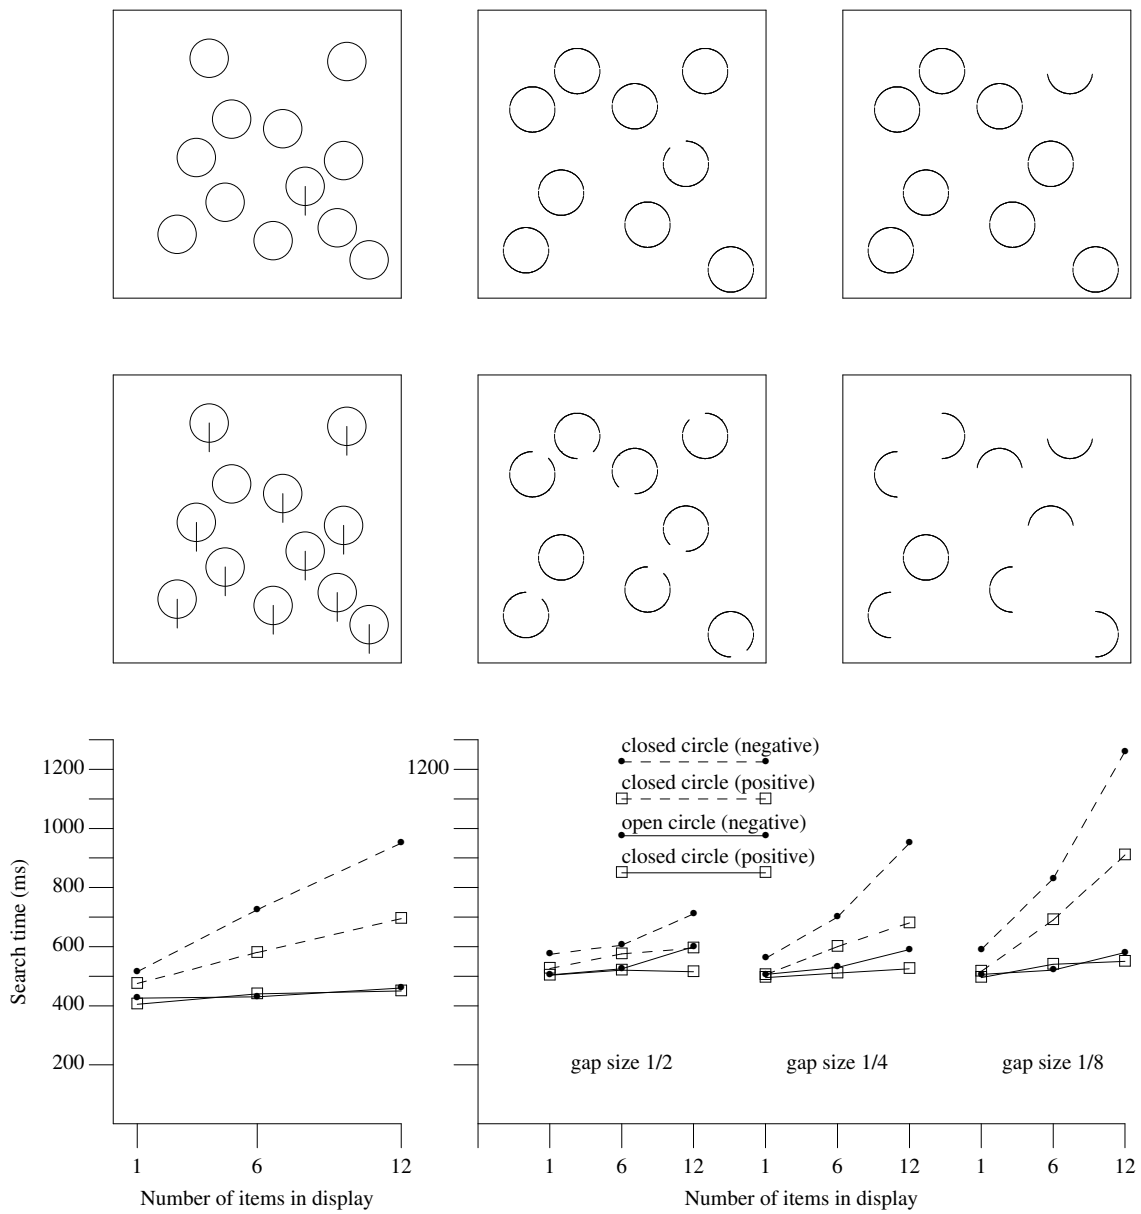

Figure 770.10: Examples of unique items among visually similar items. Those at the top include an item that has a distinguishing feature (a vertical line or a gap); those underneath them include an item that is missing this distinguishing feature. Graphs represent time taken to locate unique items (positive if it is present, negative when it is not present) when placed among different numbers of visibly similar distractors. Based on displays used in the study by Treisman and Sother.[1363]

there any organizational principles of developers' visual input that can be also be used as visual organizational principles for C source code?

Developers talk of reading source code; however, reading C source code differs from reading human language prose in many significant ways, including:

- It is possible, even necessary, to create new words (identifiers). The properties associated with these words are decided on by the author of the code. These words might only be used within small regions of text (their scope); their meaning (type) and spelling are also under the control of the original developer.
- Although C syntax specifies a left-to-right reading order (which is invariably presented in lines that read from the top, down), developers sometimes find it easier to comprehend statements using either a right-to-left reading, or even by starting at some subcomponent and working out (to the left and right) or lines reading from the bottom, up.
- Source code is not designed to be a spoken language; it is rare for more than short snippets to be verbalized. Without listeners, developers have not needed to learn to live (write code) within the constraints imposed by realtime communication between capacity-limited parties.
- The C syntax is not locally ambiguous. It is always possible to deduce the syntactic context, in C, using a lookahead of a single word[770.1] (the visible source may be ambiguous through the use of the preprocessor, but such usage is rare and strongly recommended against). This statement is not true in C++ where it is possible to write source that requires looking ahead an indefinite number of words to disambiguate a localized context.
- In any context a word has a single meaning. For instance, it is not necessary to know the meaning (after preprocessing) of `a`, `b` and `c`, to comprehend `a=b+c`. This statement is not true in computer languages that support overloading, for instance C++ and Java.
- Source code denotes operations on an abstract machine. Individually the operations have no external meaning, but sequences of these operations can be interpreted as having an equivalence to a model of some external *real-world* construct. For instance, the expression `a=b+c` specifies the abstract machine operations of adding `b` to `c` and storing the resulting value in `a`; its interpretation (as part of a larger sequence of operations) might be *move on to the next line of output*. It is this semantic mapping that creates cognitive load while reading source code. When reading prose the cognitive load is created by the need to disambiguate word meaning and deduce a parse using known (English or otherwise) syntax.

Reading and writing is a human invention, which until recently few people could perform. Consequently, human visual processing has not faced evolutionary pressure to be good at reading.

While there are many differences between reading code and prose, almost no research has been done on reading code and a great deal of research has been done on reading prose. The models of reading that have been built, based on the results of prose-related research, provide a starting point for creating a list of issues that need to be considered in building an accurate model of code reading. The following discussion is based on papers by Rayner[1147] and Reichle, Rayner, and Pollatsek.[1154]

Saccade

During reading, a person's eyes make short rapid movements. These movements are called *saccades* and take 20 ms to 50 ms to complete. No visual information is extracted during these saccades and readers are not consciously aware that they occur. A saccade typically moves the eyes forward 6 to 9 characters. Between saccades the eyes are stationary, typically for 200 ms to 250 ms (a study of consumer eye movements[1086] while comparing multiple brands found a fixation duration of 354 ms when subjects were under high time pressure and 431 ms when under low time pressure). These stationary time periods are called *fixations*. Reading can be compared to watching a film. In both cases a stationary image is available for information

[770.1] There is one exception—for the token sequence `void func (a, b, c, d, e, f, g)`. It is not known whether `func` is a declaration of a prototype or a function definition until the token after the closing parenthesis is seen.

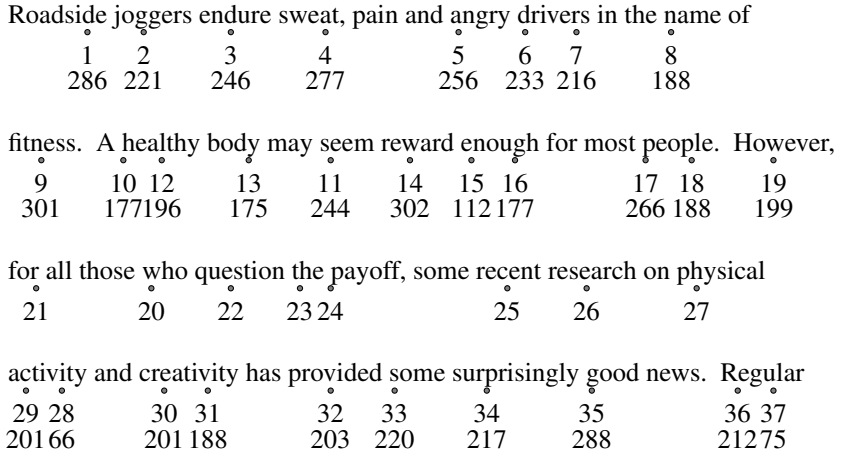

Figure 770.11: A passage of text with eye fixation position (dot under word), fixation sequence number, and fixation duration (in milliseconds) included. Adapted from Reichle, Pollatsek, Fisher, and Rayner[1153] (timings on the third line are missing in the original).

extraction before it is replaced by another (4–5 times a second in one case, 50–60 times a second in the other). However, in the case of a film the updating of individual images is handled by the projector while the film's director decides what to look at next; but during reading a person needs to decide what to look at next and move the eyes to that location.

The same reader can show considerable variation in performing these actions. Saccades might move the eyes by one character, or 15 to 20 characters (the duration of a saccade is influenced by the distance covered, measured in degrees). Fixations can be shorter than 100 ms or longer than 400 ms (they can also vary between languages[1036]). The content of the fixated text has a strong effect on reader performance.

The eyes do not always move forward during reading— 10% to 15% of saccades move the eyes back to previous parts of the text. These backward movements, called *regressions*, are caused by problems with linguistic processing (e.g., incorrect syntactic analysis of a sentence) and oculomotor error (for instance, the eyes overshot their intended target).

garden path sentence 770

visual field

Saccades are necessary because the eyes' field of view is limited. Light entering the eyes falls on the retina, where it hits light-sensitive cells. These cells are not uniformly distributed, but are more densely packed in the center of the retina. This distribution of light sensitive cells divides the visual field (on the retina) into three regions: foveal (the central 2°s, measured from the front of the eye looking toward the retina), parafoveal (extending out to 5°s), and peripheral (everything else). Letters become increasingly difficult to identify as their angular distance from the center of the fovea increases.

A reader has to perform two processes during the fixation period: (1) identify the word (or sequence of letters forming a partial word) whose image falls within the foveal and (2) plan the next saccade (when to make it and where to move the eyes). Reading performance is speed limited by the need to plan and perform saccades. If the need to saccade is removed by presenting words at the same place on a display, there is a threefold speed increase in reading aloud and a twofold speed increase in silent reading. The time needed to plan and perform a saccade is approximately 180 ms to 200 ms (known as the *saccade latency*), which means that the decision to make a saccade occurs within the first 100 ms of a fixation. How does a reader make a good saccade decision in such a short period of time?

The contents of the parafoveal region are partially processed during reading. The parafoveal region increases a reader's perceptual span. When reading words written using alphabetic characters (e.g., English or German), the perceptual span extends from 3 to 4 characters on the left of fixation to 14 to 15 letters to the right of fixation. This asymmetry in the perceptual span is a result of the direction of reading, attending to letters likely to occur next being of greater value. Readers of Hebrew (which is read right-to-left) have

a perceptual span that has opposite asymmetry (in bilingual Hebrew/English readers the direction of the asymmetry depends on the language being read, showing the importance of attention during reading[1100]).

The process of reading has attracted a large number of studies. The following general points have been found to hold:

- The perceptual span does not extend below the line being read. Readers' attention is focused on the line currently being read.
- The size of the perceptual span is fairly constant for similar alphabetic orthographies (graphical representation of letters).
- The characteristics of the writing system affect the asymmetry of the perceptual span and its width. For instance, the span can be smaller for Hebrew than English (Hebrew words can be written without the vowels, requiring greater effort to decode and plan the next saccade). It is also much smaller for writing systems that use ideographs, such as Japanese (approximately 6 characters to the right) and Chinese. 792 orthography
- The perceptual span is not hardwired, but is attention-based. The span can become smaller when the fixated words are difficult to process. Also readers obtain more information in the direction of reading when the upcoming word is highly predictable (based on the preceding text).
- Orthographic and phonological processing of a word can begin prior to the word being fixated. 792 orthography 792 phonology
- Words that can be identified in the parafovea do not have to be fixated and can be skipped. Predictable words are skipped more than unpredictable words, and short function words (like *the*) are skipped more than content words.

The processes that control eye movement have to decide where (to fixate next) and when (to move the eyes). These processes sometimes overlap and are made somewhat independently (see Figure 770.11).

Where to fixate next. Decisions about where to fixate next seem to be determined largely by low-level visual cues in the text, as follows.

- Saccade length is influenced by the length of both the fixated word and the word to the right of fixation.
- When readers do not have information about where the spaces are between upcoming words, saccade length decreases and reading rate slows considerably.
- Although there is some variability in where the eyes land on a word, readers tend to make their first fixation about halfway between the beginning and the middle of a word.
- While contextual constraints influence skipping (highly predictable words are skipped more than unpredictable words), contextual constraints have little influence on where the eyes land in a word (however, recent research[814] has found some semantic-context effects influence eye landing sites).
- The landing position on a word is strongly affected by the launch site (the previous landing position). As the launch site moves further from the target word, the distribution of landing positions shifts to the left and becomes more variable.

When to move the eyes. The ease or difficulty associated with processing a word influences when the eyes move, as follows.

- There is a spillover effect associated with fixating a low-frequency word; fixation time on the next word increases.
- Although the duration of the first fixation on a word is influenced by the frequency of that word, the duration of the previous fixation (which was not on that word) is not.

- High-frequency words are skipped more than low-frequency words, particularly when they are short and the reader has fixated close to the beginning of the word.
- Highly predictable (based on the preceding context) words are fixated for less time than words that are not so predictable. The strongest effects of predictability on fixation time are not usually as large as the strongest frequency effects. Word predictability also has a strong effect on word skipping.

2.1 Models of reading

It is generally believed that eye movements follow visual attention. This section discusses some of the models of eye movements that have been proposed and provides some of the background theory needed to answer questions concerning optimal layout of source code. An accurate, general-purpose model of eye movement would enable the performance of various code layout strategies to be tested. Unfortunately, no such model is available. This book uses features from three models, which look as if they may have some applicability to how developers read source. For a comparison of the different models, see Reichle, Rayner and Pollatsek.[1154]

2.1.1 Mr. Chips

Mr. Chips

Mr. Chips[830] is an ideal-observer model of reading (it is also the name of a computer program implemented in C) which attempts to calculate the distance, measured in characters, of the next saccade. (It does not attempt to answer the question of when the saccade will occur.) It is an idealized model of reading in that it optimally combines three sources of information (it also includes a noise component, representing imperfections in oculomotor control):

1. Visual data obtained by sampling the text through a *retina*, which has three regions mimicking the behavior of those in the human eye.
2. Lexical knowledge, consisting of a list of words and their relative frequencies (English is used in the published study).
3. Motor knowledge, consisting of statistical information on the accuracy of the saccades made.

Mr. Chips uses a single optimization principle— entropy minimization. All available information is used to select a saccade distance that minimizes the uncertainty about the current word in the visual field (ties are broken by picking the largest distance). Executing the Mr. Chips program shows it performing regressive saccades, word skips, and selecting viewing positions in words, similar to human performance.

Mr. Chips is not intended to be a model of how humans read, but to establish the pattern of performance when available information is used optimally. It is not proposed that readers perform entropy calculations when planning saccades. There are simpler algorithms using a small set of heuristics that perform close to the entropy minimization ideal (see Figure 770.12).

The eyes' handling of visual data and the accuracy of their movement control are physical characteristics. The lexical knowledge is a characteristic of the environment in which the reader grew up. A person has little control over the natural language words they hear and see, and how often they occur. Source code declarations create new words that can then occur in subsequent parts of the source being worked on by an individual. The characteristics of these words will be added to developers' existing word knowledge. Whether particular, code-specific letter sequences will be encountered sufficiently often to have any measurable impact on the lexicon a person has built up over many years is not known (see Figure 792.16).

2.1.2 The E-Z Reader model

The E-Z Reader model of eye movement control in reading is described by Reichle, Pollatsek, Fisher, and Rayner.[1153] It aims to give an account of how cognitive and lexical processes influence the eye movements of skilled readers. Within this framework it is the most comprehensive model of reading available. An important issue ignored by this model is higher order processing. (The following section describes a model that attempts to address cognitive issues.) For instance, in the sentence "Since Jay always jogs a mile

garden path sentence

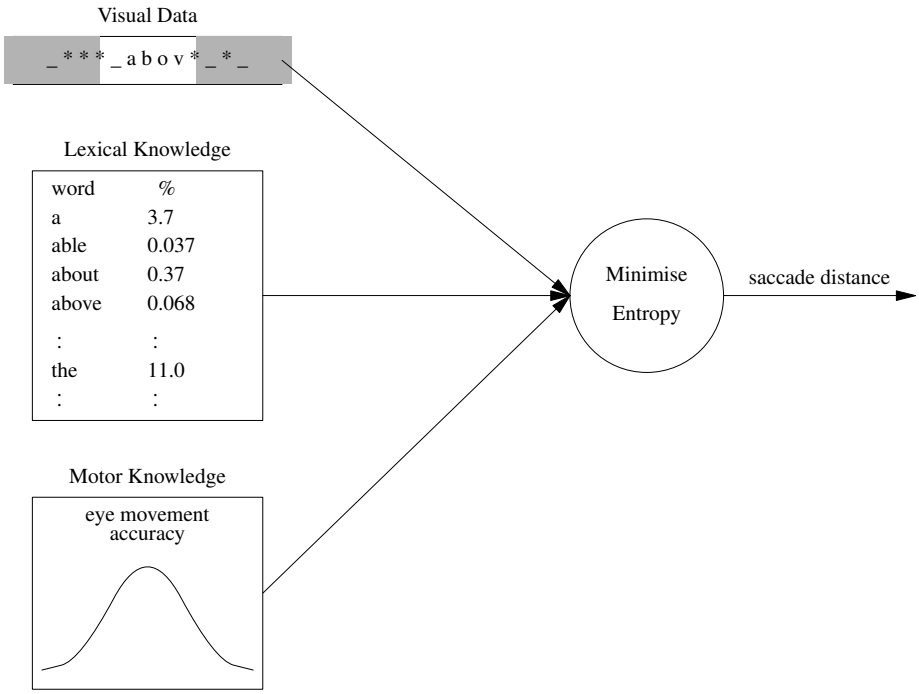

Figure 770.12: Mr. Chips schematic. The shaded region in the visual data is the parafoveal; in this region individual letters (indicated by stars) can only be distinguished from spaces (indicated by underscores). Based on Legge et al.[830]

seems like a short distance." readers experience a disruption that is unrelated to the form or meaning of the individual words. The reader has been led down a syntactic *garden path*; initially parsing the sentence so that *a mile* is the object of *jogs* before realizing that *a mile* is the subject of *seems*. Also it does not attempt to model the precise location of fixations.

The aspect of this model that is applicable to reading source code is the performance dependency, of various components to the frequency of the word being processed (refer to Figure 770.11). The *familiarity check* is a quick assessment or whether word identification is imminent, while *completion of lexical access* corresponds to a later stage when a word's identity has been determined.

2.1.3 EMMA

EMMA [1193] is a domain-independent model that relates higher-level cognitive processes and attention shifts with lower-level eye movement behavior. EMMA is based on many of the ideas in the E-Z model and uses ACT-R[35] to model cognitive processes. EMMA is not specific to reading and has been applied to equation-solving and visual search. EMMA

The *spotlight* metaphor of visual attention, used by EMMA, selects a single region of the visual field for processing. Shifting attention to a new visual object requires that it be encoded into an internal representation. The time, T_{enc}, needed to perform this encoding is:

$$T_{enc} = K(-\log f_i)e^{k\theta_i} \tag{770.1}$$

where f_i represents the frequency of the visual object being encoded (a value between 0.0 and 1.0), θ_i is its visual angle from the center of the current eye position, and K and k are constants.

The important components of this model, for these coding guidelines, are the logarithmic dependency on word frequency and the exponential decay based on the angle subtended by the word from the center of vision.

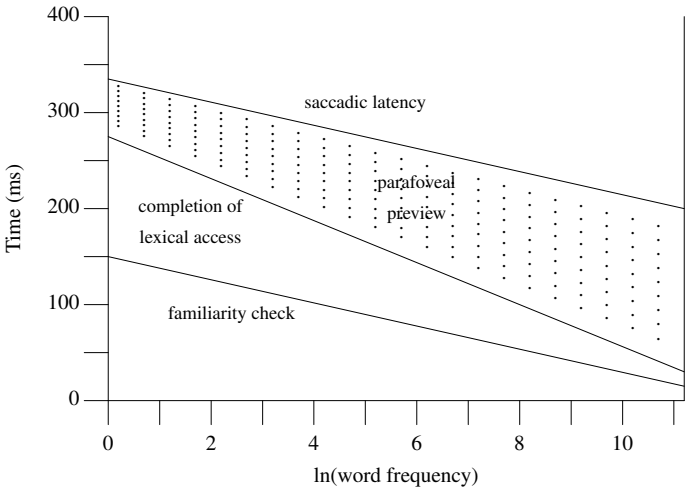

Figure 770.13: How preview benefit is affected by word frequency. The bottom line denotes the time needed to complete the familiarity check, the middle line the completion of lexical access, and the top line when the execution of the eye movement triggered by the familiarity check occurs. Based on Reichle, Pollatsek, Fisher, and Rayner.[1153]

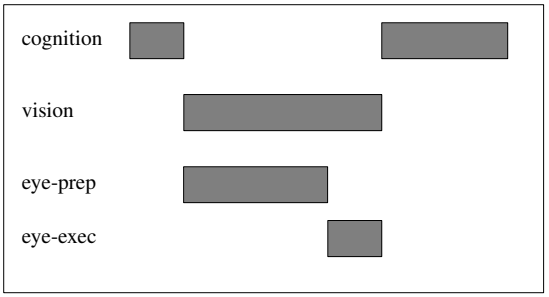

Figure 770.14: Example case of EMMA's control flow. Adapted from Salvucci.[1193]

2.2 Individual word reading (English, French, and more?)

word reading individual

When presented with a single word, or the first word in a sentence, studies have found that readers tend to pick an eye fixation point near the center of that word. The so-called *preferred viewing location* is often toward the left of center. It had been assumed that selecting such a position enabled the reader to maximize information about the letters in the word (fixating near the center would enable a reader to get the most information out of their eye's available field of view). Clark and O'Regan[245] performed a statistical analysis of several English word corpuses and a French word corpus. They assumed the reader would know the first and last letters of a word, and would have a choice of looking anywhere within a word to obtain information on more letters. (It was assumed that reliable information on two more letters would be obtained.)

Knowing only a few of the letters of a word can create ambiguity because there is more than one, human language, word containing those letters at a given position. For instance, some of the words matched by *s*at****d* include *scattered*, *spattered*, and *stationed*. The results (see Figure 770.15) show that word ambiguity is minimized by selecting two letters near the middle of the word. Clark and O'Regan do not give any explanation for why English and French words should have this property, but they do suggest that experienced readers of these two languages make use of this information in selecting the optimal viewing position within a word.

word frequency 792

There are a number of experimental results that cannot be explained by an eye viewing position theory based only on word ambiguity minimization. For instance, the word frequency effect shows that high-

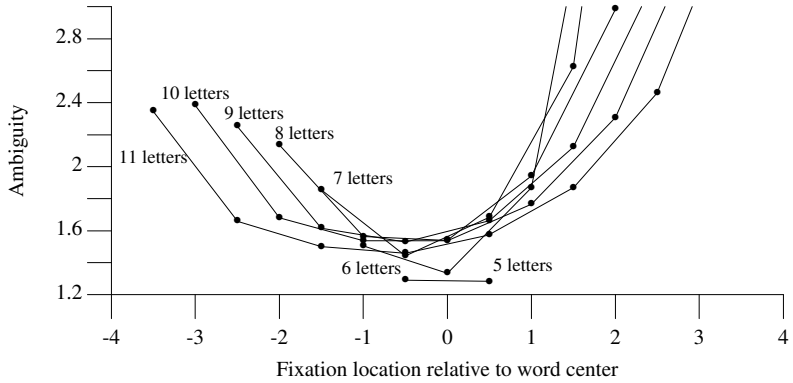

Figure 770.15: The ambiguity of patterns defined by the first and last letter and an interior letter pair, as a function of the position of the first letter of the pair. Plots are for different word lengths using the 65,000 words from CLAWS[822] (as used by the `aspell` tool). The fixation position is taken to be midway between the interior letter pair.

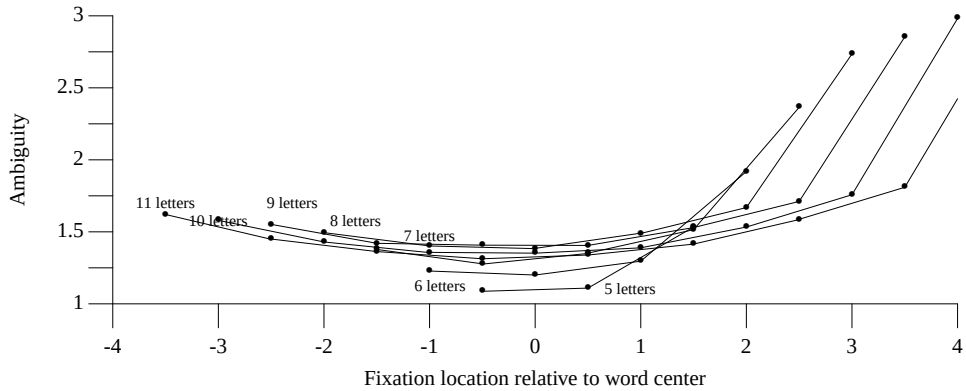

Figure 770.16: The ambiguity of source code identifiers, which can include digits as well as alphabetic characters. Plots are for different identifier lengths. A total of 344,000 identifiers from the visible form of the `.c` files were used.

frequency words are more easily recognized than low-frequency words. The ambiguity data shows the opposite effect. While there must be other reading processes at work, Clark and O'Regan propose that ambiguity minimization is a strong contributor to the optimal viewing position.

The need to read individual identifiers in source code occurs in a number of situations. Developers may scan down a list of identifiers looking for (1) the declaration of a particular identifier (where it is likely to be the last sequence of letters on a line) or (2) a modification of a particular identifier (where it is likely to be the first non-space character on a line).

If developers have learned that looking at the middle of a word maximizes their information gain when reading English text, it is likely this behavior will be transferred to reading source code. Identifiers in source code are rarely existing, human language, words. The extent to which experienced developers learn to modify their eye movements (if any modification is necessary) when reading source code is unknown. If we assume there is no significant change in eye movement behavior on encountering identifiers in source code, it can be used to predict the immediate information available to a developer on first seeing an identifier. Knowing this information makes it possible to select identifier spellings to minimize ambiguity with respect to other identifiers declared in the same program. This issue is discussed elsewhere.

792 identifier syntax

Calculating the ambiguity for different positions within C source code identifiers shows (see Figure 770.16) that the ambiguity is minimized near the center of the identifier and rises rapidly toward the end. However, there is a much smaller increase in ambiguity, compared to English words, moving toward the beginning

of the identifier. Why English speakers and developers (the source code used for these measurements is likely to be predominantly written by English speakers but not necessarily native speakers) should create words/identifiers with this ambiguity minimization property is not known.

If native-English speakers do use four letters worth of information to guide identifier lookup, will they be misled by their knowledge of English words? Of the 344,000 unique identifiers (41.6% contained between 5 and 11 characters) in the `.c` files, only 0.45% corresponded to words in the CLAWS list of 65,000 words. The letter pattern counts showed the words containing a total of 303,518 patterns, to which the list of identifiers added an additional 1,576,532 patterns. The identifiers contained letters that matched against 166,574 word patterns (9.5% for center pair) and matched against 608,471 patterns that were unique to identifiers (8.1% for center pair).

These results show that more than 80% of letter patterns appearing in identifiers do not appear in English words. Also, identifier letter patterns are three times more likely to match against a pattern that is unique to identifiers than a pattern that occurs in an English word. In most cases developers will not be misled into thinking of an English word because four-letter patterns in identifiers do not frequently occur in English words.

2.3 White space between words

words white space between
reading 770 kinds of

The use of white space between tokens in source code is a controversial subject. The use of white space is said to affect *readability*, however that might be measured. The different reasons a developer has for reading source code, and the likely strategies adopted are discussed elsewhere.

Is the cost of ownership of source code that contains a space character, where permitted, between every identifier and operator/punctuator[770.2] less than or greater than the cost of ownership of source code that does not contain such space characters? This subsection discusses the issues; however, it fails to reach a definitive conclusion.

Readers of English take it for granted that a space appears between every word in a line of text. This was not always the case. Spaces between words started to be used during the time of Charlemagne (742–814); however, as late as the seventeenth century there was still some irregularity in how spaces were used to separate letters.[138] The spread of Latin to those less familiar with it, and the availability of books (through the introduction of the printing press) to people less skilled in reading, created a user-interface problem. Spaces between words simplified life for occasional users of Latin and improved the user friendliness of books for intermittent readers. The written form of some languages do not insert spaces between words (e.g., Japanese and Thai), while other written forms add some spaces but also merge sequences of words to form a single long word (e.g., German and Dutch). Algorithms for automating the process of separating words in unspaced text is an active research topic.[1045]

ReadersofEnglishdonotneedspacesbetweenwords.Isitsimplylackofpracticethatreducesreadingrate?Thestudybyby Kolers[761] showed what could be achieved with practice. Readers of source code do not need spaces either (in a fewcontexts the syntax requires them) `a=b+c`. The difference between English prose and source code is that identifier words are always separated by other words (operators and punctuation) represented by characters that cannot occur in an identifier.

A study by Epelboim, Booth, Ashkenazy, Taleghani, and Steinmans[392] did not just simply remove the spaces from between words, they also added a variety of different characters between the words (shaded boxes, digits, lowercase Greek letters, or lowercase Latin letters). Subjects were not given any significant training on reading the different kinds of material.

Epelboim[392]

The following filler-placements were used (examples with digit fillers are shown in parentheses):

1. *Normal: Normal text (this is an example);*
2. *Begin: A filler at the beginning of each word, spaces preserved (1this 3is 7an 2example);*

[770.2] In some cases a space character is required between tokens; for instance, the character sequence `const int i` would be treated as a single identifier if the space characters were not included.

3. *End: A filler after the end of each word, spaces preserved (this1 is3 an7 example2);*
4. *Surround: Fillers surrounding each word, spaces preserved (9this1 4is3 6an7 8example2);*
5. *Fill-1: A filler filling each space (9this2is5an8example4);*
6. *Fill-2: Two fillers filling each space (42this54is89an72example39);*
7. *Unspaced: Spaces removed, no fillers (thisisanexample).*

Table 770.1: Mean percentage differences, compared to normal, in reading times (silent or aloud); the values in parenthesis are the range of differences. Adapted from Epelboim.[392]

Filler type	Surround	Fill-1	Fill-2	Unspaced
Shaded boxes (aloud)	4 (1–12)	—	3 (-2–9)	44 (25–60)
Digits (aloud)	26 (15–40)	26 (10–42)	—	42 (19–64)
Digits (silent)	40 (32–55)	41 (32–58)	—	52 (45–63)
Greek letters (aloud)	33 (20–47)	36 (23–45)	46 (33–57)	44 (32–53)
Latin letters (aloud)	55 (44–70)	—	74 (58–84)	43 (13–58)
Latin letters (silent)	66 (51–75)	75 (68–81)	—	45 (33–60)

Epelboim et al. interpreted their results as showing that fillers slowed reading because they interfered with the recognition of words, not because they obscured word-length information (some models of reading propose that word length is used by low-level visual processing to calculate the distance of the next saccade). They concluded that word-length information obtained by a low-level visual process that detects spaces, if used at all, was only one of many sources of information used to calculate efficient reading saccade distances.

Digits are sometimes used in source code identifiers as part of the identifier. These results suggest that digits appearing within an identifier could disrupt the reading of its complete name (assuming that the digits separated two familiar letter sequences). The performance difference when Greek letters were used as separators was not as bad as for Latin letters, but worse than digits. The reason might relate to the relative unfamiliarity of Greek letters, or their greater visual similarity to Latin letters (the letters α , δ, θ, μ, π, σ, τ, and ϕ were used). The following are several problems with applying the results of this study to reading source code.

- Although subjects were tested for their comprehension of the contents of the text (the results of anybody scoring less than 75% were excluded, the mean for those included was 89.4%), they were not tested for correctly reading the filler characters. In the case of source code the operators and punctuators between words contribute to the semantics of what is being read; usually it is necessary to pay attention to them.
- Many of the character sequences (a single character for those most commonly seen) used to represent C operators and punctuators are rarely seen in prose. There contribution to the entropy measure used to calculate saccade distances is unknown. For experienced developers the more commonly seen character sequences, which are also short, may eventually start to exhibit high-frequency word characteristics (i.e., being skipped if they appear in the parafoveal).
- Subjects were untrained. To what extent would training bring their performance up to a level comparable to the unfilled case?

A study by Kohsom and Gobet[759] used native Thai speakers, who also spoke English, as subjects (they all had an undergraduate degree and were currently studying at the University of Pittsburgh). The written form of Thai does not insert spaces between words, although it does use them to delimit sentences. In the study the time taken to read a paragraph, and the number of errors made was measured. The paragraph was in Thai or English with and without spaces (both cases) between words. The results showed no significant performance

differences between reading spaced or unspaced Thai, but there was a large performance difference between reading spaced and unspaced English.

This study leaves open the possibility that subjects were displaying a learned performance. While the Thai subjects were obviously experienced readers of unspaced text in their own language, they were not experienced readers of Thai containing spaces. The Thai subjects will have had significantly more experience reading English text containing spaces than not containing spaces. The performance of subjects was not as good for spaced English, their second language, as it was for Thai. Whether this difference was caused by subjects' different levels of practice in reading these languages, or factors specific to the language is not known. The results showed that adding spaces when subjects had learned to read without them did not have any effect on performance. Removing spaces when subjects had learned to read with them had a significant effect on performance.

In the case of expressions in source code, measurements show (see Table 770.2) that 47.7% of expressions containing two binary operators do not have any space between binary operators and their operands, while 43% of such expressions have at least one space between the binary operators and their adjacent operands.

Further studies are needed before it is possible to answer the following questions:

- Would inserting a space between identifiers and adjacent operators/punctuators reduce the source reading error rate? For instance, in `a=b*c` the `*` operator could be mistaken for the `+` operator (the higher-frequency case) or `&` operator (the lower frequency case).
- Would inserting a space between identifiers and adjacent operators/punctuators reduce the source reading rate? For instance, in `d=e[f]` the proximity of the `[` operator to the word `e` might provide immediate semantic information (the word denotes an array) without the need for another saccade.
- What impact does adding characters to a source line have on the average source reading rate and corresponding error rate (caused by the consequential need to add line breaks in some places)?
- Are the glyphs used for some characters sufficiently distinctive that inserting space characters around them has a measurable impact?

glyph 58

- Do some characters occur sufficiently frequently that experienced developers can distinguish them with the same facility in spaced and unspaced contexts?

letter detection 770

The results of the prose-reading studies discussed here would suggest that high-performance is achieved through training, not the use of spaces between words. Given that developers are likely to spend a significant amount of time being trained on (reading) existing source code, the spacing characteristics of this source would appear to be the guide to follow.

Table 770.2: Number of expressions containing two binary operators (excluding any assignment operator, comma operator, function call operator, array access or member selection operators) having the specified spacing (i.e., no spacing, *no-space*, or one or more whitespace characters (excluding newline), *space*) between a binary operator and both of its operands. *High-Low* are expressions where the first operator of the pair has the higher precedence, *Same* are expressions where the both operators of the pair have the same precedence, *Low-High* are expressions where the first operator of the pair has the lower precedence. For instance, `x + y*z` is *space no-space* because there are one or more *space* characters either side of the addition operator and *no-space* either side of the multiplication operator, the precedence order is *Low-High*. Based on the visible form of the `.c` files.

	Total	High-Low	Same	Low-High
no-space	34,866	2,923	29,579	2,364
space no-space	4,132	90	393	3,649
space space	31,375	11,480	11,162	8,733
no-space space	2,659	2,136	405	118
total	73,032	16,629	41,539	14,864

2.3.1 Relative spacing

operator relative spacing

The spacing between a sequence of tokens can be more complicated that presence/absence, it can also be relative (i.e., more spacing between some tokens than others. One consequence of relative spacing is that the eye can be drawn to preferentially associate two tokens (e.g., nearest neighbors) over other associations involving more distant tokens (see Figure 770.2).

A study by Landy and Goldstone[806] asked subjects to compute the value of expressions that contained an addition and multiplication operator (e.g., `2 + 3*4`). The spacing between the operators and adjacent operands was varied (e.g., sometimes there was more spacing adjacent to the multiplication operator than the addition, such as `5+2 * 3`).

The results showed that a much higher percentage of answers was correct when there was less spacing around the multiplication operator than the addition operator (i.e., the operands had a greater visual proximity to the multiplication operator). In this case subjects also gave the correct answer more quickly (2.6 vs. 2.9 seconds).

Relative spacing is sometimes used within source code expressions to highlight the relative precedence of binary operators. Table 770.2 shows that when relative spacing was used it occurred in a form that gave the operator with higher precedence greater proximity to its operands (compared to the operator of lower precedence).

943 operator precedence

2.4 Other visual and reading issues

There are several issues of importance to reading source code that are not covered here. Some are covered elsewhere; for instance, visual grouping by spatial location and visual recognition of identifiers. The question of whether developers should work from paper or a screen crops up from time to time. This topic is outside of the scope of these coding guidelines (see Dillon[358] for a review).

1707 grouping spatial location
792 word visual recognition

Choice of display font is something that many developers are completely oblivious to. The use of Roman, rather than Helvetica (or serif vs. sans serif), is often claimed to increase reading speed and comprehension. A study by Lange, Esterhuizen, and Beatty[332] showed that young school children (having little experience with either font) did not exhibit performance differences when either of these fonts was used. This study showed there were no intrinsic advantages to the use of either font. Whether people experience preferential exposure to one kind of font, which leads to a performance improvement through a practice effect, is not known. The issues involved in selecting fonts are covered very well in a report detailing *Font Requirements for Next Generation Air Traffic Management Systems*.[161] For a discussion of how font characteristics affect readers of different ages, see Connolly.[266]

font

A study by Pelli, Burns, Farell, and Moore[1070] showed that 2,000 to 4,000 trials were all that was needed for novice readers to reach the same level of efficiency as fluent readers in the letter-detection task. They tested subjects aged 3 to 68 with a range of different (and invented) alphabets (including Hebrew, Devanagari, Arabic, and English). Even fifty years of reading experience, over a billion letters, did not improve the efficiency of letter detection. The measure of efficiency used was human performance compared to an ideal observer. They also found this measure of efficiency was inversely proportional to letter perimetric complexity (defined as, inside and outside perimeter squared, divided by *ink* area).

letter detection

A number of source code editors highlight (often by using different colors) certain character sequences (e.g., keywords). The intended purpose of this highlighting is to improve program readability. Some source formatting tools go a stage further and highlight complete constructs (e.g., comments or function headers). A study by Gellenbeck[478] suggested that while such highlighting may increase the prominence of the construct to which it applies; it does so at the expense of other constructs.

A book by Baecker and Marcus[77] is frequently quoted in studies of source code layout. Their aim was to base the layout used on the principles of good typography (the program source code as book metaphor is used). While they proposed some innovative source visualization ideas, they seem to have been a hostage to some arbitrary typography design decisions in places. For instance, the relative frequent change of font, and the large amount of white space between identifiers and their type declaration, requires deliberate effort to align identifiers with their corresponding type declaration. While the final printed results look superficially

attractive to a casual reader, they do not appear, at least to your author, to offer any advantages to developers who regularly work with source code.

3 Kinds of reading

reading kinds of

The way in which source code is read will be influenced by the reasons for reading it. A reader has to balance goals (e.g., obtaining accurate information) with the available resources (e.g., time, cognitive resources such as prior experience, and support tools such as editor search commands).

Foraging theory[1289] attempts to explain how the behavioral adaptations of an organism (i.e., its lifestyle) are affected by the environment in which it has to perform and the constraints under which it has to operate. Pirolli and Card[1091] applied this theory to deduce the possible set of strategies people might apply when searching for information. The underlying assumption of this theory is that: faced with information-foraging tasks and the opportunity to learn and practice, cognitive strategies will evolve to maximize information gain per unit cost.

Almost no research has been done on the different information-gathering strategies (e.g., reading techniques) of software developers. These coding guidelines assume that developers will adopt many of the strategies they use for reading prose text. A review by O'Hara[1029] listed four different prose reading techniques:

O'Hara[1029]

> ***Receptive Reading***. *With this type of reading the reader receives a continuous piece of text in a manner which can be considered as approximating listening behavior. Comprehension of the text requires some portion of the already read text to be held in working memory to allow integration of meaning with the currently being read text.*
>
> ***Reflective Reading***. *This type of reading involves interruptions by moments of reflective thought about the contents of the text.*
>
> ***Skim Reading***. *This is a rapid reading style which can be used for establishing a rough idea of the text. This is useful in instances where the reader needs to decide whether the text will be useful to read or to decide which parts to read.*
>
> ***Scanning***. *This is related to skimming but refers more specifically to searching the text to see whether a particular piece of information is present or to locate a piece of information known to be in the text.*

Deimel and Naveda[341] provide a teachers' guide to program reading. The topic of visual search for identifiers is discussed in more detail elsewhere.

identifier 792
visual search

Readers do not always match up pairs of **if/else** tokens by tracing through the visible source. The source code indentation is often used to perform the matching, readers assuming that **if/else** tokens at the same indentation level are a matching pair. Incorrectly indented source code can lead to readers making mistakes.

```
1  void f(int i)
2  {
3  if (i > 8)
4     if (i < 20)
5        i++;
6  else
7     i--;
8  }
```

Example

```
1  #define mkstr(x) #x
2
3  char *p = mkstr(@); /* Implementation supports the @ extended character. */
```

For those wanting to teach code reading skills, Deimel and Naveda[341] offers an instructors guide (the examples use Ada). Studying those cases where the requirement is to minimize readability[256] can also be useful.

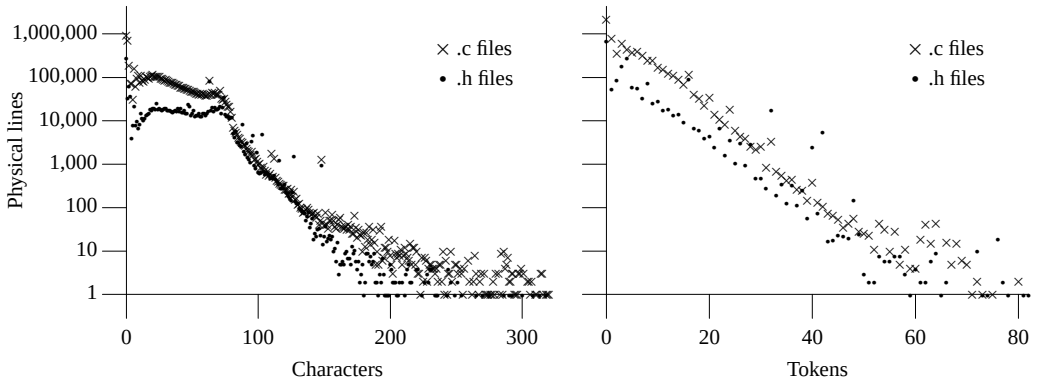

Figure 770.17: Number of physical lines containing a given number of non-white-space characters and tokens. Based on the visible form of the `.c` and `.h` files.

Usage

Table 770.3 shows the relative frequency of the different kinds of tokens in a source file (actual token count information is given elsewhere). Adding the percentages for *Preceded by Space* and *First on Line* (or followed by space and last on line) does not yield 100% because of other characters occurring in those positions. Some tokens occur frequently, but contribute a small percentage of the characters in the visible source (e.g., punctuators). Identifier tokens contribute more than 40% of the characters in the `.c` files, but only represent 28.5% of the tokens in those files.

124 translation phase 3

777 preprocessing tokens white space separation

A more detailed analysis of spacing between individual punctuators is given elsewhere.

Table 770.3: Occurrence of kinds of tokens in the visible form of the `.c` and `.h` files as a percentage of all tokens (value in parenthesis is the percentage of all non-white-space characters contained in those tokens), percentage occurrence (for `.c` files only) of token kind where it was preceded/followed by a space character, or starts/finishes a visible line. While comments are not tokens they are the only other construct that can contain non-white-space characters. While the start of a preprocessing directive contains two tokens, these are generally treated by developers as a single entity.

Token	% of Tokens in `.c` files	% of Tokens in `.h` files	% Preceded by Space	% Followed by Space	% First Token on Line	% Last Token on Line
punctuator	53.5 (11.4)	48.1 (7.5)	27.5	29.7	3.7	25.3
identifier	29.8 (43.4)	20.8 (30.6)	54.9	27.6	1.4	1.2
constant	6.9 (3.8)	21.6 (15.3)	70.3	4.4	0.1	1.6
keyword	6.9 (5.8)	5.4 (4.2)	79.9	82.5	10.3	3.6
comment	1.9 (31.0)	3.4 (40.3)	53.4	2.2	41.2	97.4
string-literal	1.0 (4.6)	0.8 (2.2)	59.9	5.7	0.7	8.0
pp-directive	0.9 (1.1)	4.9 (4.4)	4.7	78.4	0.0	18.2
header-name	0.0 (0.0)	0.0 (0.0)	–	–	–	–

Constraints

771 Each preprocessing token that is converted to a token shall have the lexical form of a keyword, an identifier, a constant, a string literal, or a punctuator.

preprocessing token shall have lexical form

Commentary

The only way a preprocessing token, which does not also have the form of a token, can occur in a strictly conforming program is for it to be either stringized, be the result of preprocessing token gluing, or be skipped as part of a conditional inclusion directive. For instance, the preprocessing token `0.1.1` does not have any of these forms.

1950 # operator 1958 ## operator conditional inclusion

Other Languages

Languages differ in their handling of incorrectly formed tokens, or lexical errors (depending on your point of view). The final consequences are usually the same; the source code is considered to be ill-formed (in some way).

Semantics

A *token* is the minimal lexical element of the language in translation phases 7 and 8. 772

Commentary

A member of the source character set or a preprocessing token is the minimal lexical element of the language in prior translation phases.

translation phases of 115

C++

The C++ Standard makes no such observation.

The categories of tokens are: keywords, identifiers, constants, string literals, and punctuators. 773

Commentary

This is a restatement of information given in the Syntax clause. Tokens do not include the preprocessor-token header names. Also the preprocessor-token pp-number is converted to the token constant (provided the conversion is defined). Some of these categories are broken into subcategories. For instance, some identifiers are reserved (they are not formally defined using this term, but they appear in a clause with the title "Reserved identifiers"), and constants might be an *integer-constant*, *floating-constant*, or *character-constant*.

C90

Tokens that were defined to be operators in C90 have been added to the list of punctuators in C99.

C++

2.6p1 *There are five kinds of tokens: identifiers, keywords, literals,[18)] operators, and other separators.*

What C calls constants, C++ calls literals. What C calls punctuators, C++ breaks down into operators and punctuators.

Other Languages

Some languages contain the category of reserved words. These have the form of identifier tokens. They are not part of the language's syntax, but they have a predefined special meaning. Some languages do not distinguish between keywords and identifiers. For instance PL/1, in which it is possible to declare identifiers having the same spelling as a keyword.

A preprocessing token is the minimal lexical element of the language in translation phases 3 through 6. 774

Commentary

Prior to translation phase 3, preprocessing tokens do not exist. The input is manipulated as a sequence of bytes or characters in translation phases 1 and 2.

translation phase 3 124
translation phase 1 116
translation phase 2 118

The categories of preprocessing tokens are: header names, identifiers, preprocessing numbers, character constants, string literals, punctuators, and single non-white-space characters that do not lexically match the other preprocessing token categories.[58)] 775

Commentary

This is a restatement of information given in the Syntax clause.

C++

In clause 2.4p2, apart from changes to the terminology, the wording is identical.

Other Languages

Many languages do not specify a mechanism for including other source files. However, it is a common extension for implementations of these languages to provide this functionality. So while language specifications do not usually define a category of token called *header names*, they often exist (although implementations very rarely provide a formal language category for this extension).

---

776 If a ' or a " character matches the last category, the behavior is undefined.

character ' or " matches

Commentary

Character constant or string literal tokens cannot include source file new-line characters. A single occurrence of a ' or " character on a logical source line might be said to fall into the category of *non-white-space character that cannot be one of the above*. However, the Committee recognized that many translators treat these two characters in a special way; they tend to simply gather up characters until a matching, corresponding closing quote is found. On reaching a new-line character, having failed to find a matching character, many existing translators would find it difficult to push back, into the input stream, all of the characters that had been read (the behavior necessary to create a preprocessing token consists of a quote character, leaving the following character available for further lexical processing). So the Committee made this as a special case.

In translation phase 7 there is no token into which the preprocessing single non-white-space token could be converted. However, prior to that phase, the token could be stringized during preprocessing; so, this specification could be thought of as being redundant. While an occurrence of this construct may be specified as resulting undefined behavior, all implementations known to your author issue some form of diagnostic when they encounter it.

136 translation phase 7
1950 # operator

One consequence of escape sequences being specified as part of the language syntax is that it is possible to have a sequence of characters that appears to be a character constant but is not. For instance:

866 escape sequence syntax
866 character constant syntax

```
1  char glob = '\d';
2  /*
3   * Tokenizes as: {char}{glob}{=}{'}{\}{d}{'}{;}
4   */
```

Other Languages

A single, unmatched ' or " character is not usually treated as an acceptable token by most languages (which often do not allow a string literal to be split across a source line).

Common Implementations

Most translators issue a diagnostic if an unmatched ' or " character is encountered on a line.

Coding Guidelines

This construct serves no useful purpose and neither would a guideline recommending against using it.

Example

```
1  #define mkstr(a) # a
2
3  char *p = mkstr('); /* Undefined behavior. */
```

---

777 Preprocessing tokens can be separated by *white space*;

preprocessing tokens white space separation

Commentary

white-space within preprocessing directive 1864
translation phase 4 129

C permits a relatively free formatting of the source code. Although there are a few limitations on what kinds of white space can occur in some contexts. Some preprocessing tokens do need to be separated by white space (e.g., an adjacent *pp-number* and *identifier*) for them to be distinguished as two separate tokens. Some preprocessing tokens do not need to be separated by white space to be distinguished (e.g., a punctuator and an identifier). White space can be significant during translation phase 4.

Preprocessing tokens are often separated by significantly more white space than the minimum required to visually differentiate them from each other. This usage of white space is associated with how developers view source code and is discussed in coding guidelines sections.

Other Languages

Fortran spaces not significant

The lexical handling of white space in C is very similar to that found in many other languages. Some languages even allow white space to separate the characters making up a single token. In Fortran white space is not significant. It can occur anywhere between the characters of a token. The most well-known example is:

```
1   DO100I=1,10
```

Here the Fortran lexer has to scan all the characters up to the comma before knowing that this is a do loop (`I` taking on values 1 through 10, the end of the loop being indicated by the label 100) and not an assignment statement:

```
1   DO 100 I=1.10
```

which assigns `1.10` to the variable `DO100I`.

Common Implementations

The time spent performing the lexical analysis needed to create preprocessing tokens is usually proportional to the number of characters in the source file. Many implementations make use of the observation that the first preprocessing token on a line is often preceded by more than one white-space character to perform a special case optimization in the lexer; after reading a new line of characters from the source file, any initial white-space characters are skipped over. (There are a few special cases where this optimization cannot be performed.)

Coding Guidelines

comment /* 934
words white space between 770
expression visual layout 940
declaration visual layout 1348
statement visual layout 1707
translation unit syntax 1810

Separating preprocessing tokens using white space is more than a curiosity or technical necessity (in a few cases). Experience has shown that white space can be used to make it easier for developers to recognize source code constructs. While optimal use of white space for this purpose may be the biggest single discussion topic among developers (commenting practices may be bigger), very little research has been carried out. Issues involving white space between preprocessing tokens are discussed in various subsections, including tokens, expressions, declarations, statements, and translation units.

Example

Some preprocessing tokens require white space:

```
1   typedef int I; /* White space required. */
2
3   I j;           /* White space required. */
4
5   int*p;         /* No white space required. */
6
7   char
8   a[2];          /* new-line is also white space. */
```

Usage

Table 770.3 shows the relative frequency of white space occurring before and after various kinds of tokens.

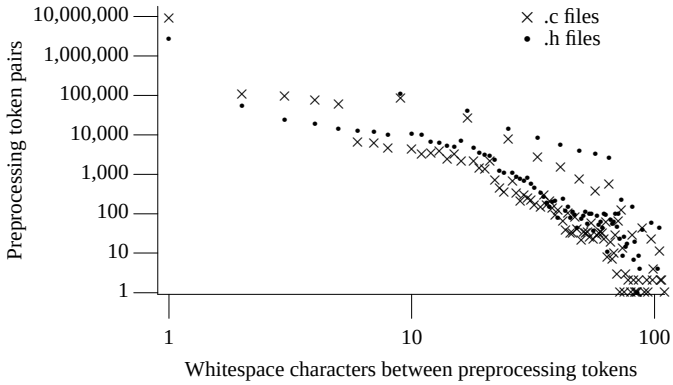

Figure 777.1: Number of *pp-token* pairs having the given number of white-space characters them (does do not include white space at the start of a line— i.e., indentation white space, and end-of-line is not counted as a white-space character). Based on the visible form of the `.c` and `.h` files.

778 this consists of comments (described later), or *white-space characters* (space, horizontal tab, new-line, vertical tab, and form-feed), or both.

white-space characters

Commentary

Comments are converted to white space in translation phase 3. The new-line character (white space) causes source code to be displayed in lines. There are no universal character names representing white space.

126 comment replaced by space

Other Languages

New-line is part of the syntax of some languages (e.g., Fortran prior to Fortran 95, Occam, and dialects of Basic). It serves to indicate the end of a statement. C (and C++) has a larger set of characters, which are explicitly defined as white space, than most other languages, which are often silent on the subject.

Coding Guidelines

Technically a comment is treated as a single space character. However, from the point of view of source code visualization, a comment is not a white-space character.

126 comment replaced by space
126 comment replaced by space

Use of horizontal tab is remarkably common (see Table 221.1). The motivation often given by developers for this usage is the desire to minimize the number of characters that they need type (i.e., not having to type multiple space characters). Another reason for this usage is tool based. Many editors support an auto-indentation feature that inserts horizontal tab characters rather than multiple space characters (e.g., `vi`). The visual appearance of the white-space character's horizontal tab, vertical tab, and form-feed depends on implementation-defined characteristics of the device on which the source code is displayed. While use of these characters might incur a cost, if the visual appearance of source code changes when a different display device is used, the benefit of a guideline recommending that they not be used does not appear to be great enough to be worthwhile.

779 As described in 6.10, in certain circumstances during translation phase 4, white space (or the absence thereof) serves as more than preprocessing token separation.

Commentary

White space between tokens is significant when it appears between tokens that are operands to the # operator.

1952 white space between macro argument tokens

780 White space may appear within a preprocessing token only as part of a header name or between the quotation characters in a character constant or string literal.

white space significant

Commentary

The purpose of white space is to separate preprocessing tokens, resolving ambiguities in some cases, and

786 EXAMPLE

Fortran 777 spaces not significant

to improve the readability of source code. Allowing white space between the characters making up other preprocessing tokens would complicate the job of the lexer, lead to confusion when reading the source code, and does not offer any advantages. A comment is not a preprocessing token, and there is no need to specify the behavior of white space that occurs within it.

Other Languages

Fortran 777 spaces not significant

White space may appear within tokens in some other languages. The space character is not significant in Fortran. All languages that support string literals or character constants allow white space to occur within them.

Common Implementations

The meaning of white space in a header name varies between implementations. Some ignore it, while others, whose hosts support file names containing white space, treat it as part of the file name. Some early translators allowed white space to occur within some preprocessing tokens (e.g., `A = = B;`).

Some translators use different programs to perform different phases of translation. A program that performs preprocessing (translation phases 1–4) is common; its output is written to a text file and read in by a program that handles the subsequent phases. Such a preprocessing program has to ensure that it does not create tokens that did not appear in the original source code. In:

```
#define X -3

int glob = 6-X; /* Expands to 6- -3 */
```

a space character has to be inserted between the `-` character and the macro replacement of `X`. Otherwise the token `--` would be created, not two `-` tokens.

Coding Guidelines

While white space in file names is very easily overlooked, both in a directory listing and in a header name, it rarely occurs in practice.

---

footnote 58

58) An additional category, placemarkers, is used internally in translation phase 4 (see 6.10.3.3); it cannot occur in source files. 781

Commentary

placemarker 1962 preprocessor

Placemarkers were introduced in C99 as a method of clarifying the operation of the # and ## preprocessor operators. They may or may not exist as preprocessing tokens within a translator. They exist as a concept in the standard and are only visible to the developer through their use in the specification of preprocessor behavior.

C90

The term *placemarker* is new in C99. They are needed to describe the behavior when an empty macro argument is the operand of the ## operator, which could not occur in C90.

C++

This category was added in C99 and does not appear in the C++ Standard, which has specified the preprocessor behavior by copying the words from C90 (with a few changes) rather than providing a reference to the C Standard.

Common Implementations

Implementations vary in how they implement translation phases 3 and 4. Some implementations use a variety of internal preprocessing tokens and flags to signify various events (i.e., recursive macro invocations) and information (i.e., line number information). Such implementation details are invisible to the user of the translator.

---

preprocessing token longest sequence of characters

If the input stream has been parsed into preprocessing tokens up to a given character, the next preprocessing token is the longest sequence of characters that could constitute a preprocessing token. 782

Commentary

This is sometimes known as the *maximal munch rule*. Without this rule, earlier phases of translation would have to be aware of language syntax, a translation phase 7 issue. The creation of preprocessing tokens (lexing) is independent of syntax in C. maximal munch

Other Languages

A rule similar to this is specified by most language definitions.

Common Implementations

Some implementations use a lexer based on a finite state machine, often automatically produced by a lexical description fed into a tool. These automatically generated lexers have the advantage of being simple to produce, but their ability to recovery from lexical errors in the source code tends to be poor. Many commercial translators use handwritten lexers, where error recover can be handled more flexibly.

While the algorithms described in many textbooks can have a performance that is quadratic on the length of the input,[1156] the lexical grammar used by many programming languages has often been designed to avoid these pathological cases.

Coding Guidelines

Developers do not always read the visible source in a top/down left-to-right order. Having a sequence of characters that, but for this C rule, could be lexed in a number of different ways is likely to require additional cognitive effort and may result in misinterpretations of what has been written. The following guideline also catches those cases where a sequence of three identical characters is read as a sequence of two characters. 770 reading kinds of

Cg 782.1

White space or parentheses shall be used to separate preprocessing tokens in those cases where the tokenization of a sequence of characters would give a different result if the characters were processed from right-to-left (rather than left-to-right).

Example

```
1  extern int ei_1, ei_2, ei_3;
2
3  void f(void)
4  {
5  ei_1 = ei_2 +++ei_3;  /* Incorrectly read as + ++ ? */
6  ei_1 = ei_2--- +ei_3; /* Incorrectly read as -- + ? */
7  }
```

---

783 There is one exception to this rule: ~~a header name preprocessing token is only recognized within a **#include** preprocessing directive, and within such a directive,~~ Header name preprocessing tokens are recognized only within **#include** preprocessing directives or in implementation-defined locations within **#pragma** directives. header name exception to rule

Commentary

This exception means that the following sequence of characters:

```
1  if (a < b && c > d)
```

is lexed as (individual preprocessing tokens are enclosed between matching braces, { }):

```
1  {if} {(} {a} {<} {b} {&&} {c} {>} {d} {)}
```

not as:

```
1   {if} {(} {a} {< b && c >} {d} {)}
```

preprocessing token 782
longest sequence of characters
#pragma 1994 directive

even though the latter meets the longest sequence of characters requirement.

An implementation may chose to support a **#pragma** directive that contains a header name. Such an implementation may need to apply this exception in this context.

The sentence was changed and split in two by the response to DR #324.

C90

This exception was not called out in the C90 Standard and was added by the response to DR #017q39.

C++

This exception was not called out in C90 and neither is it called out in the C++ Standard.

Other Languages

A method of including other source files is not usually defined by other languages. However, implementation of those languages often provide such a construct. The specification given in these cases rarely goes into the same level of detail provided by a language specification. Invariably the behavior is the same as for C—there is special case processing based on context.

Common Implementations

This is what all implementations do. No known implementation looks for header names outside of a **#include** preprocessor directive.

In such contexts, a sequence of characters that could be either a header name or a string literal is recognized as the former. 784

Commentary

header name 918 syntax
string literal 895 syntax
escape sequences 898 string literal

The syntax of header names requires a quote-delimited *q-char-sequence* which, while having the same syntax as a string literal, requires different semantic processing (e.g., no processing of escape sequences is required).

The sentence was split from the previous one by the response to DR #324.

EXAMPLE 1 The program fragment **1Ex** is parsed as a preprocessing number token (one that is not a valid floating or integer constant token), even though a parse as the pair of preprocessing tokens **1** and **Ex** might produce a valid expression (for example, if **Ex** were a macro defined as **+1**). Similarly, the program fragment **1E1** is parsed as a preprocessing number (one that is a valid floating constant token), whether or not **E** is a macro name. 785

Commentary

Standard C specifies a token-based preprocessor. The original K&R preprocessor specification could be interpreted as a token-based or character-based preprocessor. In a character-based preprocessor, wherever a character sequence occurs even within string literals and character constants, if it matches the name of a macro it will be substituted for.

EXAMPLE +++++

EXAMPLE 2 786

The program fragment **x+++++y** is parsed as **x ++ ++ + y**, which violates a constraint on increment operators, even though the parse **x ++ + ++ y** might yield a correct expression.

Forward references: character constants (6.4.4.4), comments (6.4.9), expressions (6.5), floating constants (6.4.4.2), header names (6.4.7), macro replacement (6.10.3), postfix increment and decrement operators (6.5.2.4), prefix increment and decrement operators (6.5.3.1), preprocessing directives (6.10), preprocessing numbers (6.4.8), string literals (6.4.5). 787

6.4.1 Keywords

788 *keyword*: one of

auto	**enum**	**restrict**	**unsigned**
break	**extern**	**return**	**void**
case	**float**	**short**	**volatile**
char	**for**	**signed**	**while**
const	**goto**	**sizeof**	**_Bool**
continue	**if**	**static**	**_Complex**
default	**inline**	**struct**	**_Imaginary**
do	**int**	**switch**	
double	**long**	**typedef**	
else	**register**	**union**	

Commentary

The keywords **const** and **volatile** were not in the base document. The identifier **entry** was reserved by the base document but the functionality suggested by its name (Fortran-style multiple entry points into a function) was never introduced into C. [1] base document

The standard specifies, in a footnote, the form that any implementation-defined keywords should take. [490] footnote 28

C90

Support for the keywords **restrict**, **_Bool**, **_Complex**, and **_Imaginary** is new in C99.

C++

The C++ Standard includes the additional keywords:

bool	**mutable**	**this**
catch	**namespace**	**throw**
class	**new**	**true**
const_cast	**operator**	**try**
delete	**private**	**typeid**
dynamic_cast	**protected**	**typename**
explicit	**public**	**using**
export	**reinterpret_cast**	**virtual**
false	**static_cast**	**wchar_t**
friend	**template**	

The C++ Standard does not include the keywords **restrict**, **_Bool**, **_Complex**, and **_Imaginary**. However, identifiers beginning with an underscore followed by an uppercase letter is reserved for use by C++ implementations (17.4.3.1.2p1). So, three of these keywords are not available for use by developers.

In C the identifier `wchar_t` is a typedef name defined in a number of headers; it is not a keyword.

The C99 header **<stdbool.h>** defines macros named `bool`, `true`, `false`. This header is new in C99 and is not one of the ones listed in the C++ Standard as being supported by that language.

Other Languages

Modula-2 requires that all keywords be in uppercase. In languages where case is not significant keywords can appear in a mixture of cases.

Common Implementations

The most commonly seen keyword added by implementations, as an extension, is **asm**. The original K&R specification included **entry** as a keyword; it was reserved for future use.

The processors that tend to be used to host freestanding environments often have a variety of different memory models. Implementation support for these different memory models is often achieved through the use of additional keywords (e.g., **near**, **far**, **huge**, **segment**, and **interrupt**). The C for embedded systems TR defines the keywords **_Accum**, **_Fract**, and **_Sat**.

Embedded C TR 18

Coding Guidelines

One of the techniques used by implementations, for creating language extensions is to define a new keyword. If developers decided to deviate from the guideline recommendation dealing with the use of extensions, some degree of implementation vendor independence is often desired. Some method for reducing the impact of the use of these keywords, on a program's portability, is needed. The following are a number of techniques:

extensions 95.1 cost/benefit

- *Use of macro names.* Here a macro name is defined and this name is used in place of the keyword (which is the macro's body). This works well when there is no additional syntax associated with the keyword and the semantics of a program are unchanged if it is not used. Examples of this type of keyword include **near**, **far** and **huge**.

- *Limiting use of the keyword in source code.* This is possible if the functionality provided by the keyword can be encapsulated in a function that can be called whenever it is required.

- *Conditional compilation.* Littering the source code with conditional compilation directives is really a sign of defeat; it has proven impossible to control the keyword usage.

If there are additional tokens associated with an extension keyword, there are advantages to keeping all of these tokens on the same line. It simplifies the job of stripping them from the source code. Also a number of static analysis tools have an option to ignore all tokens to the end of line when a particular keyword is encountered. (This enables them to parse source containing these syntactic extensions without knowing what the syntax might be.)

Usage

Usage information on preprocessor directives is given elsewhere (see Table 1854.1).

Table 788.1: Occurrence of keywords (as a percentage of all keywords in the respective suffixed file) and occurrence of those keywords as the first and last token on a line (as a percentage of occurrences of the respective keyword; for `.c` files only). Based on the visible form of the `.c` and `.h` files.

while	1.23	0.95	85.20	0.10	**signed**	0.02	0.01	27.20	0.00
goto	1.23	0.89	94.10	0.00	**auto**	0.00	0.00	0.00	0.00

Semantics

789 The above tokens (case sensitive) are reserved (in translation phases 7 and 8) for use as keywords, and shall not be used otherwise.

Commentary

A translator converts all identifiers with the spelling of a keyword into a keyword token in translation phase 7. This prevents them from being used for any other purpose during or after that phase. Identifiers that have the spelling of a keyword may be defined as macros, however there is a requirement in the library section that such definitions not occur prior to the inclusion of any library header. These identifiers are deleted after translation phase 4.

[136] translation phase 7

[129] translation phase 4

In translation phase 8 it is possible for the name of an externally visible identifier, defined using another language, to have the same spelling as a C keyword. A C function, for instance, might call a Fortran subroutine called xyz. The function xyz in turn calls a Fortran subroutine called `default`. Such a usage does not require a diagnostic to be issued.

Other Languages

Most modern languages also reserve identifiers with the spelling of keywords purely for use as keywords. In the past a variety of methods for distinguishing keywords from identifiers have been adopted by language designers, including:

- *By the context in which they occur (e.g., Fortran and PL/1).* In such languages it is possible to declare an identifier that has the spelling of a keyword and the translator has to deduce the intended interpretation from the context in which it occurs.
- *By typeface* (e.g., Algol 68). In such languages the developer has to specify, when entering the text of a program into an editor, which character sequences are keywords. (Conventions vary on which keys have to be pressed to specify this treatment.) Displays that only support a single font might show keywords in bold, or underline them.

- *Some other form of visually distinguishable feature* (e.g., Algol 68, Simula). This feature might be a character prefix (e.g., **'begin** or **.begin**), a change of case (e.g., keywords always written using uppercase letters), or a prefix and a suffix (e.g., **'begin'**).

The term *stropping* is sometimes applied to the process of distinguishing keywords from identifiers.

Lisp has no keywords, but lots of predefined functions.

In some languages (e.g., Ada, Pascal, and Visual Basic) the spelling of keywords is not case sensitive.

Common Implementations

Linkers are rarely aware of C keywords. The names of library functions, translated from other languages, are unlikely to be an issue.

Coding Guidelines

A library function that has the spelling of a C keyword is not callable directly from C. An interface function, using a different spelling, has to be created. C coding guidelines are unlikely to have any influence over other languages, so there is probably nothing useful that can be said on this subject.

The keyword _Imaginary is reserved for specifying imaginary types.[59)] 790

Commentary

This sentence was added by the response to DR #207. The Committee felt that imaginary types were not consistently specified throughout the standard. The approach taken was one of minimal disturbance, modifying the small amount of existing wording, dealing with these types. Readers are referred to Annex G for the details.

footnote 59

---

59) One possible specification for imaginary types appears in Annex G. 791

Commentary

This footnote was added by the response to DR #207.

6.4.2 Identifiers

6.4.2.1 General

identifier syntax

792

identifier:
identifier-nondigit
identifier identifier-nondigit
identifier digit
identifier-nondigit:
nondigit
universal-character-name
other implementation-defined characters
nondigit: one of
_ a b c d e f g h i j k l m
n o p q r s t u v w x y z
A B C D E F G H I J K L M
N O P Q R S T U V W X Y Z
digit: one of
0 1 2 3 4 5 6 7 8 9

Commentary

From the developer's point of view identifiers are the most important tokens in the source code. The reasons for this are discussed in the Coding guidelines section that follows.

C90

Support for *universal-character-name* and "other implementation-defined characters" is new in C99.

C++

The C++ Standard uses the term *nondigit* to denote an *identifier-nondigit*. The C++ Standard does not specify the use of *other implementation-defined characters*. This is because such characters will have been replaced in translation phase 1 and not be visible here.

116 translation phase 1

Other Languages

Some languages do not support the use of underscore, _, in identifiers. There is a growing interest from the users of different computer languages in having support for *universal-character-name* characters in identifiers. But few languages have gotten around to doing anything about it yet. What most other languages call operators can appear in identifiers in Scheme (but not as the first character). Java was the first well-known language to support *universal-character-name* characters in identifiers.

Common Implementations

Some implementations support the use of the $ character in identifiers.

Coding Guidelines

1 Introduction

1.1 Overview

identifier introduction

This coding guideline section contains an extended discussion on the issues involved with reader's use of identifier names, or spellings.[792.1] It also provides some recommendations that aim to prevent mistakes from being made in their usage.

Identifiers are the most important token in the visible source code from the program comprehension perspective. They are also the most common token (29% of the visible tokens in the `.c` files, with comma being the second most common at 9.5%), and they represent approximately 40% of all non-white-space characters in the visible source (comments representing 31% of the characters in the `.c` files).

From the developer's point of view, an identifier's spelling has the ability to represent another source of information created by the semantic associations it triggers in their mind. Developers use identifier spellings both as an indexing system (developers often navigate their way around source using identifiers) and as an aid to comprehending source code. From the translators point of view, identifiers are simply a meaningless sequence of characters that occur during the early stages of processing a source file. (The only operation it needs to be able to perform on them is matching identifiers that share the same spellings.)

identifier cue for recall

The information provided by identifier names can operate at all levels of source code construct, from providing helpful clues about the information represented in objects at the level of C expressions (see Figure 792.1) to a means of encapsulating and giving context to a series of statements and declaration in a function definition. An example of the latter is provided by a study by Bransford and Johnson[153] who

[792.1] Common usage is for the character sequence denoting an identifier to be called its *name*; these coding guidelines often use the term *spelling* to prevent possible confusion.

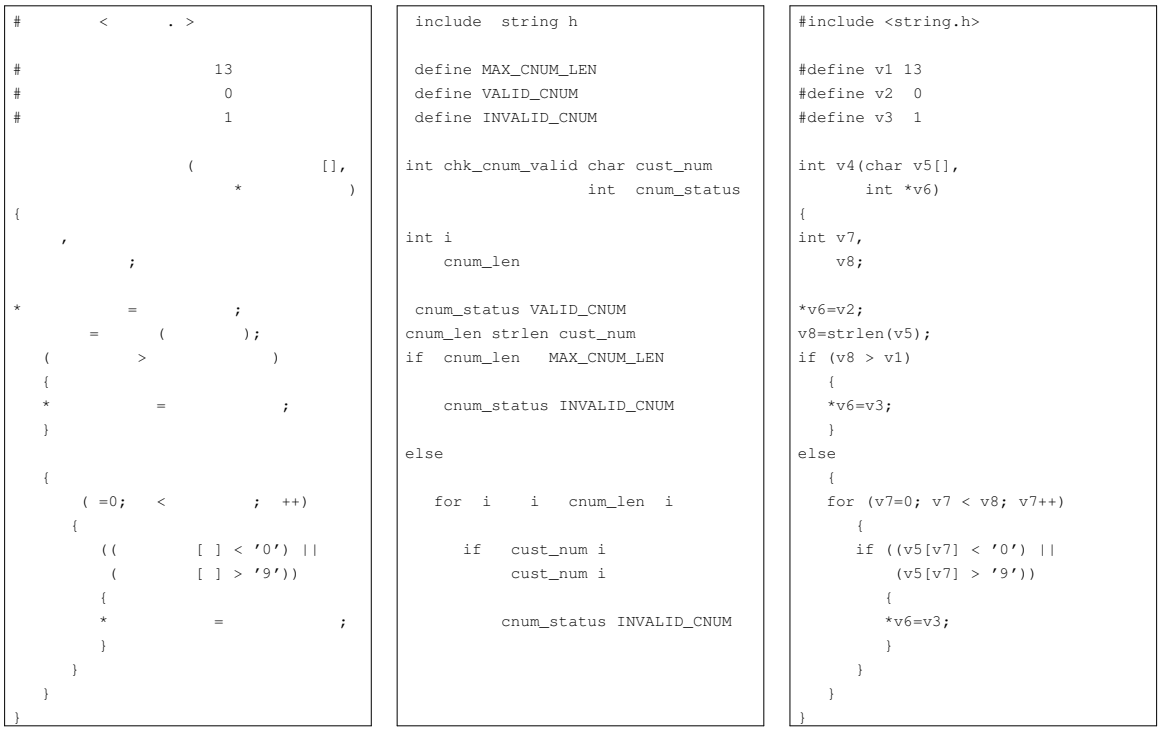

Figure 792.1: The same program visually presented in three different ways; illustrating how a reader's existing knowledge of words can provide a significant benefit in comprehending source code. By comparison, all the other tokens combined provide relatively little information. Based on an example from Laitinen.[795]

read subjects the following passage (having told them they would have to rate their comprehension of it and would be tested on its contents).

Bransford and Johnson[153]

The procedure is really quite simple. First you arrange things into different groups depending on their makeup. Of course, one pile may be sufficient depending on how much there is to do. If you have to go somewhere else due to lack of facilities that is the next step, otherwise you are pretty well set. It is important not to overdo any particular endeavor. That is, it is better to do too few things at once than too many. In the short run this may not seem important, but complications from doing too many can easily arise. A mistake can be expensive as well. The manipulation of the appropriate mechanisms should be self-explanatory, and we need not dwell on it here. At first the whole procedure will seem complicated. Soon, however, it will become just another facet of life. It is difficult to foresee any end to this task in the immediate future, but then one never can tell.

Table 792.1: Mean comprehension rating and mean number of ideas recalled from passage (standard deviation is given in parentheses). Adapted from Bransford and Johnson.[153]

	No Topic Given	Topic Given After	Topic Given Before	Maximum Score
Comprehension	2.29 (0.22)	2.12 (0.26)	4.50 (0.49)	7
Recall	2.82 (0.60)	2.65 (0.53)	5.83 (0.49)	18

The results (see Table 792.1) show that subjects recalled over twice as much information if they were given a meaningful phrase (the topic) before hearing the passage. The topic of the passage describes washing clothes.

The basis for this discussion is human language and the cultural conventions that go with its usage. People spend a large percentage of their waking day, from an early age, using this language (in spoken and written

form). The result of this extensive experience is that individuals become tuned to the commonly occurring sound and character patterns they encounter (this is what enables them to process such material automatically without apparent effort). This experience also results in an extensive semantic network of associations for the words of a language being created in their head. By comparison, experience reading source code pales into insignificance.

770 reading practice
0 automatization
792 semantic networks

These coding guidelines do not seek to change the habits formed as a result of this communication experience using natural language, but rather to recognize and make use of them. While C source code is a written, not a spoken language, developers' primary experience is with a spoken language that also has a written form.

The primary factor affecting the performance of a person's character sequence handling ability appears to be the characteristics of their native language (which in turn may have been tuned to the operating characteristics of its speakers' brain[334]). This coding guideline discussion makes the assumption that developers will attempt to process C language identifiers in the same way as the words and phrases of their native language (i.e., the characteristics of a developer's native language are the most significant factor in their processing of identifiers; one study[763] was able to predict the native language of non-native English speakers, with 80% accuracy, based on the text of English essays they had written). The operating characteristics of the brain also affect performance (e.g., short-term memory is primarily sound based and information lookup is via spreading activation).

There are too many permutations and combinations of possible developer experiences for it to be possible to make general recommendations on how to optimize the selection of identifier spellings. A coding guideline recommending that identifier spellings match the characteristics, spoken as well as written, and conventions (e.g., word order) of the developers' native language is not considered to be worthwhile because it is a practice that developers appear to already, implicitly follow. (Some suggestions on spelling usage are given.) However, it is possible to make guideline recommendations about the use of identifier spellings that are likely to be a cause of problems. These recommendations are essentially filters of spellings that have already been chosen.

792 identifier suggestions
792 identifier filtering spellings

The frequency distribution of identifiers is characterised by large numbers of rare names. One consequence of this is some unusual statistical properties, e.g., the mean frequency changes as the amount of source codes measured increases and relative frequencies obtained from large samples are not completely reliable estimators of the total population probabilities. See Baayen[68] for a discussion of the statistical issues and techniques for handling these kind of distributions.

1.2 Primary identifier spelling issues

There are several ways of dividing up the discussion on identifier spelling issues (see Table 792.2). The headings under which the issues are grouped is a developer-oriented ones (the expected readership for this book rather than a psychological or linguistic one). The following are the primary issue headings used:

identifier primary spelling issues

- *Memorability*. This includes recalling the spelling of an identifier (given some semantic information associated with it), recognizing an identifier from its spelling, and recalling the information associated with an identifier (given its spelling). For instance, what is the name of the object used to hold the current line count, or what information does the object `zip_zap` represent?
- *Confusability*. Any two different identifier spellings will have some degree of commonality. The greater the number of features different identifiers have in common, the greater the probability that a reader will confuse one of them for the other. Minimizing the probability of confusing one identifier with a different one is the ideal, but these coding guidelines attempt have the simpler aim of preventing mutual confusability between two identifiers exceeding a specified level,
- *Usability*. Identifier spellings need to be considered in the context in which they are used. The memorability and confusability discussion treats individual identifiers as the subject of interest, while usability treats identifiers as components of a larger whole (e.g., an expression). Usability factors include the cognitive resources needed to process an identifier and the semantic associations they

expression 940
visual layout

evoke, all in the context in which they occur in the visible source (a more immediate example might be the impact of its length on code layout). Different usability factors are likely to place different demands on the choice of identifier spelling, requiring trade-offs to be made.

Table 792.2: Break down of issues considered applicable to selecting an identifier spelling.

	Visual	Acoustic	Semantic	Miscellaneous
Memory	Idetic memory	Working memory is sound based	Proper names, LTM is semantic based	spelling, cognitive studies, Learning
Confusability	Letter and word shape	Sounds like	Categories, metaphor	Sequence comparison
Usability	Careful reading, visual search	Working memory limits, pronounceability	interpersonal communication, abbreviations	Cognitive resources, typing

memory 0
developer

A spelling that, for a particular identifier, maximizes memorability and usability while minimizing confusability may be achievable, but it is likely that trade-offs will need to be made. For instance, human short-term memory capacity limits suggest that the duration of spoken forms of an identifier's spelling, appearing as operands in an expression, be minimized. However, identifiers that contain several words (increased speaking time), or rarely used words (probably longer words taking longer to speak), are likely to invoke more semantic associations in the readers mind (perhaps reducing the total effort needed to comprehend the source compared to an identifier having a shorter spoken form).

If asked, developers will often describe an identifier spelling as being either *good* or *bad*. This coding guideline subsection does not measure the quality of an identifier's spelling in isolation, but relative to the other identifiers in a program's source code.

1.2.1 Reader language and culture

developer
language and
culture

During the lifetime of a program, its source code will often be worked on by developers having different first languages (their native, or mother tongue). While many developers communicate using English, it is not always their first language. It is likely that there are native speakers of every major human language writing C source code.

If English was good enough for Jesus, it is good enough for me (attributed to various U.S. politicians).

Of the 3,000 to 6,000 languages spoken on Earth today, only 12 are spoken by 100 million or more people (see Table 792.3). The availability of cheaper labour outside of the industrialized nations is slowly shifting developers' native language away from those nations' languages to Mandarin Chinese, Hindi/Urdu, and Russian.

Table 792.3: Estimates of the number of speakers each language (figures include both native and nonnative speakers of the language; adapted from Ethnologue volume I, SIL International). Note: Hindi and Urdu are essentially the same language, Hindustani. As the official language of Pakistan, it is written right-to-left in a modified Arabic script and called Urdu (106 million speakers). As the official language of India, it is written left-to-right in the Devanagari script and called Hindi (469 million speakers).

Rank	Language	Speakers (millions)	Writing direction	Preferred word order
1	Mandarin Chinese	1,075	left-to-right also top-down	SVO
2	Hindi/Urdu	575	see note	see note
3	English	514	left-to-right	SVO
4	Spanish	425	left-to-right	SVO
5	Russian	275	left-to-right	SVO
6	Arabic	256	right-to-left	VSO
7	Bengali	215	left-to-right	SOV
8	Portuguese	194	left-to-right	SVO
9	Malay/Indonesian	176	left-to-right	SVO
10	French	129	left-to-right	SVO
11	German	128	left-to-right	SOV
12	Japanese	126	left-to-right	SOV

If, as claimed here, the characteristics of a developer's native language are the most significant factor in their processing of identifiers, then a developer's first language should be a primary factor in this discussion. However, most of the relevant studies that have been performed used native-English speakers as subjects.[792.2] Consequently, it is not possible to reliably make any claims about the accuracy of applying existing models of visual word processing to non-English languages.

The solution adopted here is to attempt to be natural-language independent, while recognizing that most of the studies whose results are quoted used native-English speakers. Readers need to bear in mind that it is likely that some of the concerns discussed do not apply to other languages and that other languages will have concerns that are not discussed.

1.3 How do developers interact with identifiers?

The reasons for looking at source code do not always require that it be read like a book. Based on the various reasons developers have for looking at source the following list of identifier-specific interactions are considered:

identifier
developer
interaction
770 reading
kinds of

- When quickly skimming the source to get a general idea of what it does, identifier names should suggest to the viewer, without requiring significant effort, what they are intended to denote.
- When searching the source, identifiers should not disrupt the flow (e.g., by being extremely long or easily confused with other identifiers that are likely to be seen).
- When performing a detailed code reading, identifiers are part of a larger whole and their names should not get in the way of developers' appreciation of the larger picture (e.g., by requiring disproportionate cognitive resources).
- Trust based usage. In some situations readers extract what they consider to be sufficiently reliable information about an identifier from its spelling or the context in which it is referenced; they do not invest in obtaining more reliable information (e.g., by, locating and reading the identifiers' declaration).

trust based usage

Developers rarely interact with isolated identifiers (a function call with no arguments might be considered to be one such case). For instance, within an expression an identifier is often paired with another identifier (as the operand of a binary operator) and a declaration often declares a list of identifiers (which may, or may not, have associations with each other).

However well selected an identifier spelling might be, it cannot be expected to change the way a reader chooses to read the source. For instance, a reader might keep identifier information in working memory, repeatedly looking at its definition to refresh the information; rather like a person repeatedly looking at their watch because they continually perform some action that causes them to forget the time and don't invest (perhaps because of an unconscious cost/benefit analysis) the cognitive resources needed to better integrate the time into their current situation.

Introducing a new identifier spelling will rarely causes the spelling of any other identifier in the source to be changed. While the words of natural languages, in spoken and written form, evolve over years, experience shows that the spelling of identifiers within existing source code rarely changes. There is no perceived cost/benefit driving a need to make changes.

An assumption that underlies the coding guideline discussions in this book is that developers implicitly, and perhaps explicitly, make cost/accuracy trade-offs when working with source code. These trade-offs also occur in their interaction with identifiers.

0 cost/accuracy
trade-off

1.4 Visual word recognition

This section briefly summarizes those factors that are known to affect visual word recognition and some of the models of human word recognition that have been proposed. A word is said to be recognized when its representation is uniquely accessed in the reader's lexicon. Some of the material in this subsection is based on chapter 6 of *The Psychology of Language* by T. Harley.[542]

word
visual recognition

[792.2] So researchers have told your author, who, being an English monoglot, has no choice but to believe them.

Reading is a recent (last few thousand years) development in human history. Widespread literacy is even more recent (under 100 years). There has been insufficient time for the impact of comparative reading skills to have had any impact on our evolution, assuming that it has any impact. (It is not known if there is any correlation between reading skill and likelihood of passing on genes to future generation.) Without evolutionary pressure to create specialized visual word-recognition systems, the human word-recognition system must make use of cognitive processes designed for other purposes. Studies suggest that word recognition is distinct from object recognition and specialized processes, such as face recognition. A model that might be said to mimic the letter- and word-recognition processes in the brain is the Interactive Activation Model.[910]

The psychology studies that include the use of character sequences (in most cases denoting words) are intended to uncover some aspect of the workings of the human mind. While the tasks that subjects are asked to perform are not directly related to source code comprehension, in some cases, it is possible to draw parallels. The commonly used tasks in the studies discussed here include the following:

naming task

- *The naming task.* Here subjects are presented with a word and the time taken to name that word is measured. This involves additional cognitive factors that do not occur during silent reading (e.g., controlling the muscles that produce sounds).

lexical decision task

word non-word effects 792

- *The lexical decision task.* Here subjects are asked to indicate, usually by pressing the appropriate button, whether a sequence of letters is a word or nonword (where a word is a letter sequence that is the accepted representation of a spoken word in their native language).

semantic categorization task

- *The semantic categorization task.* Here subjects are presented with a word and asked to make a semantic decision (e.g., "is *apple* a fruit or a make of a car?").

The following is a list of those factors that have been found to have an effect on visual word recognition. Studies[16,566] investigating the interaction between these factors have found that there are a variety of behaviors, including additive behavior and parallel operation (such as the Stroop effect).

stroop effect 1641

age of acquisition

- *Age of acquisition*. Words learned early in life are named more quickly and accurately than those learned later.[1506] Age of acquisition interacts with frequency in that children tend to learn the more common words first, although there are some exceptions (e.g., *giant* is a low-frequency word that is learned early).
- *Contextual variability*. Some words tend to only occur in certain contexts (low-contextual variability), while others occur in many different contexts (high-contextual variability). For instance, in a study by Steyvers and Malmberg[1299] the words *atom* and *afternoon* occurred equally often; however, *atom* occurred in 354 different text samples while *afternoon* occurred in 1,025. This study found that words having high-contextual variability were more difficult to recognize than those having low-contextual variability (for the same total frequency of occurrence).
- *Form-based priming* (also known as *orthographic priming*). The form of a word might be thought to have a priming effect; for instance, *CONTRAST* shares the same initial six letters with *CONTRACT*. However, studies have failed to find any measurable effects.

illusory conjunctions

- *Illusory conjunctions*. These occur when words are presented almost simultaneously, as might happen when a developer is repeatedly paging through source on a display device; for instance, the letter sequences *psychment* and *departology* being read as *psychology* and *department*.
- *Length effects*. There are several ways of measuring the length of a word; they tend to correlate with each other (e.g., the number of characters vs. number of syllables). Studies have shown that there is some effect on naming for words with five or more letters. Naming time also increases as the number of syllables in a word increases (also true for naming pictures of objects and numbers with more syllables). Some of this additional time includes preparing to voice the syllables.

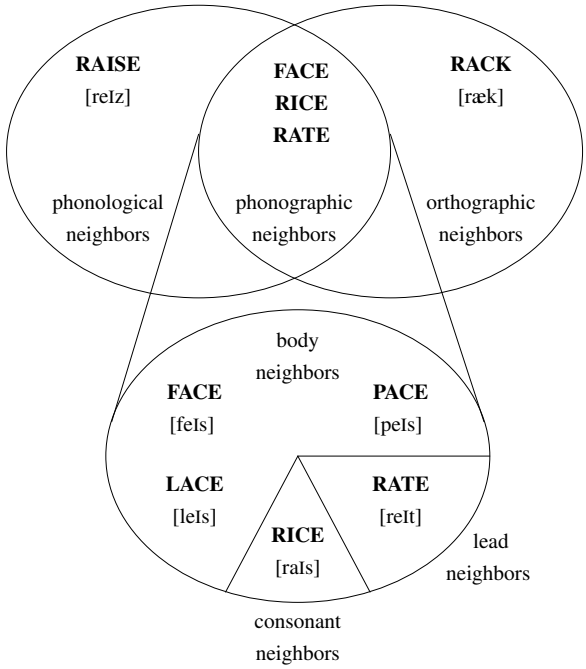

Figure 792.2: Example of the different kinds of lexical neighborhoods for the English word *RACE*. Adapted from Peereman and Content.[1068]

- *Morphology*. The stem-only model of word storage[1327] proposed that word stems are stored in memory, along with a list of rules for prefixes (e.g., *re* for performing something again) and suffixes (*ed* for the past tense), and their exceptions. The model requires that these affixes always be removed before lookup (of the stripped word). Recognition of words that look like they have a prefix (e.g., *interest*, *result*), but don't, has been found to take longer than words having no obvious prefix (e.g., *crucial*). Actual performance has been found to vary between different affixes. It is thought that failure to match the letter sequence without the prefix causes a reanalysis of the original word, which then succeeds. See Vannest[1410] for an overview and recent experimental results.

  morphology identifier

- *Neighborhood effects*. Words that differ by a single letter are known as *orthographic neighbors*. Some words have many orthographic neighbors— *mine* has 29 (*pine*, *line*, *mane*, etc.)— while others have few. Both the *density* of orthographic neighbors (how many there are) and their relative frequency (if a neighbor occurs more or less frequently in written texts) can affect visual word recognition. The *spread* of the neighbors for a particular word is the number of different letter positions that can be changed to yield a neighbor (e.g., *clue* has a spread of two— *glue* and *club*). The rime of neighbors can also be important; see Andrews[38] for a review.

  neighborhood identifier

- *Nonword conversion effect*. A nonword is sometimes read as a word whose spelling it closely resembles.[1113] This effect is often seen in a semantic priming context (e.g., when proofreading prose).

- *Other factors*. Some that have been suggested to have an effect on word recognition include meaningfulness, concreteness, emotionality, and pronounceability,

- *Phonological neighborhood*. Phonological neighborhood size has not been found to be a significant factor in processing of English words. However, the Japanese lexicon contains many homophones. For instance, there are many words pronounced as */kouen/* (i.e., park, lecture, support, etc.). To discriminate homophones, Japanese readers depend on orthographic information (different Kanji compounds). A study by Kawakami[715] showed that phonological neighborhood size affected subjects' lexical decision response time for words written in Katakana.

  phonological neighborhood identifier

  792 phonology

words 792 English

- *Proper names*. A number of recent studies[586] have suggested that the cognitive processing of various kinds of proper names (e.g., people's names and names of landmarks) is different from other word categories.
- *Repetition priming*. A word is identified more rapidly, and more accurately, on its second and subsequent occurrences than on its first occurrence. Repetition priming interacts with frequency in that the effect is stronger for low-frequency words than high-frequency ones. It is also affected by the number of items intervening between occurrences. It has been found to decay smoothly over the first three items for words, and one item for nonwords to a stable long-term value.[919]

semantic priming

- *Semantic priming*. Recognition of a word is faster if it is immediately preceded by a word that has a semantically similar meaning;[1093] for instance, *doctor* preceded by the word *nurse*. The extent to which priming occurs depends on the extent to which word pairs are related, the frequency of the words, the age of the person, and individual differences,
- *Sentence context*. The sentence "It is important to brush your teeth every" aids the recognition of the word *day*, the highly predictable ending, but not *year* which is not.

syllable frequency

- *Syllable frequency*. There has been a great deal of argument on the role played by syllables in word recognition. Many of the empirical findings against the role of syllables have been in studies using English; however, English is a language that has ambiguous and ill-defined syllable boundaries. Other languages, such as Spanish, have well-defined syllable boundaries. A study by Álvarev, Carreiras, and de Vega[22] using Spanish-speaking subjects found that syllable frequency played a much bigger role in word recognition than in English.

word frequency

- *Word frequency*. The number of times a person has been exposed to a word effects performance in a number of ways. High-frequency words tend to be recalled better, while low-frequency words tend to be better recognized (it is thought that this behavior may be caused by uncommon words having more distinctive features,[890, 1228] or because they occur in fewer contexts[1299]). It has also been shown[567] that the attentional demands of a word-recognition task are greater for less frequent words. Accurate counts of the number of exposures an individual has had to a particular word are not available, so word-frequency measures are based on counts of their occurrence in large bodies of text. The so-called *Brown* corpus[780] is one well-known, and widely used, collection of English usage. (Although it is relatively small, one million words, by modern standards and its continued use has been questioned.[182]) The British National Corpus[823] (BNC) is more up-to-date (the second version was released in 2001) and contains more words (100 million words of spoken and written British English).

word non-word effects 792

- *Word/nonword effects*. Known words are responded to faster than nonwords. Nonwords whose letter sequence does not follow the frequency distribution of the native language are rejected more slowly than nonwords that do.

1.4.1 Models of word recognition

Word recognition models of

Several models have been proposed for describing how words are visually recognized.[660] One of the main issues has been whether orthography (letter sequences) are mapped directly to semantics, or whether they are first mapped to phonology (sound sequences) and from there to semantics. The following discussion uses the Triangle model.[544] (More encompassing models exist; for instance, the Dual Route Cascade model[260] is claimed by its authors to be the most successful of the existing computational models of reading. However, because C is not a spoken language the sophistication and complexity of these models is not required.)

By the time they start to learn to read, children have already built up a large vocabulary of sounds that map to some meaning (*phonology* ⇒ *semantics*). This existing knowledge can be used when learning to read alphabetic scripts such as English (see Siok and Fletcher[1246] for a study involving logographic, Chinese, reading acquisition). They simply have to learn how to map letter sequences to the word sounds they already know (*orthography* ⇒ *phonology* ⇒ *semantics*). The direct mapping of sequences of letters to semantics (*orthography* ⇒ *semantics*) is much more difficult to learn. (This last statement is hotly contested by several

logographic 792

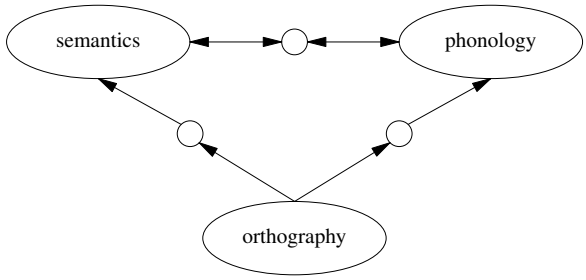

Figure 792.3: Triangle model of word recognition. There are two routes to both semantics and phonology, from orthography. Adapted from Harm.[544]

psychologists and education experts who claim that children would benefit from being taught using the *orthography* ⇒ *semantics* based methods.)

The results of many studies are consistent with the common route, via phonology. However, there are studies, using experienced readers, which have found that in some cases a direct mapping from orthography to semantics occurs. A theory of visual word recognition cannot assume that one route is always used.

The model proposed by[544] is based on a neural network and an appropriate training set. The training set is crucial— it is what distinguishes the relative performance of one reader from another. A person with a college education will have read well over 20 million words by the time they graduate.[792.3]

words domain knowledge

Readers of different natural languages will have been trained on different sets of input. Even the content of courses taken at school can have an effect. A study by Gardner, Rothkopf, Lapan, and Lafferty[472] used 10 engineering, 10 nursing, and 10 law students as subjects. These subjects were asked to indicate whether a letter sequence was a word or a nonword. The words were drawn from a sample of high frequency words (more than 100 per million), medium-frequency (10–99 per million), low-frequency (less than 10 per million), and occupationally related engineering or medical words. The nonwords were created by rearranging letters of existing words while maintaining English rules of pronounceability and orthography.

The results showed engineering subjects could more quickly and accurately identify the words related to engineering (but not medicine). The nursing subjects could more quickly and accurately identify the words related to medicine (but not engineering). The law students showed no response differences for either group of occupationally related words. There were no response differences on identifying nonwords. The performance of the engineering and nursing students on their respective occupational words was almost as good as their performance on the medium-frequency words.

The Gardner et al. study shows that exposure to a particular domain of knowledge can affect a person's recognition performance for specialist words. Whether particular identifier spellings are encountered by individual developers sufficiently often, in C source code, for them to show a learning effect is not known.

2 Selecting an identifier spelling

2.1 Overview

identifier selecting spelling

This section discusses the developer-oriented factors involved in the selection of an identifier's spelling. The approach taken is to look at what developers actually do[792.4] rather than what your author or anybody else thinks they should do. Use of this approach should not be taken to imply that what developers actually do is any better than the alternatives that have been proposed. Given the lack of experimental evidence showing

[792.3] A very conservative reading rate of 200 words per minute, for 30 minutes per day over a 10 years period.

[792.4] Some of the more unusual developer naming practices are more talked about than practiced. For instance, using the names of girl friends or football teams. In the visible form of the `.c` files 1.7% of identifier occurrences have the spelling of an English christian name. However, most of these (e.g., `val`, `max`, `mark`, etc.) have obvious alternative associations. Others require application domain knowledge (e.g., hardware devices: `lance`, floating point `nan`). This leaves a handful, under 0.01%. that may be actual uses of peoples names (e.g., `francis`, `stephen`, `terry`).

that the proposed alternatives live up to the claims made about them, there is no obvious justification for considering them.

Encoding information in an identifier's spelling is generally believed to reduce the effort needed to comprehend source code (by providing useful information to the reader).[792.5]

Some of the attributes, information about which, developers often attempt to encode in an identifier's spelling include:

- *Information on what an identifier denotes.* This information may be application attributes (e.g., the number of characters to display on some output device) or internal program housekeeping attributes (e.g., a loop counter).
- *C language properties of an identifier.* For instance, what is its type, scope, linkage, and kind of identifier (e.g., macro, object, function, etc.).
- *Internal representation information.* What an object's type is, or where its storage is allocated.
- *Management-mandated information.* This may include the name of the file containing the identifier's declaration, the date an identifier was declared, or some indication of the development group that created it.

The encoded information may consist of what is considered to be more than one distinct character sequence. These distinct character sequences may be any combination of words, abbreviations, or acronyms. Joining together words is known as *compounding* and some of the rules used, primarily by native-English speakers, are discussed elsewhere. Studies of how people abbreviate words and the acronyms they create are also discussed elsewhere. Usability issues associated with encoding information about these attributes in an identifier's spelling is discussed elsewhere.

compound 792
word abbreviating 792
identifier identifier 792
encoding usability

optimal spelling identifier

One conclusion to be drawn from the many studies discussed in subsequent sections is that optimal selection of identifier spelling is a complex issue, both theoretically and practically. Optimizing the memorability, confusability, and usability factors discussed earlier requires that the mutual interaction between all of the identifiers in a program's visible source code be taken into account, as well as their interaction with the reader's training and education. Ideally this optimization would be carried out over all the visible identifiers in a programs source code (mathematically this is a constraint-satisfaction problem). In practice not only is constraint satisfaction computationally prohibitive for all but the smallest programs, but adding a new identifier could result in the spellings of existing identifiers changing (because of mutual interaction), and different spelling could be needed for different readers, perhaps something that future development environments will support (e.g., to index different linguistic conventions).

The current knowledge of developer identifier-performance factors is not sufficient to reliably make coding guideline recommendations on how to select an identifier spelling (although some hints are made). However, enough is known about developer mistakes to be able to made some guideline recommendations on identifier spellings that should not be used.

This section treats creating an identifier spelling as a two-stage process, which iterates until one is selected:

1. *A list of candidates is enumerated.* This is one of the few opportunities for creative thinking when writing source code (unfortunately the creative ability of most developers rarely rises above the issue of how to indent code). The process of creating a list of candidates is discussed in the first subsection that follows.
2. *The candidate list is filtered.* If no identifiers remain, go to step 1. The factors controlling how this filtering is performed are discussed in the remaining subsections.

Some of the most influential ideas on how humans communicate meaning using language were proposed by Grice[520] and his maxims have been the starting point for much further research. An up-to-date, easier-

relevance 0

[792.5] The few studies that have investigated this belief have all used inexperienced subjects; there is no reliable experimental evidence to support this belief.

to-follow discussion is provided by Clark,[242] while the issue of relevance is discussed in some detail by Sperber and Wilson.[1271]

More detailed information on the theory and experimental results, which is only briefly mentioned in the succeeding subsections, is provided in the sections that follow this one.

2.2 Creating possible spellings

An assumption that underlies all coding guideline discussions in this book is that developers attempt (implicitly or explicitly) to minimize their own effort. Whether they seek to minimize immediate effort (needed to create the declaration and any associated reference that caused it to be created) or the perceived future effort of using that identifier is not known.

0 cost/accuracy trade-off

Frequency of occurrence of words in spoken languages has been found to be approximately tuned so that shorter ones occur most often. However, from the point of view of resource minimization there is an important difference between words and identifiers. A word has the opportunity to evolve— its pronunciation can change or the concept it denotes can be replaced by another word. An identifier, once declared in the source, rarely has its spelling modified. The cognitive demands of a particular identifier are fixed at the time it is first used in the source (which may be a declaration, or a usage in some context soon followed by a declaration). This point of first usage is the only time when any attempt at resource minimization is likely to occur.

792 Zipf's law

Developers typically decide on a spelling within a few seconds. Selecting identifier spellings is a creative process (one of the few really creative opportunities when working at the source code level) and generates a high cognitive load, something that many people try to avoid. Developers use a variety of cognitive load reducing decision strategies, which include spending little time on the activity.

When do developers create new identifiers? In some cases a new identifier is first used by a developer when its declaration is created. In other cases the first usage is when the identifier is referenced when an expression is created (with its declaration soon following). The semantic associations present in the developer's mind at the time an identifier spelling is selected, may not be the same as those present once more uses of the identifier have occurred (because additional uses may cause the relative importance given to the associated semantic attributes to change).

When a spelling for a new identifier is required a number of techniques can be employed to create one or more possibilities, including the following:

- *Waiting for one to pop into its creator head.* These are hopefully derived from semantic associations (from the attributes associated with the usage of the new identifier) indexing into an existing semantic network in the developers' head.

792 semantic networks

- *Using an algorithm.* For instance, *template* spellings that are used for particular cases (e.g., using `i` or a name ending in `index` for a loop variable), or applying company/development group conventions (discussed elsewhere).

1774 loop control variable
792 identifier other guideline documents

- *Basing the spelling on that of the spellings of existing identifiers* with which the new identifier has some kind of association. For instance, the identifiers may all be enumeration constants or structure members in the same type definition, or they may be function or macro names performing similar operations. Some of the issues (e.g., spelling, semantic, and otherwise) associated with related identifiers are discussed elsewhere.

517 enumeration set of named constants
792 identifier learning a list of

- *Using a tool to automatically generate possibilities for consideration by the developer*. For instance, Dale and Reiter[309] gave a computational interpretation to the Gricean maxims[520] to formulate their *Incremental Algorithm*, which automates the production of *referring expressions* (noun phrases). To be able to generate possible identifiers a tool would need considerable input from the developer on the information to be represented by the spelling. Although word-selection algorithms are used in natural-language generation systems, there are no tools available for identifier selection so this approach is not discussed further here.

822 symbolic name
0 relevance

- *Asking a large number of subjects to generate possible identifier names,* using the most common suggestions as input to a study of subjects' ability to match and recall the identifiers, the identifier having the best match and recall characteristics being chosen. Such a method has been empirically tested on a small example.[78] However, it is much too time-consuming and costly to be considered as a possible technique in these coding guidelines.

Table 792.4: Percentage of identifiers in one program having the same spelling as identifiers occurring in various other programs. First row is the total number of identifiers in the program and the value used to divide the number of shared identifiers in that column). Based on the visible form of the `.c` files.

2.2.1 Individual biases and predilections

It is commonly believed by developers that the names they select for identifiers are *obvious*, *self-evident*, or *natural*. Studies of people's performance in creating names for objects shows this belief to be false,[203, 462, 463] at least in one sense. When asked to provide names for various kinds of entities, people have been found to select a wide variety of different names, showing that there is nothing *obvious* about the choice of a name. Whether, given a name, people can reliably and accurately deduce the association intended by its creator is not known (if the results of studies of abbreviation performance are anything to go by, the answer is probably not).

abbreviating 792 identifier

A good naming study example is the one performed by Furnas, Landauer, Gomez, and Dumais,[462, 463] who described operations (e.g., hypothetical text editing commands, categories in *Swap 'n Sale* classified ads, keywords for recipes) to subjects who were not domain experts and asked them to suggest a name for each operation. The results showed that the name selected by one subject was, on average, different from the name selected by 80% to 90% of the other subjects (one experiment included subjects who were domain experts and the results for those subjects were consistent with this performance). The occurrences of the different names chosen tended to follow an inverse law, with a few words occurring frequently and most only rarely.

Zipf's law 792

Individual biases and predilections are a significant factor in the wide variety of names' selection. Another factor is an individual's past experience; there is no guarantee that the same person would select the same name at some point in the future. The issue of general developer difference is discussed elsewhere. The following subsections discuss some of the factors that can affect developers' identifier processing performance.

developer 0 differences

2.2.1.1 Natural language

Developers will have spent significant amounts of time, from an early age, using their native language in both spoken and written forms. This usage represents a significant amount of learning, consequently recognition (e.g., recognizing common sequences of characters) and generation (e.g., creating the commonly occurring sounds) operations will have become automatic.

automatization 0

The following natural-language related issues are discussed in the subsequent sections:

Identifier 792 semantics
Metaphor 792
abbreviating 792 identifier
compound 792 word
identifier 792 English as second language
identifier 792 second language spelling

- Language conventions, including use of metaphors and category formation.
- Abbreviating of known words.
- Methods for creating new words from existing words.
- Second-language usage.

2.2.1.2 Experience

People differ in the experiences they have had. The following are examples of some of the ways in which personal experiences might affect the choice of identifier spellings.

- *recent experience*. Developers will invariably have read source code containing other identifiers just prior to creating a new identifier. A study by Sloman, Harrison, and Malt[1258] investigated how subjects named ambiguous objects immediately after exposure to familiar objects. Subjects were first shown several photographs of two related objects (e.g., chair/stool, plate/bowl, pen/marker). They were then shown a photograph of an object to which either name could apply (image-manipulation software was used to create the picture from photographs of the original objects) and asked to name the object. The results found that subjects tended to use a name consistent with objects previously seen (77% of the time, compared to 50% for random selection; other questions asked as part of the study showed results close to 50% random selection).
- *educational experience*. Although they may have achieved similar educational levels in many subjects, there invariably will be educational differences between developers. A study by Van den Bergh, Vrana, and Eelen[1398] showed subjects two-letter pairs (e.g., *OL* and *IG*) and asked them to select the letter pair they liked the best (for "God knows whatever reason"). Subjects saw nine two-letter pairs. Some of the subjects were skilled typists (could touch type blindfolded and typed an average of at least three hours per week) while the others were not. The letter pair choice was based on the fact that a skilled typist would use the same finger to type both letters of one pair, but different fingers to type the letters of the other pair. Each subject scored 1 if they selected a pair typed with the same finger and 0 otherwise. The expected mean total score for random answers was 4.5. Overall, the typists mean was 3.62 and the nontypists mean was 4.62, indicating that typists preferred combinations typed with different fingers. Another part of the study attempted to find out if subjects could deduce the reasons for their choices; subjects could not. The results of a second experiment showed how letter-pair selection changed with degree of typing skill.
- *cultural experience*. A study by Malt, Sloman, Gennari, Shi, and Wang[892, 893] showed subjects (who were native speakers of either English, Chinese, or Spanish) pictures of objects of various shapes and sizes that might be capable of belonging to either of the categories— bottle, jar, or container. The subjects were asked to name the objects and also to group them by physical qualities. The results found that while speakers of different languages showed substantially different patterns in naming the objects (i.e., a linguistic category), they showed only small differences in their perception of the objects (i.e., a category based on physical attributes).

naming cultural differences

- *environmental experience*. People sometimes find that a change of environment enables them to think about things in different ways. The environment in which people work seems to affect their thoughts. A study by Godden and Baddeley[498] investigated subjects' recall of memorized words in two different environments. Subjects were divers and learned a list of spoken words either while submerged underwater wearing scuba apparatus or while sitting at a table on dry land. Recall of the words occurred under either of the two environments. The results showed that subjects recall performance was significantly better when performed in the same environment as the word list was learned (e.g., both on land or both underwater). Later studies have obtained environmental affects on recall performance in more mundane situations, although some studies have failed to find any significant effect. A study by Fernández and Alonso[40] obtained differences in recall performance for older subjects when the environments were two different rooms, but not for younger subjects.

2.2.1.3 Egotism

It is not uncommon to encounter people's names used as identifiers (e.g., the developer's girlfriend, or favorite film star). While such unimaginative, ego-driven naming practice may be easy to spot, it is possible that much more insidious egotism is occurring. A study by Nuttin[1020] found that a person's name affects

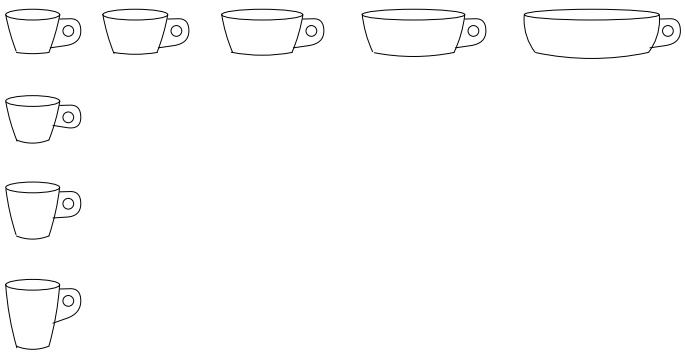

Figure 792.4: Cup- and bowl-like objects of various widths (ratios 1.2, 1.5, 1.9, and 2.5) and heights (ratios 1.2, 1.5, 1.9, and 2.4). Adapted from Labov.[789]

their choice of letters in a selection task. Subjects (in 12 different European countries) were given a sheet containing the letters of their alphabet in random order and spaced out over four lines and asked to circle six letters. They were explicitly told not to think about their choices but to make their selection based on those they felt they preferred. The results showed that the average probability of a letter from the subject's name being one of the six chosen was 0.30, while for non-name letters the probability was 0.20 (there was some variation between languages, for instance: Norwegian 0.35 vs. 0.18 and Finnish 0.35 vs. 0.19). There was some variation across the components of each subject's name, with their initials showing greatest variation and greatest probability of being chosen (except in Norwegian). Nuttin proposed that ownership, in this case a person's name, was a sufficient condition to enhance the likelihood of its component letters being more attractive than other letters. Kitayama and Karasawa[743] replicated the results using Japanese subjects.

A study by Jones, Pelham, Mirenberg, and Hetts[688] showed that the amount of exposure to different letters had some effect on subject's choice. More commonly occurring letters were selected more often than the least commonly occurring (a, e, i, n, s, and t vs. j, k, q, w, x, and z). They also showed that the level of a subject's self-esteem and the extent to which they felt threatened by the situation they were in affected the probability of them selecting a letter from their own name.

2.2.2 Application domain context

context naming affected by

The creation of a name for a new identifier, suggesting a semantically meaningful association with the application domain, can depend on the context in which it occurs.

A study by Labov[789] showed subjects pictures of individual items that could be classified as either cups or bowls (see Figure 792.4). These items were presented in one of two contexts— a neutral context in which the pictures were simply presented and a food context (they were asked to think of the items as being filled with mashed potatoes).

The results show (see Figure 792.5) that as the width of the item seen was increased, an increasing number of subjects classified it as a bowl. By introducing a food context subjects responses shifted towards classifying the item as a bowl at narrower widths.

The same situation can often be viewed from a variety of different points of view (the term *frame* is sometimes used); for instance, commercial events include buying, selling, paying, charging, pricing, costing, spending, and so on. Figure 792.6 shows four ways (i.e., buying, selling, paying, and charging) of looking at the same commercial event.

2.2.3 Source code context

source code context identifier naming conventions identifier 792 other guideline documents hungarian naming identifier

It is quiet common for coding guideline documents to recommend that an identifier's spelling include encoded information on the source code context of its declaration. The term *naming conventions* is often used to refer to these recommendations. Probably the most commonly known of these conventions is the Hungarian naming convention,[1244] which encodes type information and other attributes in the spelling of an identifier.

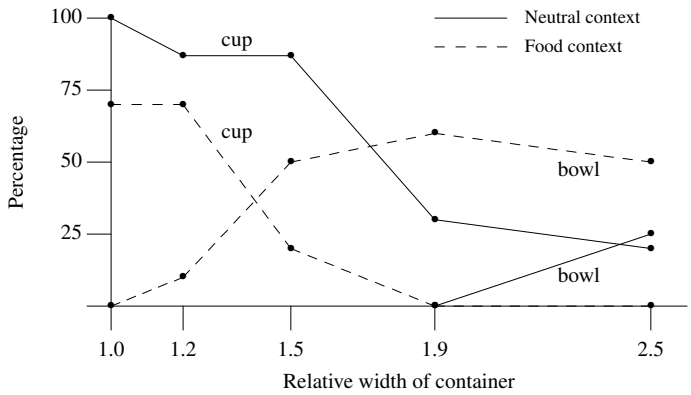

Figure 792.5: The percentage of subjects who selected the term *cup* or *bowl* to describe the object they were shown (the paper did not explain why the figures do not sum to 100%). Adapted from Labov.[789]

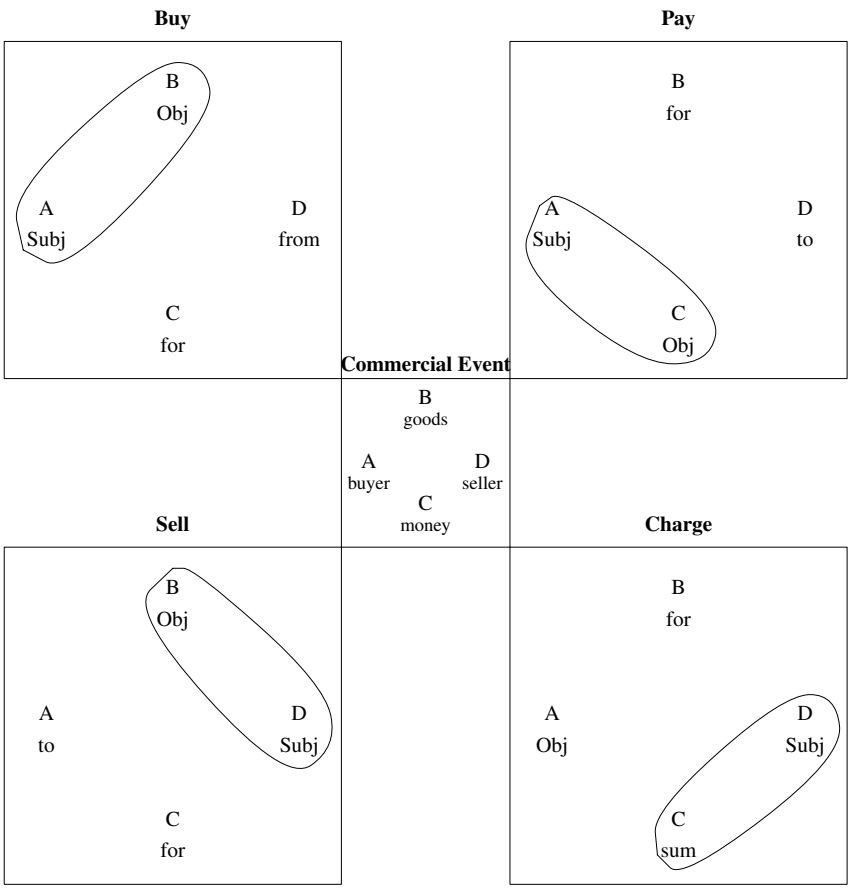

Figure 792.6: A commercial event involving a buyer, seller, money, and goods; as seen from the buy, sell, pay, or charge perspective. Based on Fillmore.[423]

identifier 792 encoding usability

As discussed elsewhere, such information may not be relevant to the reader, may reduce the memorability of the identifier spelling, may increase the probability that it will be confused with other identifiers, and increase the cost of maintaining code.

The two language contexts that are used to influence the spelling of identifiers are namespace and scope. The following subsections briefly discusses some of the issues and existing practices.

2.2.3.1 Name space

macro naming conventions

Macro naming conventions

There is a very commonly used convention of spelling macro names using only uppercase letters (plus underscores and digits; see Table 792.5). Surprisingly this usage does not consume a large percentage of available character combinations (3.4% of all possible four-character identifiers, and a decreasing percentage for identifiers containing greater numbers of characters).

The use of uppercase letters for macro names has become a C idiom. As such, experienced developers are likely to be practiced at recognizing this usage in existing code. It is possible that an occurrence of an identifier containing all uppercase letters that is not a macro name may create an incorrect belief in the mind of readers of the source.

macro parameter naming conventions

preprocessor 1854 directives syntax

There are no common naming conventions based on an identifier being used as a macro parameter. The logical line based nature of macro definitions may result in macro parameter names containing only a few characters having less cost associated with them than those containing many characters.

tag naming conventions

Tag and typedef naming conventions

There is a commonly seen naming convention of giving a tag name and an associated typedef name the same spelling (during the translation of individual translation units of this book's benchmark programs 30% of the tag names declared had the same spelling as that used in the declaration of a typedef name). Sharing the same name has advantage of reducing the amount of information that developers need to remember (once they have learned this convention). As well as this C existing practice, C++ developers often omit the keyword before a tag name (tags are in the same name space as identifiers in C++).

tag 441 name space

syntactic 438 context

Given that one of three keywords immediately precedes a tag name, its status as a tag is immediately obvious to a reader of the source (the only time when this context may not be available is when a tag name occurs as an argument in a macro invocation). Given the immediate availability of this information there is no benefit in a naming convention intended to flag the status of an identifier as a tag.

typedef naming conventions

typedef name 792 no lowercase

The following are several naming conventions that are often seen for typedef names. These include:

- No lowercase letters are used (i.e., uppercase letters, digits, and underscore are used).
- Information on the representation of the type is encoded in the spelling. This encoding can vary from the relatively simply (e.g., `INT_8` indicates that an object is intended to hold values representable in an integer type represented in eight bits; a convention that is consistent with that used in the **`<stdint.h>`** header), or quite complex (e.g., hungarian naming).

MISRA 0 hungarian 792 naming identifier

It is possible for type information, in an identifier's spelling, to be either a benefit or a cost, for readers of the source. For instance, readers may assume that the following equality holds `sizeof(INT_8) == sizeof(char)`, when in fact the author used type **`int`** in the declaration of all `INT_` typedef names.

member naming conventions

Member naming conventions

Some coding guideline documents recommend that the names of members contain a suffix or prefix that denotes their status as members. The cost/benefit of specifying this information in the spelling of an identifier name is discussed elsewhere.

member 443 namespace

label naming conventions

Label naming conventions

There are no common C naming conventions for identifiers that denote labels. However, some coding guideline documents recommend that label names visually draw attention to themselves (e.g., by containing lots of characters). Label name visibility was an explicit goal in the specification of the syntax of labels in Ada. Other coding guideline documents recommend that label names not be visible at all (i.e., they only

labeled 1722 statements syntax

appear within macro replacement lists).

Given that identifiers denoting label names can only occur in two contexts, and no other kinds of identifiers can occur in these contexts, there is no benefit in encoding this information (i.e., is a label) in the spelling. Whether it there is a worthwhile cost/benefit in visually highlighting the use of a label needs to be evaluated on a usage by usage basis. There are a variety of techniques that can be used to provide visual highlighting, it is not necessary to involve an identifier's spelling.

Enumeration constant naming conventions

enumeration constant naming conventions

Some coding guideline documents recommend that the names of members contain a suffix or prefix (e.g., `E_` or `_E`) that denotes their status as members. Unlike member and label names it is not possible to deduce that an identifier is an enumeration constant from the syntactic context in which it occurs. However, there does not appear to be a worthwhile cost/benefit in encoding the status of an identifier as an enumeration constant in its spelling.

The issue of selecting the names of enumeration constants defined in one enumeration type to form a distinct set of symbols is discussed elsewhere.

517 enumeration set of named constants

Function naming conventions

function naming conventions

Some coding guideline documents recommend that the names of functions contain a verb (sometimes a following noun is also specified). A study by Caprile and Tonella[197] created a word grammar describing function names (which was structured in terms of actions) and were able to parse a large percentage of such names in a variety of programs (80% in the case of the mosaic sources).

2.2.3.2 Scope

Tools that automatically generate source code might chose to base part of the spelling of an identifier on its scope to simplify the task of writing the generator. If names followed a fixed unusual, pattern the possibility of duplicates being declared is likely to be reduced.

scope naming conventions

File scope

file scope naming conventions

Some coding guideline documents require identifiers declared in file scope to include a prefix denoting this fact (it is rare to find suffixes being used). The reasons given for this requirement sometimes include issues other than developer readability and memorability; one is management control of globally visible identifiers (exactly why management might be interested in controlling globally visible identifiers is not always clear, but their authority to silence doubters often is).

792 identifier other guideline documents

What are the attributes of an identifier at file scope that might be a consideration in the choice of its name?

- They are likely to be referenced from many function definitions, (unlike block scope identifiers a reader's knowledge of them needs to be retained for longer periods of time).
- They are unlikely to be immediately visible while a developer is looking at source code that references them (unlike block scope identifiers, their declaration is likely to be many lines— hundreds— away from the points of reference).
- They will be unique (unlike block scope names, which can be reused in different function definitions).

During code maintenance new identifiers are often defined at file scope. Does the choice of spelling of these file scope identifiers need to take account of the spelling of all block scope identifiers defined in source files that **`#include`** the header containing the new file scope declaration? The options have the following different costs:

1. Changing the spelling of any block scope identifiers, and references to them, to some other spelling. (This will be necessary if the new, file scope identifier has identical spelling and access to it is required from within the scope in which the local identifier is visible.) There is also the potential cost associated with the block scope identifier not having the ideal attributes, plus the cost of developer relearning associated with the change of an existing identifier spelling.

792 identifier primary spelling issues

2. Selecting another spelling for the file scope identifier. To know that a selected spelling clashes with another identifier requires that the creator of the new identifier have access to all of the source that **#include** the header containing its declaration. There is also the potential cost associated with the file scope identifier not having the ideal attributes. There is no relearning cost because it is a new identifier.

identifier 792 primary spelling issues

3. Accepting the potential cost of deviating from the guideline recommendation dealing with identifier spellings.

Each of these options has different potential benefits; they are, respectively:

identifier 792 primary spelling issues

1. The benefits of following the identifier spelling guideline recommendations are discussed elsewhere. The benefit is deferred.
2. No changes to existing source need to be made, and it is not necessary for developers declaring new file scope identifiers to have access to all of the source that **#include** the header containing its declaration. The benefit is deferred.
3. There is no benefit or immediate cost. There may be a cost to pay later for the guideline deviation.

block scope naming conventions

Block scope

Because of their temporary nature and their limited visibility some coding guideline documents recommend the use of short identifiers (measured in number of characters) for block scope object definitions. What is the rationale for this common recommendation?

typing minimization 0

Some developers openly admit to using short identifiers because they are quicker to type. As pointed out elsewhere, the time taken by a developer to type the characters of an identifier is not significant, compared to the costs to subsequent readers of the source code of a poorly chosen name. Your author suspects that it is the cognitive effort required to create a meaningful name that many developers are really trying to avoid.

What are the properties of identifiers, in block scope, that might be a consideration in the choice of their names?

- They are likely to appear more frequently within the block that defines them than names having file scope (see Figure 1821.5).
- The semantic concepts they denote are likely to occur in other function definitions.
- A program is likely to contain a large number of different block scopes.
- Their length is likely to have greater impact on the layout of the source code than other identifiers.
- Translators do not enforce any uniqueness requirements for names appearing in different block scopes.
- They need to be memorable only while reading the function definition that contains them. Any memories remaining after that block has been read should not cause confusion with names in other function definitions.

2.2.4 Suggestions for spelling usage

identifier suggestions

The following list provide suggestions on how to make the best use of available resources (a reader's mental capabilities) when creating identifier spellings. The studies on which these suggestions are based have mostly used English speakers as subjects. The extent to which they are applicable to developers readers of non-English languages is not known (other suggestions may also be applicable for other languages).

identifiers 792 Greek readers

These suggestions are underpinned by the characteristics of both the written and spoken forms of English and the characteristics of the device used to process character sequences (the human brain). There is likely to be a great deal of interdependence between these two factors. The characteristics of English will have been shaped by the characteristics of the device used to create and process it.

- *Delimiting subcomponents.* Written English separates words with white space. When an identifier spelling is composed of several distinct subcomponents, and it is considered worthwhile to provide a visual aid highlighting them, use of an underscore character between the subcomponents is the closest available approximation to a reader's experience with prose. Some developers capitalize the first letter of each subcomponent. Such usage creates character sequences whose visual appearance are unlike those that readers have been trained on. For this reason additional effort will be needed to process them. In some cases the use of one or more additional characters may increase the effort needed to comprehend constructs containing the identifier (perhaps because of line breaks needed to organize the visible source). Like all identifier spelling decisions a cost/benefit analysis needs to be carried out.

770 words white space between

- *Initial letters.* The start of English words are more significant than the other parts for a number of reasons. The mental lexicon appears to store words by their beginnings and spoken English appears to be optimized for recognizing words from their beginnings. This suggests that it is better to have differences in identifier spelling at the beginning (e.g., *cat*, *bat*, *mat*, and *rat*) than at the end (e.g., *cat*, *cab*, *can*, and *cad*).

initial letters identifier
792 identifier recall
792 words English

- *Pronounceability.* Pronounceability may appear to be an odd choice for a language that is primarily read, not spoken. However, pronounceability is an easy-to-apply method of gauging the extent to which a spelling matches the characteristics of character sequences found in a developers native language. Given a choice, character sequences that are easy to pronounce are preferred to those that are difficult to pronounce.

- *Chunking.* People find it easier to remember a sequence of short (three or four letters or digits) character sequences than one long character sequence. If a non-wordlike character sequence has to be used, breaking the character sequence into smaller chunks by inserting an underscore character between them may be of benefit to readers.

0 memory chunking

- *Semantic associations.* The benefits of identifier spellings that evoke semantic associations, for readers are pointed out in these and other coding guideline documents. However, reliably evoking the desired semantic associations in different readers is very difficult to achieve. Given a choice, an identifier spelling that evokes, in many people, semantic associations related to what the identifier denotes shall be preferred to spellings that evoke them in fewer people or commonly evokes semantic associations unrelated to what the identifier denotes.

- *Word frequency.* High-frequency words are processed more rapidly and accurately than low-frequency words. Given a choice, higher-frequency words are preferred to lower-frequency words.

792 word frequency

2.2.4.1 Existing conventions

In many cases developers are adding identifiers to an existing code base that already contains thousands, if not tens of thousands, of identifiers. The maintainers of this existing code will have learned the conventions used (if only implicitly). Having new identifier spellings follow existing conventions enables maintainers to continue to obtain the benefits from what they have learned, and does not increase costs by requiring that exceptions be handled or new conventions learned. Following an existing convention has a benefit in its own right, independently of the original reasons (which may not even have been valid at the time) for adopting it.

0 implicit learning

One problem with existing source code conventions is finding out what they are. It is possible that the conventions used will vary across the files making up a program (perhaps following the habits and characteristics of the original authors). The following discussion attempts to highlight the main *convention domains* that affect identifier spellings:

- Natural language usage conventions. For instance, word order and creating new words by joining together— *compounding*— existing words. There are often rules for ordering and compounding words and speakers of languages often are sensitive to these rules (usually implicitly following them without consciously being aware of it or even explicit having knowledge of what the rules are).

0 implicit learning

- General software development conventions. For instance, using the abbreviation `ptr` to denote something related to pointers.
- C language developer conventions. For instance, using uppercase letters for identifier spellings denoting macro definitions or typedef names.
- Development group conventions. It is your author's experience that these are rarely effectively enforced and noncompliance is common (even among developers attempting to follow them).[792.6] Without measurements confirming that any development group guidelines are followed in the source being maintained, it is suggested that these conventions be ignored from the point of view of achieving a benefit by considering them when creating new identifier spellings. However, claiming to follow them may reduce the effort of dealing with management, a topic that is outside the scope of this book.
- Host environment conventions. Developers who primarily work within a particular host environment (e.g., Linux or Microsoft Windows) often follow conventions specific to that environment. Whether this is because of the influence of a particular vendor or simply the drifting apart of two communities, is not known.
- An individual's past experience. For all the supposed dynamism of the software business, developers can be remarkably conservative in their identifier-naming habits, often being very resistant to change.

macro 792 naming conventions
typedef 792 naming conventions

Table 792.5: Occurrence of identifier declarations in various scopes and name spaces (as a percentage of all identifiers within the scope/name space in the visible form of the `.c` files; unique identifiers are in parentheses) containing particular character sequences (the phrase *spelled using upper-case letters* is usually taken to mean that no lower-case letters are used, i.e., digits and underscore are included in the possible set of characters; for simplicity and accuracy the set of characters omitted are listed).

	no lower-case	no upper-case	no underscore	no digits	only first character upper-case
file scope objects	0.8 (1.0)	80.3 (79.1)	29.6 (25.4)	87.3 (85.7)	5.2 (5.7)
block scope objects	1.3 (1.8)	91.9 (81.3)	79.9 (58.9)	96.3 (93.0)	1.3 (3.1)
function parameters	0.1 (0.4)	94.2 (82.9)	88.6 (67.4)	96.8 (94.8)	1.4 (2.9)
function definitions	0.2 (0.2)	59.0 (62.1)	27.1 (24.1)	87.1 (86.4)	29.9 (27.3)
struct/union members	0.5 (0.8)	78.5 (71.8)	65.7 (51.3)	93.2 (91.4)	12.0 (14.2)
function declarations	0.7 (0.5)	55.5 (57.1)	27.3 (26.5)	88.7 (87.5)	32.4 (30.1)
tag names	5.7 (6.6)	60.7 (63.8)	25.6 (21.6)	88.1 (85.9)	18.4 (14.5)
typedef names	14.0 (17.0)	37.0 (33.5)	45.0 (40.4)	89.7 (89.3)	39.8 (37.4)
enumeration constants	55.8 (56.0)	10.8 (10.6)	16.0 (15.0)	79.9 (77.9)	32.1 (32.0)
label names	27.2 (48.1)	69.2 (47.4)	70.8 (65.6)	67.4 (46.3)	2.2 (2.3)
macro definitions	78.4 (79.9)	4.9 (5.0)	15.5 (13.0)	70.9 (69.3)	13.1 (11.1)
macro parameters	19.8 (20.4)	77.6 (68.7)	96.0 (83.6)	94.2 (90.7)	1.4 (5.0)

2.2.4.2 Other coding guideline documents

identifier other guideline documents

Other coding guideline documents invariably include recommendations on identifier spelling. These recommendations are sometimes vague to the point of near worthlessness (e.g., "Use meaningful names for identifiers"), or the over-exaggeration of the importance of certain kinds of information with an associated lack of consideration of all the factors involved with identifier usage. Examples of the latter include:

hungarian 792 naming identifier

- *Hungarian notation.* The information provided by this notation is often not needed by the reader, who unnecessarily has to process characters that are essentially noise. This notation also creates maintenance effort in that identifier spellings have to be updated when their types are changed.
- *Meaningful names as brief sentences.* Here priority is given to semantic associations created by an identifiers spelling. The disadvantages of using large numbers of characters in an identifier spelling is discussed elsewhere.

identifier 792 number of characters

[792.6] This experience comes from many onsite visits where a development group's source code was analyzed by a tool configured to enforce that group's identifier-naming conventions.

- *Short names for local identifiers.* Here priority is given to the effort needed to type identifiers and potential use of short-term memory resources (shorter names are likely to require less time to pronounce).
- *Use of prefixes.* Adding prefixes to words has a long history. French scribes in the middle ages would add an *h* to the start of words that were derived from Latin words that started with the letter *h*.[946] The *h* not being pronounced (e.g., modern French *habile* and *honneur*). The introduction of these words into English resulted in either the *h*'s being dropped (*able*), remaining silent (*honour*), or causing a change of pronunciation (*hospital*). The importance of the initial letters, at least for native English speakers, is pointed out above. Mandating the use of prefixes is equivalent to specifying that the information they denote is more important than any other information evoked by an identifiers spelling. If this is true the recommendation to use prefixes is correct, otherwise it causes needless waste of a reader's cognitive resources.
- *No lowercase letters are used (that is, uppercase letters, digits, and underscore are used) for macro definitions and typedef names.* This usage appears to give priority to signaling implementation details to the reader. (While there is a prose text convention, at least in English, that words written using all uppercase letters denote important text, this usage in source code is more of a visual convention than an indication that these kinds of identifiers are more important than others.) Using uppercase letters for macro definitions prevents them from being treated as interchangeable with function definitions (at least for function-like macros). Requiring that macro names be spelled using only uppercase letters creates additional work if the source code is modified. For instance, a macro name that is changed to an enumerated constant or is replaced by an object either has to remain in uppercase or be converted to lowercase. Similarly for a function definition that is remapped to a macro definition (going from lowercase to uppercase). Typedef names appear less often in source code than other kinds of ordinary identifiers. While the syntactic context in which they appear signifies the kind of identifier they represent, readers are likely to be expecting to see a keyword in these contexts (this is the common case). When readers are quickly scanning the source, use of all uppercase letters in the spelling of a typedef name may provide an alternative visual mechanism for rapid recognition (potentially reducing the effort needed to rapidly scan source).

1933 macro function-like

typedef name no lowercase

- *Management/project control.* Here priority is given to information used in the management and coordination of a programs source code. Reserving a set of identifier spellings, usually for future usage, sometimes occurs.

Some coding guideline documents apply identifier-naming conventions that might be applicable in some programming languages (e.g., Cobol[1013]) but are not applicable in C (in the case of Cobol because of the different declaration syntax and in some cases semantics).

2.3 Filtering identifier spelling choices

identifier filtering spellings

This subsection makes guideline recommendations on what identifier spellings should not be used. It does not aim to extensively discuss other spelling filtering issues that developers might consider, although some are covered. It is unlikely to be practical for developers to manually apply these guideline recommendations. Automatic enforcement is assumed to be the most likely method of checking adherence to these recommendations. Whether this automated process occurs at the time an identifier is declared, or sometime later, is a practical cost/benefit issue that is left to the developer to calculate.

The discussion on creating optimal identifier spellings pointed out the need to consider all identifiers declared in the translation of a program. However, the computational cost of considering all identifiers is significant and the guideline recommendations that follow often specify a smaller set of possible identifier spellings that need to be considered.

792 optimal spelling identifier

The basis for these filtering recommendations is the result of the studies described in the major subsections following this one. The major issues are the characteristics of the human mind, the available cognitive resources (which includes a reader's culture and training), and usability factors.

The basic assumption behind the guideline recommendations is that a reduction in similarity between identifiers will result in a reduction in the probability that readers will mistake one for another. The similarity between two identifiers is measured using the typed letters they contain, their visual appearance, and spoken and semantic forms.

2.3.1 Cognitive resources

Other subsections of this coding guideline separate out discussion of issues relating to the functioning of the human brain, and cultural and educational factors. Here they are grouped together as cognitive resources.

An algorithm for calculating the cognitive resources needed to process an identifier spelling is not yet available. For simplicity the following discussion treats each resource as being independent of the others.

2.3.1.1 Memory factors

The primary human memory factors relevant to the filtering of identifier spellings are the limited capacity of short-term memory and its sound-based operating characteristics. The STM capacity limitation issues associated with identifier spelling are discussed elsewhere.

memory 0 developer
identifier 792 STM required

Memory lookup based on the sound sequence representation of a character sequence can sometimes result in information relating to a similar, previously remembered, sound sequence being returned. Also, if two identifiers are both referenced in a related section of source code, it is possible that both of their sound representations will be held in a reader's phonological loop (audio short-term memory) at the same time.

phonological loop 0

The following guideline recommendation is intended to reduce the likelihood of interference, in long and short term memory, between two character sequences that are mapped to similar sound sequences.

Rev 792.1 A newly declared identifier shall have a Levenstein distance, based on the phonemes in its spoken form, of at least two from existing identifiers declared in a program.

This guideline recommendation may be overly restrictive, preventing otherwise acceptable spellings from being used. The following deviation is based on studies showing, at least for native-English speakers, that the start of a word has greater salience than its middle or end.

Dev 792.1 A newly declared identifier may have a Levenstein distance, based on phonemes, of one from existing identifiers declared in a program provided the difference occurs in the first phoneme.

2.3.1.2 Character sequences

Every natural language has patterns in the way in which sounds are joined together to form words. This in turn leads to patterns (at least for nonlogographic orthographies) in the character sequences seen in the written form (even in an irregularly spelled language such as English). Proficient users of a language have overlearned these patterns and can effortlessly recognize them.

logographic 792
orthography 792

While novice readers may read words a letter at a time, experts make use of their knowledge of commonly occurring character sequences (which may be complete words) to increase their reading rate. The penalty for making use of statistical information is an increased likelihood of making mistakes, particularly when reading character sequences that are not required to be words (e.g., identifier spellings).

```
1   enum {OO, O0, l1, ll} glob;
```

Word recognition is driven by both bottom-up processes (the visible characters) and top-down processes (reader expectations). Minimizing the visual similarity between identifier spellings is one technique for reducing the likelihood of a reader mistakenly treating one identifier for another, different, identifier. Although the data needed to calculate an accurate value for the visual similarity between two identifiers is not yet available, the following guideline recommendation is still considered to be worth making.

identifier 792 visual similarity

Cg 792.2 A newly declared identifier shall have a Levenstein distance, based on visual similarity of corresponding characters, of at least two when compared against all identifiers declared in the visible source of a program.

For the purpose of this guideline recommendation, the visual similarity Levenstein distance of two identifiers is defined as the sum, over all pairs of characters, of the visual distance between two characters (one from each identifier) occurring at the same position in the identifier spelling (a space character is used to pad the shorter identifier). The visual distance between two characters is defined as (until a more accurate metric becomes available):

1. zero if they are the same character,
2. zero if one character represents the letter *O* (uppercase oh) and the other is the digit zero,
3. zero if one character represents the letter *l* (lowercase ell) and the other is the digit one,
4. otherwise, one.

2.3.1.3 Semantic associations

The spelling of an identifier is assumed to play a significant role in a readers recall of the semantic information associated with it (another factor is the context in which the identifier occurs). Having two different identifiers with the same spelling and:

identifier semantic associations 438 name space

- with different semantic information associated with them is likely to be create a cost (i.e., recall of information associated with other identifiers sharing the same spelling),
- with the same semantic information associated with them is likely to be create a benefit (i.e., improved recall performance).

0 power law of learning

Cg 792.3 A newly declared identifier shall not have the same spelling as another identifier declared in the same program.

Dev 792.3 A newly declared identifier may have the same spelling as another identifier declared in the same program provided they are both used to denote the same information and both have block scope.

Some identifiers are formed by concatenating two or more known words, abbreviations, or acronyms (these subcomponents are called *conceptual units* here). The interpretation given to a sequence of these conceptual units may not depend significantly on their relative ordering. For instance, either `widget_total` or `total_widget` might be considered to denote a count of the total number of widgets.

The following guideline recommendation is motivated by possible semantic confusion, not by the possibility of typing mistakes. While the general block-edit string matching problem is NP-complete,[868] limiting the comparison to known *conceptual units* significantly reduces the computational cost of checking adherence.

Rev 792.4 A newly declared identifier shall have a Levenstein distance, based on individual conceptual units, of at least two from existing identifiers declared in a program.

Dev 792.4 A newly declared identifier defined in a function definition shall have a Levenstein distance, based on individual conceptual units, of at least two from existing identifiers defined in other function definitions.

In some cases developers may consider two identifiers, differing by a Levenstein distance of one, to be semantically distinct. For instance, `widget_num` or `num_widget` might be considered to denote a number assigned to a particular widget and some count of widgets, respectively. Such an interpretation is dependent on knowledge of English word order and conventions for abbreviating sentences (e.g., "widget number 27" and "number of widgets"). However, this distinction is subtle and relies on too fine a point of interpretation (and could quite easily be given the opposite interpretation) for any form of deviation to be justified.

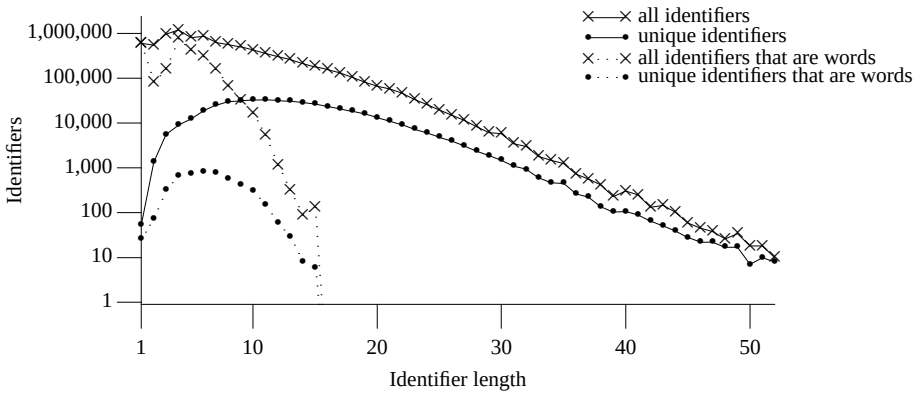

Figure 792.7: Number of identifiers (unique and all) of different length in the visible form of the `.c` files. Any identifier whose spelling appeared in the `aspell` 65,000 word dictionary was considered to be a word.

2.3.2 Usability

identifier encoding usability
identifier 792 usability

The following discussion briefly summarizes the general issues associated with identifier. This issue is discussed in more detail elsewhere.

2.3.2.1 Typing

Developers make mistakes when typing the characters that form an identifier spelling. If two identifier spellings differ by a single character, it is possible that an uncorrected mistake will cause a different identifier to be accessed.

Cg 792.5

A new identifier shall have a Levenstein distance, based on individual characters, of at least two from existing identifiers declared in a program.

An identifier may differ by a Levenstein distance of one from another identifier and not be accessible at the point in the source a typing mistake occurs because it is not visible at that point. Requiring a Levenstein distance of two for all new identifiers may be overly restrictive (preventing otherwise acceptable spellings from being used).

Dev 792.5

An identifier defined in a function definition may have a Levenstein distance, based on individual characters, of one from existing identifiers defined in other function definitions.

2.3.2.2 Number of characters

identifier number of characters
external 283 identifier significant characters
internal 282 identifier significant characters

The C Standard minimum requirements on the number of significant characters in an identifier spelling (the first 31 in an external identifier, and 63 in an internal linkage or macro name) is not usually an issue in human-written code. The issue of translators that have yet to support the new limits (the requirements specified in the previous version of the Standard were lower) are discussed in the limits sentences.

2.3.2.3 Words unfamiliar to non-native speakers

The usual reason for including a word in an identifier spelling is to obtain the benefit of the semantic associations it evokes. If the source is likely to be maintained by developers whose native language is different from that of the author, it is necessary to consider the possibility that some character sequences will not be recognized as words.

Experience shows that technical words often cause the fewest problems. Within a particular application domain, the vocabulary of technical words used at the source code level is usually relatively small (compared to natural languages and even the specific application domain). They are relatively easy for native speakers to identify and L2 speakers may not be embarrassed by their ignorance of these technical terms.

Identifying nontechnical words that may be unfamiliar to non-native speakers is often more difficult. Native speakers rarely have the necessary experience and asking non-native speakers about their language competence may be awkward or impractical.

Although there have been some surveys of L2 vocabulary knowledge,[632] the available information does not appear to be sufficiently extensive to enable a guideline recommendation (that words likely to be unfamiliar to L2 speakers not be used) to be enforced; so none is given here.

2.3.2.4 Another definition of usability

In some cases identifier spelling usability might be defined in terms of satisfying a management requirement other than minimizing future maintenance costs. For instance, the customer may require adherence to a coding guideline document, which recommends that various kinds of semantic information be explicitly encoded in an identifier's spelling (e.g., the MISRA C Guidelines contain an advisory rule that the spellings of typedef names contain information on the number bits in the storage representation of the defined arithmetic type).

0 MISRA

Definitions of usability based on these alternative requirements are not discussed further in this coding guideline section.

3 Human language

This section discusses the characteristics of human languages, primarily in their written form. These empirical and theoretical findings provide background material for the discussion on the three primary requirement issues (memorability, confusability, usability). The section concludes with a more detailed discussion of one language, English.

human language characteristics

3.1 Writing systems

A writing system,[1194] known as an *orthography*, uses written characters to represent the structure of a linguistic system. If the character-to-sound rules are relatively simple and consistent (e.g., German, Spanish, Japanese hirigana), the orthography is said to be *shallow*; while if they are complex and inconsistent (e.g., English), it is said to be *deep*. A writing system is more than a set of characters and the sequences of them used to represent words; there are also the conventions adopted by its writers (e.g., direction of writing and some written abbreviations have no equivalent spoken form).

orthography

Table 792.6: Number of people using particular types of writing system for the top 50 world languages in terms of number of speakers. Literacy rates from UNESCO based on typical countries for each language (e.g., China, Egypt, India, Spain). Adapted from Cook.[273]

Total languages out of 50	Speakers (millions)	Readers (millions, based on illiteracy rates)
Character-based systems— 8 (all Chinese) + Japanese	1,088	930
Syllabic systems— 13 (mostly in India) + Japanese, Korean	561	329
Consonantal systems— 4 (two Arabic) + Urdu, Persian	148	no figures available
Alphabetic systems— 21 (worldwide)	1,572	1,232

Most existing source code is written using only characters from the basic source character set. The introduction of Universal Character Names and growing tool support for extended characters continues to increase the likelihood that developers will encounter identifiers spelled using characters outside of the invariant Latin subset.

221 basic source character set
815 universal character name syntax
215 extended characters
24 ISO 646

There are three kinds of writing systems:

1. *alphabetic.* These writing systems contain a small set of letters. Sequences of one or more of these

grapheme

letters represent the basic spoken units of a word (this sequence of letters is known as a *grapheme* and the sound units it represents is a phoneme) or a complete word. One or more graphemes may be written in sequence to represent a spoken word. This writing system has two varieties:

phoneme 792

- Abjads, or consonant alphabets, predominantly use only consonants in their written forms. Vowels can be added, usually by means of diacritics, but this is not common (Arabic and Hebrew use them in poetry and children's books). Most abjads, with the exception of Divehi hakura and Ugaritic, are written from right-to-left.
- Alphabets, or phonemic alphabets, nearly always represent consonants and vowels in written works (acronyms may not contain any vowels).

Some scripts, for instance Arabic, are used both as an abjad and as an alphabet.

2. *syllabic.* These writing systems use individual characters to represent syllables; for instance, Bengali, Cherokee, and Japanese Katakana.

syllable 792

logographic

3. *logographic.* These writing systems, or logosyllabaries, are the most complex natural language writing systems. They can be broken down into the following:

   - Logograms are symbols that represent whole words, without a phonetic component. Some logograms resemble, or originally resembled, the things they represent and are sometimes known as *pictograms* or *pictographs*.
   - Ideograms are symbols that graphically represent abstract ideas, without a phonetic component.
   - Semantic–phonetic compounds are symbols that include a semantic element, which represents or hints at the meaning of the symbol, and a phonetic element, which denotes or hints at the pronunciation. Some of these compound symbols can be used for their phonetic value alone, without regard for their meaning.

   Examples include Chinese, Japanese Kana, and Ancient Egyptian.

3.1.1 Sequences of familiar characters

When a writing system breaks the representation of a word into smaller components (e.g., alphabetic, phonemic, or syllabic), readers learn not only the visual form of the characters, but also implicitly learn the likelihood of encountering particular character sequences. For instance, readers of English would expect the letter *t* to be followed by *h* and would be surprised to see it followed by *q*. Information on frequency of occurrence of letter sequences in different languages is sufficiently reliable that it is used by cryptographers to help break codes,[470] by OCR software for correcting errors in scanned text, and by mobile phones for predictive text entry.

The frequency of occurrence of particular letter sequences varies between different languages. It will depend on how letter sequences are mapped to phonemes and the frequency of the different phonemes used in the spoken form of a language.

phoneme 792

In his famous paper, *A Mathematical Theory of Communication* Shannon[1220] gave the following example of letter sequences that successively approximated English.

- Zero-order approximation (symbols independent and equiprobable): XFOML RXKHRJFFJUJ ZLP-WCFWKCYJ FFJEYVKCQSGHYD QPAAMKBZAACIBZLHJQD.
- First-order approximation (symbols independent but with frequencies of English text): OCRO HLI RGWR NMIELWIS EU LL NBNESEBYA TH EEI ALHENHTTPA OOBTTVA NAH BRL.
- Second-order approximation (digram structure of English): ON IE ANTSOUTINYS ARE T INCTORE ST BE S DEAMY ACHIN D ILONASIVE TUCOOWE AT TEASONARE FUSO TIZIN ANDY TOBE SEACE CTISBE.

- Third-order approximation (trigram structure of English): IN NO IST LAT WHEY CRATICT FROURE BIRS GROCID PONDENOME OF DEMONSTURES OF THE REPTAGIN IS REGOACTIONA OF CRE.

The entropy of English has been estimated as 1.75 bits per character[1333] (a random selection from 26 letters or space would have an entropy of 4.75 bits per character). It is this predictability, coupled with a reader's knowledge of it, built up through years of practice, that enables people to process words from their first language much more quickly than words from an unfamiliar language. However, a reader's rate of information extraction does not increase; they simply learn to take account of the redundancy present in the input.

792 identifier information extraction

Information on common letter sequences has been used in models of reader eye movements and typing performance.

770 Mr. Chips
792 typing mistakes

Many of the top 12 languages (see Table 792.3) use letters from the invariant Latin character set (with the exception of English, they also include a few additional characters). Because these languages each use slightly different sets of phonemes and use different letters sequences to represent them, letter sequences that are common in one language may be rare in another.

24 ISO 646

If an identifier spelling contains a word belonging to some natural language, readers unfamiliar with that language may break the character sequence up into different letter sequences than the original author did. The letter sequences may be shorter, possibly a single letter. Some of the issues involved in a reader's handling of unknown character sequences, nonwords, is discussed elsewhere.

792 word pronounceability
792 word nonword effects
792 characters mapping to sound
792 identifier nonword spelling

3.1.2 Sequences of unfamiliar characters

Developers do not need to know anything about any human language, expressed using a particular writing system, to comprehend source code containing instances of that writing system. To comprehend source code readers need to be able to

reading characters unknown to reader

- deduce when two identifiers have the same, or different, spellings. This same/different task only requires the ability to visually compare two identifiers.
- store a representation of some previously seen identifiers (those considered worth remembering). This task requires a mapping from the visual form of the identifier to some internal, in the developer's mind, representation.

How do readers perform when presented with an unfamiliar writing system (e.g., written using universal character names)?

815 universal character name syntax

A study by Brooks[164] investigated subject's performance in identifying character sequences built from characters they were unfamiliar with— for instance, Π*)*(Π*(*. One group of subjects was first taught a character-to-letter mapping (Π⇒*N*, *)*(⇒*E*, Π⇒*A*, *(*)⇒*P*), while the other group was not. Both groups of subjects were asked to learn associations between a number of character sequences and a corresponding spoken response. The spoken form of each character sequence corresponded to the English pronunciation of the word formed by mapping the characters to the letters (which only one group of subjects had been taught). Subject's performance (time taken to speak all character sequences, presented to them in a random order, they had learned) was measured. The results showed an initial performance advantage for subjects using purely visual recognition (they had not been taught a mapping to letters). The performance of both groups of subjects improved with practice. However, given sufficient practice, the performance of subjects who had learned the character to letter mapping exceeded that of subjects who had not learned it. The amount of practice needed seemed to depend on the number of character sequences that had to be learned and their visual form.

A study by Muter and Johns[984] asked subjects (native speakers of English) to learn to identify either a set of logographs (Chinese characters) or words written in an unfamiliar alphabetic code (Devanagari— the written form of Hindi). As expected subjects reaction time and error rates improved with practice. However, the initial performance with logographs was significantly better than alphabetic codes (see Figure 792.8).

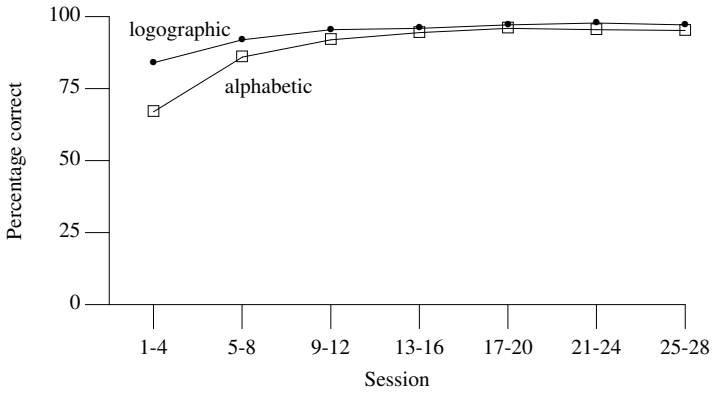

Figure 792.8: Improvement in word-recognition performance with number of sessions (most sessions consisted of 16 blocks of 16 trials). Adapted from Muter and Johns.[984]

letter detection 770

The result of this and other character learning studies shows that people relatively quickly achieve high proficiency. However, previous experience with an alphabetic character set would not seem to confer any advantage during the initial learning phrase of a new set of alphabetic characters.

3.2 Sound system

word sound system

The sounds used by individual natural languages do not use all possible combinations that the human vocal tract is capable of producing.[132] While there may be thousands of possibilities, a particular language usually uses less than a hundred (English uses approximately 44, depending on regional accent).

phoneme

The *phoneme* is the minimal segment of sound that distinguishes one word from another word. These are generally divided into vowels (open sounds, where there are no obstructions to the flow of air from the mouth; known languages contain from 2 to 25 vowels) and consonants (created by some form of obstruction to the passage of air through the speech tract; known languages contain between 5 and more than 100 consonants). Hawaiian contains 12 phonemes, while !Xu (spoken near the Kalahari desert in Southern Africa) has as many as 141. The most commonly encountered vowels, in different languages, are */i/*, */e/*, */a/*, */o/*, */u/*, and the most commonly encountered constants are */p/*, */k/*, */t/*. The vowel */a/* is believed to be the only phoneme that occurs in all languages.

An *allophone* is a phonetically distinct variant of a phoneme. The position of a phoneme within a word can cause it to be pronounced slightly differently; for instance, the */t/* sounds in *hit* and *tip* are allophones. Some languages do not distinguish between different pairs of phonemes; for instance, Japanese treats */l/* and */r/* as being the same phoneme, but different allophones.

phonology

Phonology is the study of spoken sounds (i.e., sequences of phonemes).

Languages contain regularities in the ordering of phonemes. For instance, English words tend to follow a CVC structure (Consonant Vowel Consonant), and even within this structure certain patterns are heard much more frequently than others.[730]

syllable

The next higher-level unit of speech above a segment is known as a *suprasegmental*. The particular suprasegmental of interest to these coding guidelines is the syllable. A *syllable* consists of three parts: (1) the *onset*, (2) the *peak* or *nucleus*, and (3) the *coda*; for instance, for the syllable */man/*, */m/* is the onset, */a/* the peak, and */n/* the coda. A definition of syllable that readers might be familiar with is that of a consonant followed by a vowel (CV); however, this definition cannot be used to syllabify the structure CVCCV— is it CV-CCV or CVC-CV.

English syllables can have zero to three consonants before the vowel and zero to four consonants after the vowel. There has been relatively little research on automatically deducing how to divide a word into its component syllables.[1507] Kessler and Treiman[730] investigated the structure of English syllables and found a correlation between a vowel and its following consonant. However, the correlation between a consonant and its following vowel was significantly lower, meaning the start of an English syllable is more informative

(distinctive) than its ending.

The same syllables can be spoken at various levels of intensity. Varying the intensity, when speaking, enables certain parts of what is being said to be *stressed*. A languages stress pattern is of interest to these coding guidelines because it can affect how words are abbreviated. Different languages stress words in different ways. The difference between stressed and unstressed syllables in English[459] is greater than most other languages and it is common for the odd-numbered syllables to be stressed, with the first receiving the most stress (in prefixed words the primary stress usually falls on the first syllable of the root[212]). The same word may be stressed differently in different languages: English *GRAMmar* (from the French *gramMAIRE*) and *CHOColate* (from the Spanish *chocoLAte*).

word stress
792 abbreviating identifier

The *morpheme* is the smallest grammatical unit of speech. There are two basic types; a *bound morpheme* is defined in terms of how it is attached to the other form, the *free morpheme*. The most common bound morphemes are prefixes and suffixes (e.g., *re-* and *-ed*; see Hawkins and Gilligan[554] for a discussion of prefixing and suffixing universals).

morpheme

The term *morphology* refers to the study of word structure and formation— the syntax of words. Pirkola[1090] discusses the morphology of the world's languages from the perspective of information retrieval. Bauer[100] and Selkirk[1213] discuss English word formation.

morphology

With the exception of logographic writing systems, there is some degree of correspondence between the written and spoken form of a word (spelling is discussed elsewhere). Although C source is not designed to be a spoken language, many developers create a spoken form for it. The norms for this spoken form are most noticeable when they are broken (e.g., self-taught C programmers do not always have the opportunity to listen to C being spoken and invent their own pronunciations for some operators).

792 spelling

3.2.1 Speech errors

Cutler[303] provides a review of speech error data. A systematic, cross-linguistic examination of speech errors in English, Hindi, Japanese, Spanish, and Turkish by Wells-Jensen[1452] found (reformatting a quote from her paper):

- *Languages are equally complex.* No overall differences were found in the numbers of errors made by speakers of the five languages in the study. This supports the basic assumption that no language is more difficult than any other.
- *Languages are processed in similar ways.* Fifteen English-based generalizations about language production were tested to see to what extent they would hold true across languages. It was found that, to a large degree, languages follow similar patterns. For example, all of the languages exhibited the same pattern of semantically-based errors in open-class words, and all exhibited more errors with inflectional than derivational affixes. It was found, however, that the relative numbers of phonological anticipations and perseverations in other languages did not follow the English pattern.
- *Languages differ in that speech errors tend to cluster around loci of complexity within each.* Languages such as Turkish and Spanish, which have more inflectional morphology, exhibit more errors involving inflected forms, while languages such as Japanese, with rich systems of closed-class forms, tend to have more errors involving closed-class items.

3.2.2 Mapping character sequences to sounds

It is believed that there are two possible routes by which readers convert character sequences to sound, (1) memory lookup, a direct mapping from the character sequence to sound; and (2) grapheme-to-phoneme conversion. Irregularly spelled words have to use the first route; for instance, the phrase "pint of water" does not contain any words that rhyme with *mint*. A study by Monsell, Patterson, Graham, Hughes, and Milroy[960] asked subjects to name lists of words, nonwords, or a mixture of both. The results showed that when nonword lists contained a few words, subjects tended to regularize (use the second route) the pronunciation of the words (the error rate was double that for lists containing words only).

characters mapping to sound
792 Word recognition models of

A study by Andrews and Scarratt[39] investigated how people pronounce nonwords. For instance, would subjects pronounce *jead* using the regular grapheme-to-phoneme correspondence heard in *mead*, or would they use the irregular form heard in *head*? The results showed that 90% of pronunciations followed regular grapheme-to-phoneme rules. This is not to say that the pronunciations used for a particular word were always unique. In 63% of cases a nonword received one or two pronunciations, while 9.7% of nonwords received more than four different pronunciations. There seemed to be a common factor for nonwords where an irregular pronunciation was used; these nonwords did not have any regular word-body neighbors. This latter result suggests that perhaps speakers do not use grapheme-to-phoneme rules to build the pronunciations used for nonwords, but rather base it on the pronunciation of words they know that have similar spellings.

neighborhood identifier 792

A study by Gibson, Pick, Osser, and Hammond[487] found that significantly more different pronunciations were used by subjects for letter sequences having a first-order approximation to English than letter sequences having a higher-order approximation. Deshmukh[347] discusses using maximum likelihood estimators to generate (potentially) multiple pronunciations, each with an associated likelihood probability.

Text-to-speech conversion is a very active research area with a growing number of commercial applications. To obtain high-quality output most systems rely on a dictionary of word-to-sound mappings. A number of rule-based algorithms have been proposed for converting letter sequences (graphemes) to sounds (phonemes).

Early work on creating a grapheme-to-phoneme mapping for a language involved a great deal of manual processing. For instance, Berndt, Reggia, and Mitchum[116] manually analyzed 17,310 words to derive probabilities for grapheme-to-phoneme mapping of English. Automating this process has obvious advantages. Daelemans and van den Bosch[307] created a language-independent conversion process that takes a set of examples (words and their corresponding phonetic representation) and automatically creates the grapheme-to-phoneme mapping. More recent research, for instance Pagel, Lenzo, and Black,[1042] has attempted to handle out of vocabulary words (i.e., not in the training set); however, the quality of the conversion varies significantly. An evaluation of publicly available algorithms,[312] using a 16,280 word dictionary, found correct conversion rates of between 25.7% and 71.8%.[792.7]

Divay and Vitale[364] provide a discussion of recent algorithms for grapheme–phoneme conversion of English and French, while Peereman and Content[1069] provide quantitative information on the regularity of the mapping between orthography and phonology in English and French.

A category of letter sequences that often does not have the characteristics of words are people's names, particularly surnames. Correct pronunciation of people names is important in many applications and algorithms have been designed to specifically handle them. What can be learned from attempts to convert the written form of people's names to sound? A comparison of eight name-pronunciation systems[502] (two of which were human) found that acceptable (400-name test set, as judged by a panel of 14 listeners) performance varied from 78% to 98% for high-frequency names to 52% to 96% for very low-frequency names. Many of the systems tested included a pronunciation dictionary of several thousand to handle common cases and to help supplement the rules used (a collegiate-level English dictionary usually lists approximately 250,000 words). A list of unique surnames (in the USA) contains more than 1.5 million entries. To cover 50% of the surnames in the USA requires 2,300 names, while 50% of ordinary words can be covered in 141 words).

Vitale[1425] and Llitjós[862] found that by taking into account the language of origin of proper names (statistical properties of the letter sequences in a name have been found to be a good indicator of its language of origin) it was possible to improve the accuracy of the phoneme transcription.

The Soundex algorithm[588] is often mentioned in textbooks which discuss *sounds-like*, and has been used in a number of applications where a sounds-like capability is needed. This algorithm converts a word to a code consisting of the first letter of the word followed by up to three digits (obtained by looking up a value between zero and seven for subsequent letters). Its very simplistic approach delivers results that are better than might be expected (a 33% success rate, with a 25% failure rate has been found for surnames[233]).

[792.7] Some researchers quote phoneme-conversion accuracy on a per letter-basis, while others use a per phoneme basis. A 90% per letter conversion accuracy equates to a $0.9^6 = 53\%$ word-conversion accuracy (for a six-letter word).

3.3 Words

Words do not exist in isolation; they belong to one or more human languages. Until relatively recently people experienced words in spoken form only. A number of studies[823] have found significant differences between spoken and written language usage. Because of the relatively high cost of analyzing spoken words compared to analyzing (invariably automated, using computers) written words, there has been significantly more published research on the written form. Source code is a written language and the studies quoted in this coding guideline section have primarily been of written text.

Many languages allow new words to be created by joining together, *compounding*, existing words. Other techniques used to create words include *prefixation* (*sleep* ⇒ *asleep*, *war* ⇒ *miniwar*) and *suffixation* (*kitchen* ⇒ *kitchenette*, *sea* ⇒ *seascape*).

In agglutinative languages, such as Japanese, the definition of a word is not always clear-cut. Words can be built up, like beads-on-a-string, using a series of affixes to the *root* word (the word that appears in a dictionary). There may also be letter changes at morpheme for phonetic reasons. For instance,[1028] the Turkish root word *uygar*, meaning civilized, might have suffixes added to build the single word (translated as "(behaving) as if you were one of those whom we not be able to civilize", written with the components separated by + rather being immediately adjacent):

agglutinative languages

792 morpheme

```
uygar+laş+tir+ama+yabil+ecek+ler+imiz+den+miş+siniz+cesine
```

Part of the process of learning a language is producing and understanding compound words. The rules used and the interpretation given varies across languages. A study by Boucher[141] investigated the problems French students have in forming English compound words. He found that students made a number of different mistakes: used more than two terms, used incorrect affixes, pluralized the first word, or applied the French rules. For instance, when asked the word for "a dog which hunts birds", answers included *dog-bird* and *bird-dog-hunting*. A later project by Boucher, Danna, and Sébillot[142] produced an intelligent tutoring system to teach students how to form English compound words.

While there might be general agreement on the pattern of usage of common compound words and phrases, there can be significant variation for rarer combinations. Technical terms often show variation between disciplines. One study[308] found 15 different forms of the term *Epithelial cell*.

The formation of compound words in English is discussed in more detail elsewhere.

792 compound word

3.3.1 Common and rare word characteristics

Are there any differences in the characteristics of common and rare words?

An often-quoted study[803] investigated whether there were any differences in characteristics between high- and low-frequency English words (apart from their frequency of occurrence). The analysis suggested that differences existed; however, the analysis used four-letter words only, and words at the two frequency extremes. A later study by Frauenfelder, Baayen, Hellwig, and Schreuder[449] performed a more extensive analysis, for English and Dutch, using words containing between three and eight characters, with a range of frequencies.

Several of the Landauer et al. results (e.g., neighborhood density is higher for high-frequency words) were replicated for the case of four-letter English words. However, their findings did not hold across all word lengths. The results, for Dutch words, showed a weak but significant correlation between neighborhood density and word frequency. Although other differences were found (both for English and Dutch words), the authors were not able to find any significant word-frequency effects that applied across more than a few words lengths.

792 neighborhood identifier

A study by Howes and Solomon[599] found that the time taken to identify a word was approximately a linear function of the log of its relative frequency (the 75 most common words in the Thorndike–Lorge word counts were used).

3.3.2 Word order

Identifier names are sometimes built up from a sequence of words corresponding to a phrase or short sentence in a natural language familiar to the developer. Given a developer's natural language experience, the order of

these words is likely to be the one that has semantic meaning in that language.

A few natural languages permit arbitrary word order, but in most cases the order used will have a semantic significance in the language used. For instance, the English sentence "Tanya killed Masha" has a different meaning than "Masha killed Tanya", while the words in the equivalent Russian sentence "Tanja ubila Mašu" could appear in any of the six permutations of the three words and still be a grammatically valid sentence with the same meaning. (However, the order SVO is the most frequently used in Russian; other languages having free word order also tend to have a frequently used order.)

The three principle components of a natural language sentence are the *object*, *subject*, and *verb*. While the order in which these three components occur can vary within a single language, most languages have a preferred order (the frequency with which different orders occur within a particular language will depend on whether it uses a pragmatic word order— *topic-prominent* such as in Chinese and Japanese— or uses a grammatical word order — *subject-prominent* such as in English and Spanish). Much of the material in this subsection is derived from *Language Universals and Linguistic Typology* by Bernard Comrie.[265]

Table 792.7: Known number of languages commonly using a particular word order. Based on Comrie.[265]

Common order	Languages	Example
None	no figures	Sanskrit
SOV	180	Turkish "Hansan ököz-ü aldı" ⇒ "Hassan ox bought"
SVO	168	English "The farmer killed the duckling"
VSO	37	Welsh "Lladdodd y ddraig y dyn" ⇒ "killed the dragon the man"
VOS	12	Malagasy "Nahita ny mpianatra ny vehivavy" ⇒ "saw the student the woman"
OVS	5	Hixkaryana "Toto yahosi-ye kamara" ⇒ "man it-grabbed-him jaguar"
OSV	2	Apurinã none available

There are three other major word-order parameters, plus many minor ones. The following are the major ones:

- Within a sentence a noun may be modified by an adjective (becoming a *noun phrase*). The two possible word orderings are AN (English "the green table") and NA (French "le tapis vert" ⇒ "the carpet green"). Languages that use the order NA are more tolerant of exceptions to the rule than those using the order AN.
- A noun phrase may also contain a possessive (the technical term is *genitive*). The two possible word orderings are GN (Turkish "kadın-ın çavuğ-u" ⇒ "woman chicken-her") and NG (French "la plume de ma tante" ⇒ "the pen of my aunt"). English uses both forms of possessive (the Saxon genitive "the man's hat" and the Norman genitive "the roof of the house"). Although the Norman genitive is the more frequent, it is not possible to specify that it is the basic order.
- A language may contain prepositions, Pr (English "in the house"), or postpositions, Po (Turkish "adam için" ⇒ "man for the").

There are 24 possible combinations of object/subject/verb, noun/adjective, noun/genitive, and preposition/postposition that can occur in languages. However, empirical data on existent languages shows the following common patterns:

- VSO/Pr/NG/NA
- SVO/Pr/NG/NA
- SOV/Po/GN/AN
- SOV/Po/GN/NA

As well as using an order for different kinds of words, speakers also preferentially order the same kinds of words; for instance, the relative order in which adjectives occur.

word order 792
adjectives

3.4 Semantics

Identifier semantics

The hypothesis that all human languages have the same expressive power and are expressively complete in the sense that a proposition that can be expressed in one of them can be expressed in any of them is known as the *effability principle*. However, propositions that can be succinctly expressed in one language may require a great many words to be expressed in another language.

Cross-language research has shown that there are very few concepts (they mostly relate to the human condition) that might be claimed to be universal. For a discussion of semantic universals across languages see Wierzbicka[1461] and more recently von Fintel and Matthewson.[1428]

language affecting thought

The extent to which the language used by a person influences their thought processes has been hotly debated over the centuries; more recently researchers have started to investigate how thought processes influence language use (Lucy[871] provides a detailed history). The proposal that language does influence thought is commonly known as the *Sapir-Whorf* or *Whorfian* hypothesis. Some people hold what is known as the *strong language-based* view, believing that the language used does influence its speakers' conceptualization process. People holding the so-called *weak language-based* view believe that linguistic influences occur in some cases. The *language-as-strategy* view holds that language affects speakers performance by constraining what can be said succinctly with the set of available words (a speed/accuracy trade-off, approximating what needs to be communicated in a brief sentence rather than using a longer sentence to be more accurate).[607]

3.4.1 Metaphor

Metaphor

A data structure containing information about a politician's past record might include information about elections for which they have been a candidate. In the US politicians *run* for office, while in Spain and France they *walk*, and in Britain they *stand* for office. These are metaphors, and developers are likely to make use of them in the naming of identifiers (e.g., `ran_for`, `is_standing`).

Concepts involving time are often expressed using a spatial metaphor. These metaphors take two forms—one in which time is stationary and we move through it (e.g., "we're approaching the end of the year"); in the other case, we are stationary and time moves toward us (e.g., "the time for action has arrived").

A study by Boroditsky[139] investigated subject's selection of either the ego-moving or the time-moving frame of reference. Subjects first answered a questionnaire dealing with symmetrical objects moving to the left or to the right. The questions were intended to prime either an ego-moving or object-moving perspective. Subjects then read an ambiguous temporal sentence (e.g., "Next Wednesday's meeting has been moved forward two days"). The results found that 71.3 subjects responded in a prime-consistent manner. Of the subjects primed with the ego-moving frame, 73.3% thought the meeting was on Friday and 26.7% thought it was on Monday. Subjects primed with the object-moving frame showed the reverse bias (30.8% and 69.2%).

For a readable introduction to metaphors in everyday English see Lakoff and Johnson.[797]

3.4.2 Categories

Studies of color categorization provide a good example of the interaction between how peoples bodies work (in this case the eye), the category members supported by a language (in this case the different basic color terms), and human perception (see Hardin and Maffi[541] for an up-to-date discussion).

It was once thought that, across languages, color categories were arbitrary (i.e., the color terms used by different languages divided up the visible spectrum differently). In a now-classic study of 98 languages Berlin and Kay[115] isolated what they called the *basic color terms*. While the boundaries between color terms varied, the visual appearance of the basic color terms was very similar across languages (color matching has been found to be driven by physiological factors in the eye). They also found that the number and kind of basic color terms in languages followed a consistent pattern (see Figure 792.9).

A survey of empirical behavioral and linguistic uses of color term studies by Corbett and Davies[281] found (languages studied included English, Russian, Japanese, French, Hebrew, and Spanish) that:

- time taken to name a color was faster for the basic color terms;
- when asked to name a color, the basic color terms were usually listed first;

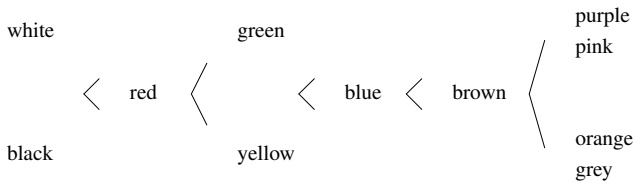

Figure 792.9: The original Berlin and Kay[115] language color hierarchy. The presence of any color term in a language, implies the existence, in that language, of all terms to its left. Papuan Dani has two terms (black and white), while Russian has eleven. (Russian may also be an exception in that it has two terms for blue.)

- the rank frequency of basic color terms in text matched that predicted by Berlin and Kay (more occurrences of the more basic color terms).

English is the *world language* of business (and software development) and a study of Japanese by Stanlaw[1282] found that English color loan words were supplanting the native ones (in an inverse order to the Berlin and Kay sequence).

3.5 English

words English

Languages have evolved complex processes for expressing subtle ideas. Although these processes may be obvious to native speakers, they tend to be unappreciated by inexperienced non-native speakers. This subsection uses English as an example for a discussion of some of the complexities of a human language. For a detailed discussion of English word formation, see Bauer[100] or Selkirk.[1213] Bauer[101] discusses international varieties of English, as used by native speakers. Pinker[1089] provides a readable discussion of word rules, taking as his subject regular and irregular verbs.

implicit 0 learning

Many of the points covered in the following subsections will be familiar to those developers who speak English as a native language (although in some cases this knowledge will be implicit). The intent is to show to these developers the complexities of the language constructs they take for granted. Knowledge of, and practice using, these complexities takes many years of practice. Native speakers acquire it *for free* while growing up, while many non-native speakers never acquire it.

English optimized for

Analysis of the properties of English words suggest that they are optimized for recognition, based on their spoken form, using their initial phonemes.[303, 1215, 1406]

phoneme 792

Technically, the terms *consonant* and *vowel* refer to spoken sounds— phonemes. In the written form of English individual letters are not unambiguously one or the other. However, the letters *a*, *e*, *i*, *o*, and *u* often represent vowel sounds. In some contexts *y* represents a vowel (e.g., *nylon*) and in some contexts *u* does not represent a vowel (e.g., *quick*).

3.5.1 Compound words

compound word

The largest group of compounds is formed using two nouns; noun+noun ⇒ stone wall, rainbow. (A study of technical terms in a medical database[308] found that 80% of unique multiword terms involved two nouns; see Costello[288] for a computational model.) Other compound forms include: verb+noun ⇒ *killjoy*, *spoilsport*; noun+verb ⇒ *homemade*, *rainfall*; adjective/adverb+noun ⇒ *quick-frozen*, *nearsighted* (see Costello[289] for a computational model); preposition+noun ⇒ *overload*, *underdog*; preposition+verb ⇒ *underestimate*, *overstep*; verb+particle ⇒ *makeup*, *breakdown*.

The creation and use of noun+noun compounds has been the subject of a number of studies. These studies have looked for restrictions that English speakers might place on permissible combinations (none found by Downing[368]) and the attributes associated with the individual words used to form the meaning of the new word.

A noun+noun combination has two parts in English. The first word acting as the modifier concept, while the second word is the head concept. Surveys[287, 1477] have found the main kinds of combinations that occur are:

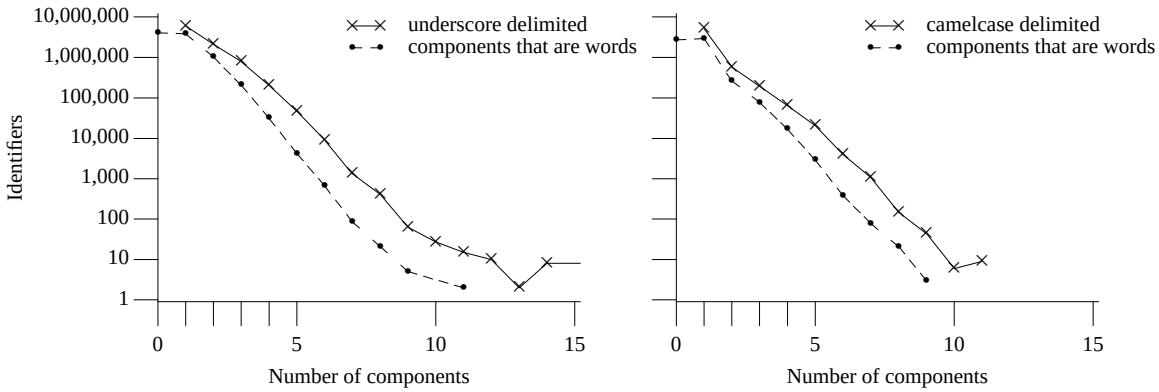

Figure 792.10: Number of identifiers containing a given number of *components*. In the left graph a component is defined as a character sequence delimited by one or more underscore characters, _, the start of the identifier, or its ending, e.g., the identifier `big_blk_proboscis` is considered to contain three components, one of which is a word. In the right graph a component is any sequence of lower-case letters, a sequence of two or more upper-case characters (i.e., the sequence is terminated by one or more digit characters or a letter having opposite case), or an upper-case character followed by a sequence of lower-case letters (this form of identifier might be said to be written in *camelCase*). For instance, the identifier `bigBlk4proboscis` is considered to contain three components, one of which is a word. A word is defined by the contents of the `ispell` 65,000 word list (this means, for instance, that the character sequence proboscis is not considered to be a word). Based on the visible form of the `.c` files.

- *conjunctive*, where concepts from both words are combined; for instance, *pet bird* is a bird that is also a pet. These have been found to occur in less than 10% of compounds.
- *property*, where a property is transferred from one of the concepts to the other; for instance, an *elephant fish* is a big fish. Like relational interpretations, these have been found to occur between 30% to 70% of the time. The frequency of property combinations has been found to increase if the concepts are similar to each other.[1476] For a study comparing the different theories of property combinations, see Costello.[290]
- *relational*, where a relation exists between two concepts; for instance, an *apartment dog* is a small dog that lives in city apartments. These have been found to be occur 30% to 70% of the time.

Words used to form an identifier might be a noun phrase rather than a compounded word. In this case word order differences may exist among dialects of English; for instance, British English uses *River Thames*, while American English uses *Hudson River*.

3.5.2 Indicating time

Tense is the linguistic term given to the way languages express time. In English tense is expressed using a verb and is divided into three zones: past, present, and future (see Table 792.8). Not all languages provide an explicit method of denoting the three tenses available in English; for instance, Japanese and Russian have no future tense.

Table 792.8: The 12 *tenses* of English (actually three tenses and four aspects). Adapted from Celce-Murcia.[213]

	Simple	Perfect	Progressive	Perfect progressive
Present	write/writes walk/walks	has/have written has/have walked	am/is/are writing am-is/are walking	has/have been writing has/have been walking
Past	wrote walked	had written had walked	was/were writing was/were walking	had been writing had been walking
Future	will write will walk	will have written will have walked	will be writing will be walking	will have been writing will have been walking

Time concepts that can be expressed in some other languages include distinctions between now versus not now and approximate versus not approximate.

3.5.3 Negation

English negation

The meaning of adjectives and adverbs can be inverted by adding a prefix (or sometimes a suffix). The following examples are from Celce-Murcia:[213]

```
happy ⇒ unhappy
appropriate ⇒ inappropriate
possible ⇒ impossible
logical ⇒ illogical
relevant ⇒ irrelevant
ordered ⇒ disordered
typical ⇒ atypical
life ⇒ lifeless
sense ⇒ nonsense
body ⇒ nobody
like ⇒ dislike
```

un- does not always indicate negativity; sometimes it indicates reversal (e.g., *unwrap*, *unfasten*). There are also words that do not follow this pattern (e.g., *inflammable* and *flammable* have the same meaning).

A noun can be negated by either adding *non-* or creating a non-phrase; for instance, *alternative* ⇒ *no alternative* and *sugar* ⇒ *sugar free*.

English also has two word forms that can be used to form a negation (i.e., not-negation and no-negation). Use of negation is much more common in speech that written text[121] (conversation is interactive and speakers have the opportunity to agree or disagree with each other, while written material usually represents the views of a single person). Studies of English grammar usage[121] have found that no-negation can be replaced with not-negation approximately 80% of the time (replacement in the other direction is possible in approximately 30% of cases), and that use of not-negation is several times more common than no-negation.

! 1103 operand type

The use of negation in C expressions is discussed elsewhere.

3.5.4 Articles

The English articles are: *definite* (e.g., *the* in "the book" would normally be taken to refer to a specific book), *indefinite* (e.g., *a/an* in "a book" does not refer to a specific book; the unstressed *some* is used for plural forms), and use of no article at all.

Most Asian and Slavic languages, as well as many African languages have no articles, they use article-like morphemes, or word order to specify the same information (e.g., the topic coming first to signal new information).

Experience shows that inexperienced users of English, whose native language does not have articles (e.g., Russian), have problems using the appropriate article. For instance, saying "have you book?" rather than"have you the book?" or "do you have a book?".

3.5.5 Adjective order

word order adjectives

In English adjectives precede the noun they modify. This is not always true in other languages. For instance, in French adjectives relating to age, size, and evaluation precede the noun, while adjectives referring to color or origin follow it:

```
une grande voiture jaune
    (big)   (car)  (yellow)
une vielle femme Italienne
    (old) (woman) (Italian)
```

Although it is rare for more than two adjectives to modify the same noun, the relative position of many of them has been found to have a consistent ordering. Svatko[1319] used responses from 30 subjects to deduce a probability for the relative ordering of certain kinds of adjectives (see Table 792.9).

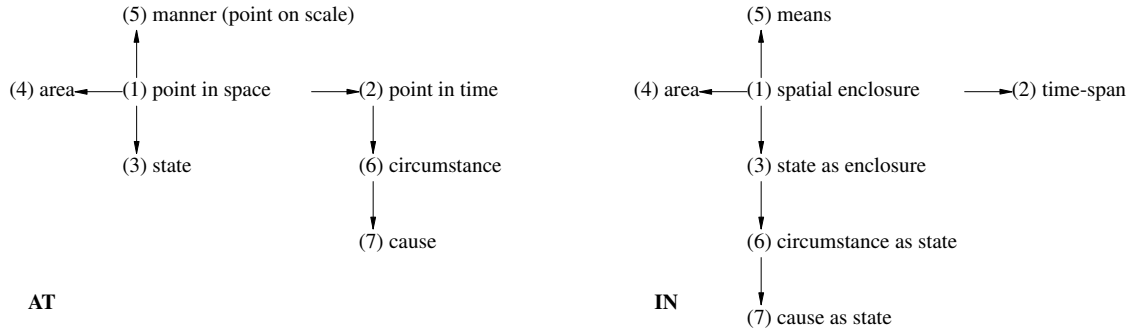

Figure 792.11: Examples, using "**at**" and "**in**" of extensions of prepositions from physical to mental space. Adapted from Dirven.[361]

Table 792.9: Probability of an adjective occurring at a particular position relative to other adjectives. Adapted from Celce-Murcia.[213]

determiner	option	size	shape	condition	age	color	origin	noun
	0.80	0.97	0.66	0.79	0.85	0.77	1.0	
an	ugly	big	round	chipped	old	blue	French	vase

3.5.6 Determine order in noun phrases

Within a noun phrase, determiners follow a general order; for instance:

```
pre core post
All our  many hopes . . .
core  post post
These next two weeks . . .
```

Table 792.10: Subcategories of determiners. Adapted from Celce-Murcia.[213]

Predeterminers	Core determiners	Post determiners
qualifiers: *all, both, half*, etc. fractions: *such a, what a*, etc. multipliers: *double, twice, three times*, etc.	articles: *a, an, the*, etc. possessives: *my, our*, etc. demonstratives: *this, that*, etc.	cardinal numbers: *one, two*, etc. ordinal numbers: *first, second*, etc. general ordinals: *next, last, another*, etc.
	quantifiers: *some, any, no, each, every, either, neither, enough*, etc.	quantifiers: *many, much, (a) few (a) little, several, more, less most, least*, etc. phrasal quantifiers: *a great deal, of, a lot of, a good number of*, etc.

Like adjective order, speakers of English as a second language often have problems using the appropriate determiner in the correct word order.

3.5.7 Prepositions

Prepositions are used to show role relationships. In some languages (e.g., Japanese) prepositions appear after the noun, in which case they are called *postpositions*. The same task is performed in some other languages (e.g., German, Russian) through the use of inflections. Prepositions

A single preposition can express a wide range of relationships (it said to be *polysemous*); for instance, the networks in Figure 792.11 highlight the relationships between the following phrases:

1. Point in space: "**at** the station", or spatial enclosure: "**in** the station"

2. Point in time: "**at** six o'clock", time-span: "**in** one hour"
3. State: "**at** work", or "**in** search of"
4. Area: "good **at** guessing", or "rich **in** coal"
5. Manner: "**at** full speed", or "**in** a loud voice"
6. Circumstance: "**at** these words (he left)", or "she nodded **in** agreement"
7. Cause: "laugh **at**", or "revel **in**"

Tyler and Evans[1382] give a detailed analysis of the range of meanings associated with spatial particles and provide a detailed analysis of the word *over*.[1381] Allen[15] gives a temporal algebra that can be used to describe intervals of time.

3.5.8 Spelling

English spelling

English spelling has many rules and exceptions. Proposals to regularize, or simplify, the spelling of English have more than 200 years of history.[1414] Experienced writers have learned to apply many of these rules and exceptions. For instance, the letter *e* is required after certain letters (*give*, *freeze*), or it may modify the pronunciation (*mat* vs. *mate*, *not* vs. *note*), or help to indicate that a word is not plural (*please*, *raise*), or it can indicate a French or Latin origin of a word (*-able*, *-age*).

A study by Venezky[1415] of the 20,000 most frequent words led him to create his *seven principles of English orthography*, covering the correspondence from writing to sounds.

1. *Variation is tolerated.* Words can have alternate spellings, either across dialects (American *honor* versus British *honour*) or within a single community (*judgment* vs. *judgement*).
2. *Letter distribution is capriciously limited.* Only a few of the letter combinations that are possible are permitted. For instance, doubling is prohibited for the letters a, i, h, v, z (there are a few exceptions like *skivvy*).
3. *Letters represent sounds and mark graphemic, phonological and morphemic features.*
4. *Etymology is honored.* That is, spelling relates to the history of English. For instance, a word that was borrowed early from French will have a */tS/* correspondence for *ch* (e.g., *chief*), while a word that was borrowed from French at a later period will have a */S/* correspondence (e.g., *chef*).
5. *Regularity is based on more than phonology.* For instance, there is the so-called *three letter rule*. All one- or two-letter words are function words[792.8] (e.g., *I*, *by*, *to*, *an*, *no* etc.), while content words have three or more letters (e.g., *eye*, *bye*, *two*, *Ann*, *know*).
6. *Visual identity of meaningful word parts takes precedence over letter-sound.* The claims that English spelling is illogical are often based on the idea that spelling should correspond to speech sounds. However, English spelling attempts to represent the underlying word forms (stripped of features attached to them by phonological rules), not represent sounds. English uses a lexical spelling system: one spelling, one morpheme, whatever the permutations of pronunciation; for instance, *cup*/*cupboard*, *critic*/*criticise*, *like*/*liked*/*likes*, *sign*/*signature*,

phonology 792

7. *English orthography facilitates word recognition* for the initiated speaker of the language rather than being a phonetic alphabet for the non-speaker.

In English the pronunciation of a particular sequence of letters can depend on their position in the word. For instance, the letter sequence *ghoti* could be pronounced as *fish* (*gh* as in *cough*, *o* as in *women*, and *ti* as in *nation*).[792.9]

When experienced English speakers are asked to spell spoken words, they are sensitive to the context in which the vowels occur,[1362] the position of the phoneme within the word,[1076] and other idiosyncratic factors.

[792.8] There are some rarely used words that are exceptions to this rule *e.g., *ox*, *ax* a US and old English spelling of *axe*) and specialist words such as *id*.

[792.9] George Bernard Shaw's original observation referred to the possible spelling of the sound */fish/*.

3.6 English as a second language

identifier English as second language

English is not only the *world language* of business, but also of software development. Information encoded in an identifier's spelling can only be extracted by readers if they are familiar with the English grammar, or English words, that it makes use of. Developers writing source that will include a non-native speaker of English readership might want to consider the benefits of restricting their usage of English to constructs likely to be familiar to this audience.

Even in those cases where developers appear to have near-native English-speaking ability there may be significant differences in their grammar usage.[280] Grammar plays a role in identifier spelling because, in English, words may have forms that reflect their grammatical role within a sentence. The learning of grammatical morphemes (e.g., *-ing*, *-s*) has been found to occur (in children and adults) in a predictable sequence.[503] The following list is based on Cook,[272] who also provides a good introduction to the linguistic factors involved in second-language teaching:

1. plural *-s* (e.g., "Girls go")
2. progressive *-ing* in present continuous form (e.g., "Girls going")
3. copula forms of *be* (e.g., "Girls are here")
4. auxiliary form of *be* (e.g., "Girls are going")
5. definite and indefinite articles— *the* and *a* (e.g., "The girls go" or "A girl go")
6. irregular past tense (i.e., verbs that do not have the form *-ed*)— (e.g., "The girls went")
7. third person *-s* (e.g., "The girl goes")
8. possessive *s* (e.g., "The girl's book")

The ordering of this sequence does not imply an order of difficulty in learning to use a construct. Studies[821] have found some significant variation in the ease with which learners acquire competence in the use of these constructs.

How many words does a speaker of English as a second language need to know? English contains (per *Webster's Third International Dictionary*, the largest dictionary not based on historical principles) around 54,000 word families (*excited*, *excites*, *exciting*, and *excitement* are all part of the word family having the headword *excite*). A variety of studies[995] have shown that a few thousand word families account for more than 90% of words encountered in newspapers and popular books. A variety of basic word lists,[995] based on frequency of occurrence in everyday situations, have been created for people learning English. All application domains have their own terminology and any *acceptable use* list of words will need to include these.

Non-native speaker's ability to extract information from identifiers created by native speakers may currently be the primary commercial developer language concern. However, the amount of source written (and therefore identifiers created) by non-native speakers continues to grow. The importance of native speakers, and speakers having a different first language to the original developer, to extract information from identifiers created by non-native speakers will grow as the volume of code increases. Handling different developer *interlanguages*[1320] (see Figure 792.12) is likely to be difficult.

There are lower-level reading issues associated with developers who have English as a second language, including (see Henser[562] for a survey of research on language-specific thoughts about bilinguals, and Carlo and Sylvester[199] for research on second-language reading):

792 neighborhood identifier

- A study by van Heuven, Dijkstra, and Grainger[1402] found that the orthographic neighborhood of both languages affected the performance of bilinguals.
- A study by Ziegler, Perry, Jacobs, and Braun[1512] investigated how identical words and nonwords (in some cases there were minor spelling differences) were read in English and German. They found that body neighborhood had a larger impact on naming time in English than German. The error rates were consistent across the various conditions tested at 1.8% and 3.7% for English and German, respectively.

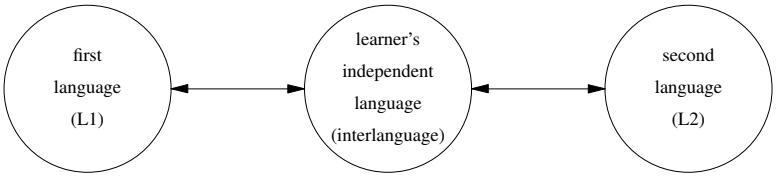

Figure 792.12: A learner's independent language— *interlanguage*. This language changes as learners go through the various stages of learning a new language. It represents the rules and structures invented by learners, which are influenced by what they already know, as they acquire knowledge and proficiency in a new language.

- A study by Malt and Sloman[891] asked second language users of English to name household objects (e.g., bottles, jars, plates, and bowls). They found that the names given by subjects did not fit the categorization patterns of native English speakers (subject performance was found to depend on the number of years of experience using English in a non-classroom setting). In the same way that the name applied to an object, by a native speaker, can depend on the context in which it occurs, there are cultural differences that affect the name given for an object.

4 Memorability

identifier
memorability
memory 0
developer

An overview of human memory is given in Sentence 0. To summarize, short-term memory is primarily sound-based (some studies have found a semantic component), while long-term memory is semantics-based (meaning).[792.10]

This section discusses specific issues, those relating to identifiers, in more depth. In this coding guideline section memorability refers to the different ways developers recall information associated with an identifier in the source code. The kinds of information and their associations include:

- The spelling of one or more identifiers may need to be recalled. Spelling recall is usually indexed by semantic rather than letter associations. These associations may relate to information denoted by the identifier (e.g., the kind of information held in an object), its usage in the source code (e.g., a loop variable or the names of file scope objects modified by a call to a function), or some unique aspect of its declaration (e.g., a single parameter or label in a function definition).
- The information denoted by an identifier need may need to be recalled. This recall is usually indexed by the character sequence of an identifier's spelling.
- A previously seen identifier may need to be recognized as denoting the same entity when it is encountered again while reading source code.
- The locations in the source code that reference, or declare, an identifier may need to be recalled. This recall may be indexed by information on spelling or semantic associations.
- All the members of a list of identifiers may need to be recalled. The indexing information used for the recall and the kind of information required to be recalled varies with the identifier list and the context in which it is referenced. For instance, writing a **`switch`** statement whose controlling expression has an enumerated type requires knowledge of the names of the enumeration constants for that type, and use of designators in an initializer requires knowledge of the names of structure members. However, while a function invocation requires information on the expected arguments, that information is associated with the name of the function and the names of any parameters are rarely of interest.

designator 1648
. identifier

In most cases the required information is available in the source code (using identifiers in third-party libraries is one exception). However, readers would need to invest resources in locating it. The trade-offs people make when deciding whether to invest resources in locating information or to use information in their heads is discussed elsewhere.

cost/accuracy 0
trade-off

[792.10] Designers of IDEs ought to note that at least one study[1005] found that highlighting parts of a word did not produce any improvement in subject's recall performance.

The different kinds of developer interaction with identifiers places different demands on human memory resources. For instance, identifiers defined within functions are often referred to, by developers, as being *temporary* (a temporary object, temporary storage, or just a temporary). For a reader of the source the time interval over which they are *temporary* is the time needed to obtain the required information about the function being read. In the case of functions containing a few lines of code this might only be a few seconds, but in most cases it is likely to be more than a minute. During a day's work reading source code, a developer is likely to read many function definitions, each containing zero or more of these *temporary* identifiers, and some possibly sharing the same spelling.

792 identifier developer interaction

What is needed is the ability to be able to recall them while reading the body of the function that declares them and then to forget about them after moving on to the next function definition. Rather like walking out of a supermarket and recalling where the car is parked, but not being confused by memories for where it was parked on previous visits. Unfortunately, people do not have the ability to create and erase information in their memory at will.

While the brain mechanisms underlying human memory is a very active research area, it is not yet possible to give a definitive answer to any fundamental questions (although some form of semantic network for connecting related individual concepts is often used in modelling). Without a reliable model, it is not possible to describe and predict memory performance, and this section approaches the issue by trying to draw conclusions based on the various studies involving words and nonwords, that have been performed to date.

792 semantic networks

The following subsection discusses some of the studies that have been performed on human recall of different kinds of names (e.g., proper names and common names) and the various research projects aimed at finding out how people make the connection between a name and what it denotes. This is followed by three subsections that discuss the issues listed in the preceding three bullet points.

4.1 Learning about identifiers

It might be thought that developers would make an effort to remember the names of identifiers; for instance, by reading the locally declared identifiers when first starting to read the source of a function definition. However, your author's experience is that developers often read the executable statements first and only read declarations on an as-needed basis. Developers only need information on locally declared identifiers while reading the source of the function that contains them. The cost of rehearsing information about locally declared identifiers to improve recall performance is unlikely to be recouped. Whether looking up identifier information on an as-needed basis is the optimal cognitive cost-minimization technique is an open question and is not discussed further here.

What information do developers remember about identifiers? There is no research known to your author addressing this question directly. The two most common important memory lookup queries involving identifiers are their spelling and semantic associations. Before these two issues are discussed in the last two subsections of this section on memorability, there is a discussion on the results from various memory studies and studies of people's performance with proper names.

Information about identifiers is provided by all of the constructs in which they occur, including:

- A declaration (which may include an associated comment) provides information on the type, scope, and various other attributes. It is likely that the reader will want to recognize this declared identifier later and recall this information about it.
- An expression will reference identifiers that need to be recognized and information about them recalled. Being referenced by an expression is also potentially useful information to be remembered, along with the identity of other identifiers in the same expression.

The issue of how readers represent identifier information associated with declarations and expressions in memory is discussed elsewhere.

1348 declaration syntax
940 expressions

4.2 Cognitive studies

The power law of learning implies that the more often an identifier is encountered (e.g., by reading its name

0 power law of learning

memory 0
information
elaboration

or thinking about what it represents) the more likely it is to be correctly recalled later. Studies have also found that the amount of processing performed on to-be-remembered information can affect recall and recognition performance.

Human memory for pairs of items is not always symmetrical. For instance, a person who has learned to recall *B* when prompted with *B* might not recall *A* so readily when prompted with *B*. This issue is not discussed further here (see Kahana[704] for a discussion).

The performance of human memory can be depend on whether information has to be recalled or whether presented information has to be recognized. For instance, a person's spelling performance can depend on whether they are asked to recall or recognize the spelling of a word. A study by Sloboda[1255] asked subjects to choose which of two words was correctly spelled. The results showed (see Table 792.11) significantly more mistakes were made when the alternative was phonologically similar to the correct spelling (191 vs. 15); that is, the spelling looked sufficiently plausible.

Table 792.11: Example words and total number of all mistakes for particular spelling patterns (–*C*– denotes any consonant). Adapted from Sloboda.[1255]

Spelling pattern	similar phonologically	mistakes made	dissimilar phonologically	mistakes made
-ent -ant	clement clemant	46	convert convart	1
-ce -se	promice promise	9	polich polish	1
w- wh-	weight wheight	3	sapely shapely	1
-er -or	paster pastor	7	parret parrot	6
-le -el	hostle hostel	11	assits assist	1
-ayed -aid	sprayed spraid	18	slayer slair	0
-ea- -ee-	deamed deemed	24	dearth deerth	3
-CC- -C-	deppress depress	33	preessed pressed	0
-ancy -ency	currancy currency	27	corractly correctly	0
-al -el	rival rivel	13	livas lives	2

4.2.1 Recall

identifier
recall
initial letters 792
identifier
morphology 792
identifier

The initial letters of a word are a significant factor in several word related activities (it has been suggested[1326, 1328] that readers use information on the first few characters of a character sequence, researchers have yet to agree on whether orthographic, phonotactic, or syllabific boundaries are used, to build an internal representation that is then used to perform a search of their mental lexicon). The first study below describes their role in the *tip-of-the-tongue* phenomenon. The second gives an example of how context can affect recall performance. Recall is discussed in general, along with memory performance, elsewhere.

memory 0
developer

identifier
tip-of-the-tongue

- A study by Rubin[1184] investigated the so-called *tip-of-the-tongue* phenomenon. People in the tip-of-the-tongue state know that they know a word, but are unable to name it. Rubin gave subjects definitions of words and asked them to name the word (e.g., somebody who collects stamps, a *philatelist*). Those subjects who knew the word, but were unable to name it, were asked to write down any letters they thought they knew. They were also asked to write down the number of syllables in the word and any

similar-sounding words that came to mind. The results showed that letters recalled by subjects were often clusters at the start or the end of the word. The clusters tended to be morphemes (in some cases they were syllables). For instance, in the case of *philatelist* many subjects recalled either *phil* or *ist*.

identifier context cueing recall

- Context can also play an important role in cueing recall. A study by Barclay, Bransford, Franks, McCarrell, and Nitsch[93] investigated how cued recall varied with context. Subjects were divided into two groups and each group was shown a different list of sentences. For instance, the list of sentences seen by the members of one group might include— "The secretary put the paper clips in the envelope", while the other group would see a different sentence relating to secretaries and envelopes "The secretary licked the envelope". After seeing the sentences, subjects heard a list of cues and were asked to write down the noun from the list of sentences each cue reminded them of. Examples of cues included "Something that can hold small objects" and "Something with glue". It was predicted that cues matching the sentence context would produce better recall. For instance, the cue "Something that can hold small objects" is appropriate to paperclips (small objects) and envelopes (being used to hold something), but not directly to an envelope being licked (where the glue cue would have a greater contextual match). The results showed that subjects hearing cues matching the context recalled an average of 4.7 nouns, while subjects hearing cues not matching the context averaged 1.5 nouns.
- The visual similarity of words can affect serial recall performance. A study by Logie, Sala, Wynn, and Baddeley[865] showed subjects a list of words that was acoustically similar (to reduce the possibility of phonological information being used to distinguish them), but one set was visually similar (e.g., *FLY*, *PLY*, *CRY*, *DRY*) while the other set was visually distinct (e.g., *GUY*, *THAI*, *SIGH*, *LIE*). The results showed that the mean number of words recalled in the visually similar list was approximately 10% lower, across all serial positions, than for the visually dissimilar list.

4.2.2 Recognition

Recognition is the process of encountering something and remembering that it has been encountered before. Recognition is useful in that it enables previously acquired information to be reused. For instance, a reader may need to check that all the operands in an expression have a given type. If an identifier occurs more than once in the same expression and is recognized when encountered for the second time, the information recalled can remove the need to perform the check a second time.

Failing to recognize a previously seen identifier incurs the cost of obtaining the needed information again. Incorrectly recognizing an identifier can result in incorrect information being used, increasing the likelihood of a fault being introduced. The first study below describes one of the processes people use to work out if they have encountered a name before. The other two studies discuss how semantic context effects recognition performance. See Shiffrin and Steyvers[1228] for a recent model of word-recognition memory.

- A study by Brown, Lewis, and Monk[168] proposed that people use an estimate of a word's memorability as part of the process of deciding whether they had previously encountered it in a particular situation. For instance, names of famous people are likely to be more memorable than names of anonymous people. If presented with a list of famous names and a list of non-famous names, people are more likely to know whether a particular famous name was on the famous list than whether a non-famous name was on the non-famous list. The results of the study showed that in some cases name memorability did have an affect on subject's performance.
- A study by McDermott[913] asked subjects to memorize short lists of words. The words were chosen to be related to a nonpresented word (e.g., *thread*, *pin*, *eye*, *sewing*, *sharp*, and *thimble* are all related to *needle*). Subjects were then presented with words and asked to specify whether they were in the list they had been asked to memorize. The results showed that subjects recalled (incorrectly) the related word as being on the list more frequently than words that were on the list. The effect persisted when subjects were explicitly told not to guess, and a difference of 30 seconds or 2 days between list learning and testing did not change the observed pattern.

- A study by Buchanan, Brown, Cabeza, and Maitson[175] used a list of words that were either related to each other on a feature basis (e.g., *cat* and *fox* share the features: four legs, fur, tail, etc.) or by association (e.g., thread, pin, eye, sewing, thimble). The activation in a semantic network organized by features would be expected to spread to words that were related in the number of features they shared, while in an associated organization, the activation would spread to words that were associated with each other, or often occurred together, but did not necessarily share any features. The results showed that for an associated words list, subjects were much more likely to falsely recall a word being on the list, than when a feature-based words list was used.

identifier 792 phonetic symbolism

Recognition through the use of phonetic symbolism is discussed elsewhere.

4.2.3 The Ranschburg effect

Ranschburg effect

Some identifiers consist of a sequence of letters having no obvious pronunciation; for instance, `hrtmb`. In this case readers usually attempt to remember the individual letters of the sequence.

When the same letter occurs more than once in a letter sequence, a pattern of short-term memory behavior known as the *Ranschburg effect* occurs.[564] If occurrences of the same letter are separated by other letters, `hrtrb`, recall performance for the duplicate letter is reduced (compared to the situation where a nonduplicate letter appears at the same position in the sequence). If occurrences of the same letter occur together, `hrrtb`, recall performance for the duplicate letter is improved. This effect has also been found to occur for digits.[1459]

4.2.4 Remembering a list of identifiers

identifier learning a list of

In many contexts a sequence of identifiers occur in the visible source, and a reader processes them as a sequence. In some cases the identifiers in the sequence have a semantic association with each other and might be referred to as a list of identifiers. In other cases the only association connecting the identifiers is their proximity in the source.

```
1   typedef int ZIPS;
2
3   enum e_t {aa, bb, cc, dd};
4   struct s_t {
5               int mem_1;
6               long ee;
7              } xyz;
8
9   void f(int p_1, float foo)
10  {
11  ZIPS average;
12  int loc;
13  double bar;
14  /* ... */
15  bar=average+foo+xyz.ee-cc;
16  }
```

primacy 0 effect memory
recency 0 effect memory
identifier 792 confusability
identifier 792 semantic associations

A number of factors have been found to be significant when information on a sequence of identifiers needs to be recalled or remembered. The primacy and recency effects, confusability, and semantic issues are discussed elsewhere.

A study by Horowitz[594] illustrates how some of these factors affect subject's performance. Subjects were asked to learn a list of 12 trigrams. One list, known as *L4* was created using the four letters F, S, V, and X, while another list, known as *L12*, was created from 12 different consonants. Because there were only four letters to choose from, the trigrams in the first list often shared one or more letters with other trigrams in the list. The trigrams in the second list were chosen so that a particular pair of letters occurred in only one item.

A trial consisted of showing the subjects one of the lists of 12 trigrams. One group was then asked to write down as many as they could freely recall, while a second group had to arrange slips of paper (each containing a single, presented trigram) into the same order as the presentation. Subjects' performance was measured after each of 10 trials (each using a different order of the 12 trigrams).

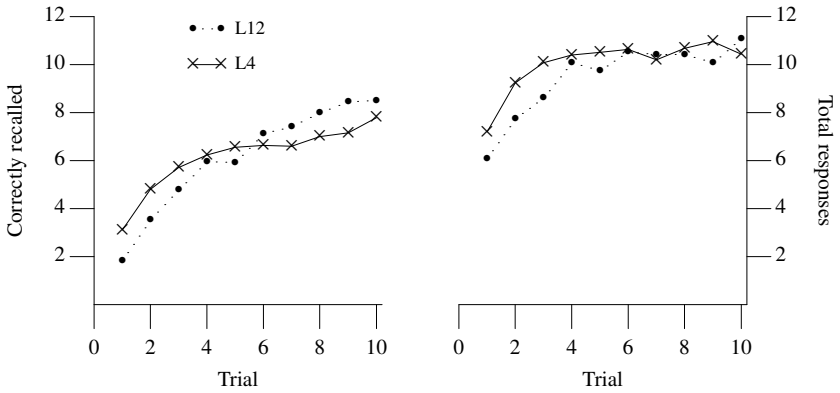

Figure 792.13: Mean correct recall scores and mean number of responses (correct and incorrect) for 10 trials. Adapted from Horowitz.[594]

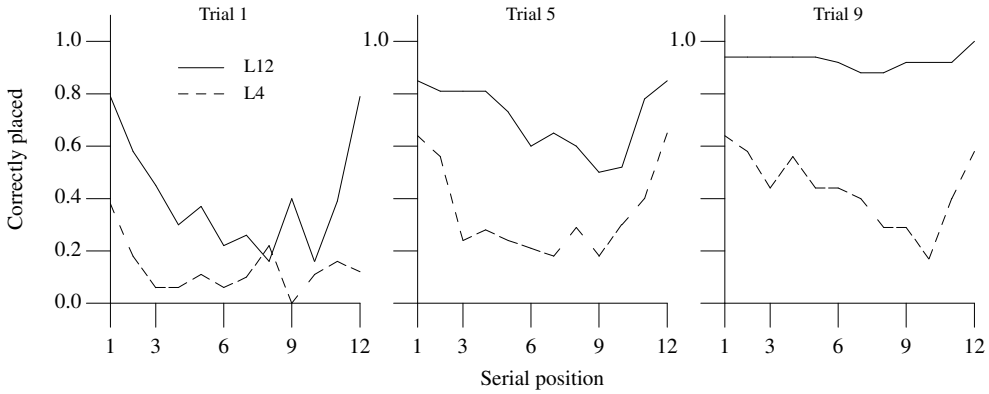

Figure 792.14: Percentage of correct orderings as a function of the trigram position within the list learned for three different trials. Adapted from Horowitz.[594]

The results for the free recall of trigrams (see Figure 792.13) show that initially subjects working with the L4 list performed best (the probability of randomly combining four letters to produce a correct three-letter trigram is 50%; this difference may be due to the much higher probability of being able to randomly pick a correct answer for the L4 list, compared to the L12 list). With practice (approximately six trials) recall performance of the group working with the L12 list exceeded that of the group using the L4 list.

The results for the ordering of trigrams (see Figure 792.14) show primacy and recency effects for both lists. The performance of subjects working with the L12 list is significantly better than those using the L4 list over all trials.

0 primacy effect memory
0 recency effect memory

A few studies have found that semantic information appears to be represented in short-term memory rather than simply being retrieved from long-term memory. A consequence of this representation is that semantic information associated with an identifier can affect recall performance. A study by Haarmann and Usher[530] showed subjects a list of six pairs of semantically related words and asked them to recall as many words as possible. In one list the semantically related words were adjacent to each other (e.g., "broader horizon king leader comfort uneasy kittens fluffy get purchase eating lunch"), while in the other they were separated by five unrelated words (e.g., "broader king comfort kittens get eating horizon leader uneasy fluffy purchase lunch"). The results showed that recall from the list of semantically adjacent words had an improved recency effect; that is, recall of words at the end of the list was better for semantically adjacent words than semantically separated words.

0 working memory information representation

0 recency effect memory

4.3 Proper names

A number of researchers have been investigating people's memory performance for proper names.[792.11] The results appear to show that the human brain does not handle different kinds of names in the same way. Studies of patients with aphasia (damage to the brain that causes problems with words) have found that different kinds of damage cause different kinds of problems. One study[506] found that some subjects had problems naming body parts but could name geographical locations, while others had problems naming geographical locations but could name body parts. Categories of names subject to these problems include animate versus inanimate objects, numbers versus letters, referential versus descriptive, and common versus proper names. Another study[504] found that brand names were handled differently in the brain than proper names.

Proper name recall performance has been found to decrease with age,[251] although in part this may be due to differences in mnemonic strategies (or lack of strategies).[165]

Many people experience greater difficulty remembering people's names than remembering other kinds of names. A number of possible reasons for this behavior have been proposed, including:

- Proper names are unique, and no alternatives are available. A study by Brédart[155] showed subjects the faces of people having two well-known names (e.g., Sean Connery alias James Bond and Peter Falk alias Columbo) and people having a well-known and a little-known name (e.g., Julia Roberts is not closely associated with any character's name she has played). Subjects were *blocked* (i.e., no correct answer given) on those faces having a single well-known name in 15.9% of cases, but were only *blocked* for 3.1% of faces having two well-known names (giving either name counted as a non-blocked response).

- The rate of learning of new common nouns slows as people reach adulthood. Adults learn technical names through further education and work experience, but learning new names in general usage is rare. However, people continue to learn new proper names throughout their lives. Being introduced to a *Mr. Dreaner* would not be considered unusual, but being told that a person was a *dreaner* might lead the listener to conclude they had misheard the job description. The range of plausible phonologies[157] is much greater for proper names than for common names. Having a set of known common names makes it easier to guess a particular name, given limited information about it (e.g., the first few letters).

A study by McWeeny, Young, Hay, and Ellis[924] asked subjects to learn to associate various names and professions with pictures of unfamiliar faces. Subjects were then presented with each picture in turn and asked to recall the associated name and profession. In those cases where only one association could be recalled there was a significant probability that it would be the profession rather than the name. In some cases the labels used could be either a name or a profession (e.g., Baker or Potter). Subjects asked to associate these ambiguous labels with a profession were more likely to recall them than those subjects asked to associate them with a name. This has been termed the *Baker–baker* paradox. The difficulty of recalling people's names is not directly related to the features of the name, such as its frequency of occurrence.

A number of other studies[1396] have confirmed that generally, recall of semantic properties associated with a person is faster than recall of that person's name. A study by Cohen[250] tested the hypothesis that the reason for this difference in performance was because peoples names are meaningless labels. There is no semantic association, in the subjects head, between the name and the person. In the first experiment subjects were asked to learn an association between a photograph, a name, an occupation, and either a meaningless nonword or a meaningful word (e.g., "Mr Collins; he is a teacher; he has a wesp", or "Mr Collins; he is a teacher; he has a boat").

[792.11] English, and most Indo-European languages, distinguish between two kinds of nouns. Names that denote individuals are called *proper names* (or *proper nouns*), while all other names (referring to classes of objects) are called *common names*.

Table 792.12: Mean number of each kind of information recalled in each condition (maximum score: 48). Adapted from Cohen.[250]

	Name	Occupation	Possession
Nonword	18.6	37.1	16.5
Word	23.6	37.0	30.4

The results (see Table 792.12) show that in the nonword case recall of both names and possessions was similar (the slightly greater recall rate for names could be caused by a frequency effect, the nonword names being names familiar to the subjects). When words were used for names and possessions, the relative recall rate changed dramatically. Cohen points out that information on real-world possessions has many semantic associations, which will trigger more connections in the subject's lexical network. A word used as a person's name is simply a label and is unlikely to have any semantic associations to an individual.

To what extent can parallels be drawn between different kinds of source code identifiers and different kinds of natural language names? For instance, are there similarities between the way developers treat the members of a structure and body parts, or between the way they think about labels and geographical locations? Identifiers do not always consist of a single word or non-word; they can form a phrase (e.g., `total_time`). Your author has not been able to find any studies looking at how human memory performance varies between words and phrases.

The two conclusions that can be drawn from studies about the recall of names is that richness of semantic associations can improve performance and that it is possible for different kinds of names to have different recall characteristics.

4.4 Word spelling

spelling

Spelling is the process of generating the sequence of characters that are generally accepted by native speakers of the language to represent the written form of a particular word. Software developers have extended this definition to include source code identifiers, whose names are commonly said to have a *spelling*.

Typing an identifier on a keyboard involves using memory to recall the sequence of letters required (or a rule to derive them) and motor skills to type the character sequence. This section provides a general discussion on the studies that have been made of spelling. The motor activities associated with typing are discussed elsewhere.

792 typing mistakes

Research into spelling has been carried out for a number of reasons, including learning about cognitive processes in the brain, trying to improve the teaching of children's reading and writing skills, and the creation of automated spelling correction programs . A lot of this research has used English speakers and words. It is possible that the models and theories applicable to users of a language that has a deep orthography may not apply to one that has a shallow orthography (e.g., Spanish[698]). Given that the spelling of identifiers is often more irregular than English, the availability of so much research on irregular spellings is perhaps an advantage.

Beware of heard,
a dreadful word,
That looks
like beard and
sounds like bird,
And dead:
it's said like
bed, not bead,
For Goodness'
sake, don't
call it deed!
Watch out
for meat and
great and threat,
They rhyme
with suite and
straight and debt.
– Anon

In some languages spelling is trivial. For instance, in Spanish if a person can say a word, they can spell it. Writers of other languages experience even more problems than in English. For instance, agglutinative languages build words by adding affixes to the root word. The effect of having such a large number of possible words (nouns have approximately 170 basic forms in Turkish and 2,000 in Finnish) on the characteristics of native speaker spelling mistakes is not known (automating the process of determining the root word and its affixes is a difficult problem in itself[1028]).

If people make spelling mistakes for words whose correct spelling they have seen countless times, it is certain that developers will make mistakes, based on the same reasons, when typing a character sequence they believe to be the spelling of an identifier. The following subsections discuss studies of spelling mistakes and some of the theories describing readers spelling performance. The aim is to find patterns in the mistakes made, which might be used to reduce the cost of such mistakes when typing identifier spellings. The fact that an identifier spelling may contain words, which may be misspelled for the same reasons as when they occur

792 agglutinative

in prose, is a special case.

4.4.1 Theories of spelling

How do people produce the spelling of a word? The two methods generally thought to be used are mapping from phonemes to graphemes (rule-based) and memory lookup (memory-based). The extent to which either of these methods is used seems to vary between people (those who primarily use the rule-based method are sometimes called *Phoenicians*, and those primarily using the memory-based method are called *Chinese*). A study by Kreiner and Gough[771] showed that good spellers made use of both methods.

Another possible method is that spelling is performed by analogy. A person uses a word for which the spelling is known which is phonemically or graphemically similar as a model, to produce the spelling of the unknown word.

4.4.2 Word spelling mistakes

The idea that there is a strong correlation between the kinds of spelling mistakes people make when writing prose and the kinds of spelling mistakes they make when writing C identifiers sounds appealing. Some broad conclusions about common prose spelling patterns can be drawn from studies of spelling mistakes (both written and typed). Kukich[784] provides a review of automatic spelling correction of text. However, the data on which these conclusions are based was obtained from disparate sources performing under very different conditions. Given the task and subject differences between these studies and developers writing code, any claims that these conclusions can be extended to developer performance in spelling identifiers needs to be treated with caution. For this reason the next subsection discusses the spelling mistake data, used in reaching these conclusions in some detail.

The following are some of the general conclusions drawn from the studies of spelling mistakes (a mistake is taken to be one of the operations insertion, deletion, substitution, or transposition):

- Between 69% to 94% of misspelled words contain a single instance of a mistake. The remaining misspelled words contain more than one instance.
- Between 1.4% to 15% of misspellings occurred on the first letter (this does not confirm the general belief that few mistakes occur in the first letter).
- Studies of typing performance have found strong keyboard adjacency effects (a letter adjacent to the one intended is typed). However, no spelling study has analyzed the effects of keyboard adjacency.
- There is insufficient data to analyze whether the number of mistakes made in a word is proportional to the number of letters in that word. (One study[771] found that the probability of a mistake being made increased with word length.)
- The pronunciation used for a word has a strong effect on the mistakes made. An incorrect spelling is often a homophone of the correct spelling.

Table 792.13: Breakdown of 52,963 spelling mistakes in 25 million typed words. Adapted from Pollock and Zamora.[1102]

Kind of Mistake	Percentage Mistakes
omission	34
insertion	27
substitution	19
transposition	12.5
more than one	7.5

Many of the spelling mistake data sets are derived from words people have chosen to use. However, people tend to limit the words they use in written prose to those they know how to spell.[966] Developers often have to use identifiers created by others. The characteristics of spelling mistakes for words chosen by other people

are of interest. An analysis by Mitton[946] looked at the differences in spelling mistakes made by 15 year-old children in written prose and a spelling test. The results show that, compared to mistakes in prose, mistakes in spelling test words contain more multiple mistakes in longer words (longer words are used less often in prose because people are less likely to be able to spell them).

A study by Adams and Adams[4] asked subjects to either spell a word (generation) or to select one of three possible spellings (recognition). Subjects also had to rate their confidence in the answer given. The results showed subjects were underconfident at low confidence levels and overconfident at high confidence levels, a commonly seen pattern. However, subjects' estimates of their own performance was more accurate on the recognition task.

0 overconfidence

Measuring spelling mistakes is not as straight-forward as it sounds. The mistakes made can depend on the subjects educational level (the educational level of many of the subjects at the time the data was obtained was lower than that typical of software developers, usually graduate-level), whether they or other people selected the words to be spelled, whether the mistakes were manually or automatically detected. Also, the English language accent, or dialect, spoken by a person has been found to affect word spelling performance for adults[1361] and children.[133, 346, 1291]

Like any other character, the space character can be mistyped. The difference between the space character and other characters is that it cannot occur within identifiers. An extra space character will cause a word to be split in two, which in C is very likely to cause a syntax violation. Omitting a space character is either harmless (the adjacent character is a punctuator) or will cause a syntax violation (in C). For these reasons, mistakes involving the space character are not discussed further here.

4.4.2.1 The spelling mistake studies

The spelling mistake studies and their findings are described next.

- Bourne[144] measured spelling mistakes in a bibliographic database. The results showed a misspelling rate that varied between 0.4% and 22.8% (mean 8.8%) for the index terms. The ratio of citations to misspelled terms varied between 0.01% and 0.63% (mean 0.27%).

- Kukich[783] analyzed spelling mistakes in the text messages sent over Bellcore's Telecommunications Network for the Deaf. Of the 10.5% of words automatically flagged as being in error, a manual check found that half were not in the dictionary used and the actual error rate was 5% to 6%

- Kundu and Chaudhuri[787] analyzed 15,162,317 of handwritten Bangla, a highly inflectional and phonetic language spoken in Indian, and 375,723 words of typed (mostly computer input) text. For the handwritten material, a mistake occurred every 122 words (0.82%) and in 53% of cases a word contained a single mistake (25% with two mistakes). The overall rate for typed text was 1.42%, and in 65% of cases a word contained a single mistake (11% with two mistakes).

- Mitton[946] looked at handwritten essays by 925 fifteen year old school children. The rate of mistakes of those classified as *poor* spellers was 63 per 1,000 words; it was 14 per 1,000 for *passable* spellers. The *poor* spellers formed approximately a third of the children and contributed more than half of the mistakes. An analysis of the Wing and Baddeley[1473] data found that few mistakes occurred near the start of a word.

- Pollock and Zamora[1102] (see Table 792.13) automatically flagged (using a dictionary of 40,000 words) mistakes in 25 million words from a scientific citations database. The overall rate of mistakes was 0.2%, and in 94% a word contained a single mistake (with 60% of mistakes being unique).

- Wing and Baddeley[1473] looked at the handwritten exam papers of 40 males applying to be undergraduates at Cambridge University (in engineering, mathematics, or natural sciences). The rate of mistakes was around 1.5% of words written. Of these, 52% were corrected by the subject after they had been made. Mistakes were less likely to be made at the beginning or end of words.

- Yannakoudakis and Fawthrop[1491] used information on 1,377 spelling error forms (obtained from published papers and checking written essays) to create what a list of "rules" for spelling errors (the mappings from correct one- or two-letter sequences to the incorrect one- or two-letter sequences were part of their data). They proposed that these spelling errors were based on phonological and letter sequence considerations; for instance, *BATH* may be pronounced *B-A-TH* in Northern England, but *B-AR-TH* or *B-OR-TH* in Southern England, potentially leading to different spelling errors. The letter sequence errors were mostly transpositions, letter doublings, and missed letters.

phonology 792

The words used in some analyses of spelling mistakes are based on words flagged by spell checking programs. These programs usually operate by checking the words in a document against a dictionary of correctly spelled words (letter trigram probabilities have also been used[1500]). One problem with the dictionary-based method is that some correctly spelled words will be flagged because they are not in the dictionary, and some incorrectly spelled words will not be flagged because the spelling used happens to match a word in the dictionary. As the number of words in the dictionary increases, the number of correctly spelled words that are flagged will decrease, but the number of unflagged spelling mistakes will also decrease. For instance, the rarely used word *beta* may be a misspelling of the more common *beat*, or its use may be intended. The word *beta* is unlikely to be in a small dictionary, but it will be in a large one. An analysis by Peterson[1081] found that the number of possible undetected spelling mistakes increases linearly with the size of the dictionary used (taking no account of word frequency). An analysis by Damerau and Mays[311] found that increasing the size of a spell checker's dictionary from 50,000 to 60,000 words eliminated the flagging of 3,240 correctly spelled words and caused 19 misspellings to be missed (in a 21,910,954 word sample).

4.4.3 Nonword spelling

identifier
nonword spelling

How do people spell nonwords (which may be dictionary words they are not familiar with)? For spoken languages a possible spelling might be based on the available sequence of sounds. Studies have found that, for English, people do not always spell a nonword spoken to them using the most common spelling pattern for the sound sequence heard. The choice of spelling is influenced by words they have heard recently. For instance, subjects who heard the word *sweet* just before the nonword */priːt/* tended to spell it as *preet*, while those who heard *treat* first tended to spell it as *preat*. Barry and Seymour[95] have proposed a model based on a set of probabilistic sound-to-spelling mappings and includes the influence of recently heard words.

4.4.4 Spelling in a second language

identifier
second language
spelling

A study by Cook[274] compared the spelling mistakes made by 375 overseas students at the University of Essex, against those made by the students in the Wing and Baddeley[1473] study. The results showed that students made fewer omissions (31.5% vs. 43.5%), but more substitutions (31.7% vs. 26.7%), transposition (3.1% vs. 1.4%), and other mistakes. Many of the mistakes were caused by close sound–letter correspondence (e.g., interchanging *a*, *e*, or *i*). There were many more different kinds of changes to consonants by overseas students compared to native speakers (38 vs. 21 different pairs).

A study by Okada[1033] investigated the kinds of English spelling mistakes made by native Japanese speakers. He proposed that the teaching and use of romaji (a method of representing spoken Japanese syllables using sequences of one or more letters from the English alphabet (only 19 to 21 of the 26 letters available are used, e.g., *c*, *l*, and *v* are not used)) was the root cause of particular kinds of spelling mistakes, i.e., subjects were using the romaji letter sequence/Japanese syllable sound association they were familiar with as an aid to spelling English words. The significant phonological differences between the spoken forms of Japanese and English can result in some spellings being dramatically incorrect. A later study[1034] looked at errors in the word-initial and word-final positions.

syllable 792

phonology 792

Your author does not know of any other study investigating the English spelling performance of native speakers of a language whose alphabet shares many letters with the English alphabet.

A study by Brown[167] compared the spelling abilities of native-English speakers with those for whom it was a second language (47 subjects whose first language varied and included Spanish, French, Japanese, Chinese, German, Hebrew, Arabic). The relative pattern of performance for high/low frequency words with

regular/irregular spellings (see Table 792.14) was the same for both native and non-native English speakers.

Table 792.14: Mean number of spelling mistakes for high/low frequency words with regular/irregular spellings. Adapted from Brown.[167]

	High Frequency Regular Spelling	Low Frequency Regular Spelling	High Frequency Irregular Spelling	Low Frequency Irregular Spelling
Native speaker	0.106	4.213	0.596	7.319
Second language	0.766	7.383	2.426	9.255
Example	cat, paper	fen, yak	of, one	tsetse, ghoul

4.5 Semantic associations

A semantic association occurs in the context of these coding guidelines when source code information causes other information to *pop* into a reader's mind. (It is believed[34] that people's recall of information from long-term memory is based on semantic associations.) Other semantic issues are discussed elsewhere.

792 identifier semantic associations
792 Identifier semantic confusability
792 semantic priming
792 Identifier semantic usability
792 semantic networks
770 reading kinds of

A particular identifier is likely to have several, out of a large number of possible, attributes associated with it. Which of these attributes a reader will be want to recall can depend on the purpose for reading the code and the kind of reference made in a usage of an identifier. The following are some of these attributes:

- *Identifiers in general.* What it denotes in the programs model of the application (e.g., `Node_Rec` might denote the type of a node record and `total_ticks` might denote a count of the number of clock ticks—its visibility), what other locations in the program's source reference the identifier (locations are usually the names of functions and relative locations in the function currently being read), associated identifiers not present in the source currently visible (e.g., a reference to a structure member may require other members of the same type to be considered), or who has control of its definition (e.g., is it under the reader's control, part of a third-party library, or other members of the project).
- *For an object.* The possible range of values that it might hold (e.g., `total_ticks` might be expected to always contain a positive value and a specification for the maximum possible value may exist), its type. (Some of the reasons for wanting to know this information include the range of possible values it can represent or whether it is a pointer type that needs dereferencing.)
- *For a function call.* A list of objects it references (for any call a subset of this list is likely to be needed, e.g., those objects also referenced in the function currently being read), or the value returned and any arguments required.

The following studies investigated the impact of semantic associations on recall of various kinds of information that might be applicable to developer interaction with identifiers.

- A study by McClelland, Rawles, and Sinclair[908] investigated the effects of search criteria on recall performance after a word-classification task. Subjects were given a booklet with pages containing categories and an associated list of words. For instance, the category *dangerous fish* and the words *shark*, *poison*, *trout*, and *paper*. They were asked to write down how many components (zero, one, or two) each word had in common with the category. After rating all category/word pairs, they then had to write down as many words from each of the lists as possible. The results showed that those words sharing two components with the category (e.g., *shark*) were most frequently recalled, those sharing one component with the category (e.g., *poison*, *trout*) were recalled less often, and those sharing no components (e.g., *paper*) were recalled least often. A second experiment measuring cued recall found the same pattern of performance. A study by Hanley and Morris[540] replicated these results.
- Several studies[869, 1182] have investigated readers incidental memory for the location of information in text printed on pages. The results show that for short documents (approximately 12 pages) subjects were able to recall, with reasonable accuracy, the approximate position on a page where information

occurred. These memories were incidental in that subjects were not warned before reading the material that they would be tested on location information. Recall performance was significantly lower when the text appeared on a written scroll (i.e., there were no pages).

5 Confusability

identifier confusability

For any pair of letter sequences (an identifier spelling) there is a finite probability that a reader will confuse one of them for the other. Some studies have attempted to measure confusability, while others have attempted to measure similarity. This section discusses the different ways readers have been found to treat two different character sequences as being the same. The discussion of individual issues takes the lead from the particular study being described in either using the term *confusability* or *similarity*. The studies described here involve carrying out activities such as searching the visual field of view, reading prose, recalling lists, and listening to spoken material. While all these activities are applicable to working with source code, the extent of their usage varies.

The following are the character sequence confusability, or similarity, factors considered to be important in this subsection:

- *Visual similarity.* Letter similarity, character sequence similarity, word shape (looks like)
- *Acoustic confusability.* Word sounds like, similar sounding word sequences
- *Semantic confusability.* Readers' existing knowledge of words, metaphors, categories

Metaphor 792

A reader of a C identifier may consider it to be a word, a pronounceable nonword, an unpronounceable nonword, or a sequence of any combination of these. This distinction is potentially important because a number of studies have shown that reader performance differs between words and nonwords. Unfortunately many of the published studies use words as their stimulus, so the data on readers' nonword performance is sparse.

word non-word effects 792

When categorizing a stimulus, people are more likely to ignore a feature than they are to add a missing feature. For instance, *Q* is confused with *O* more often than *O* is confused with *Q*. A study by Plauché, Delogu, and Ohala[1092] found asymmetries in subjects' confusion of consonants. For instance, while the spoken consonant */ki/* was sometimes interpreted by their subjects as */ti/*, the reverse did not occur (*/ki/* contains a spectral burst in the 3 to 4 KHz region that is not present in */ti/*).

distinguishing features 770

guideline recommendation enforceable 0

It is intended that these guideline recommendations be enforceable. This requires some method of measuring confusability. While there are no generally applicable measures of confusability, there is a generally used method of measuring the similarity of two sequences (be they letters, phonemes, syllables, or DNA nucleotides)— the Levenstein distance metric. The basic ideas behind this method of measuring similarity are discussed first, followed by a discussion of the various attributes, which might be sources of confusion.

5.1 Sequence comparison

Levenstein distance

The most common method used to measure the similarity of two sequences is to count the minimum number of operations needed to convert one sequence into the other. This metric is known as the *edit* or *Levenstein* distance. The allowed operations are usually insertion, deletion, and substitution. Some variants only allow insertion and deletion (substitution is effectively one of each), while others include transposition (swapping adjacent elements).

The Levenstein distance, based on letters, of *INDUSTRY* and *INTEREST* is six. One of the possible edit sequences, of length six, is:

```
INDUSTRY delete Y ⇒ INDUSTR
INDUSTR delete R ⇒ INDUST
INDUST substitute D by R ⇒ INRUST
```

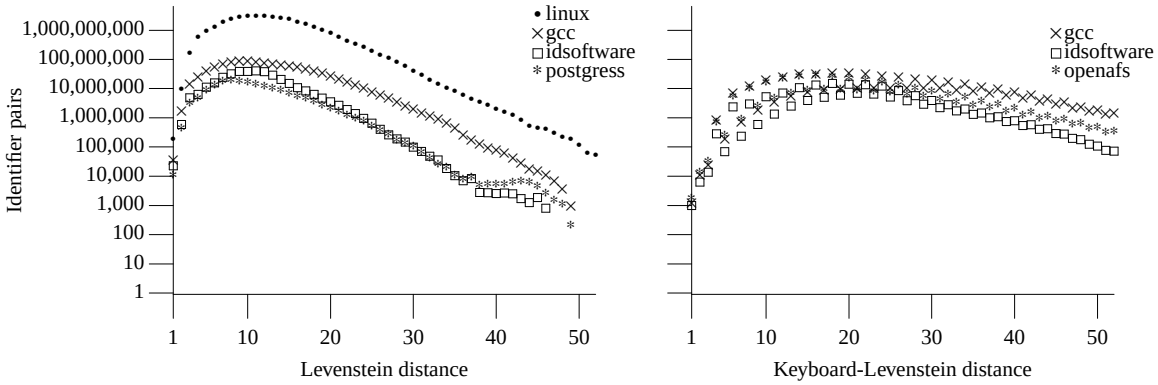

Figure 792.15: Number of identifiers having a given Levenstein distance from all other identifiers occurring in the visible form of the `.c` files of individual programs (i.e., identifiers in gcc were only compared against other identifiers in gcc). The *keyboard-levenstein* distance was calculated using a weight of 1 when comparing characters on immediately adjacent keyboard keys and a weight of 2 for all other cases (the result was normalized to allow comparison against unweighted Levenstein distance values).

```
INRUST substitute U by E ⇒ INREST
INREST insert T ⇒  INTREST
INTREST insert E ⇒ INTEREST
```

When all operations are assigned the same weight, the cost of calculating the Levenstein distance is proportional to the product of the lengths, $m \geq n$, of the two sequences. An $O(mn/\log n)$ algorithm is known,[900] but in practice only has lower cost for sequence lengths greater than 262,419. However, in its general form the Levenstein distance can use different weights for every operation. When operations can have different weights, the complexity of the minimization problem becomes $O(mn^2/\log n)$. Possible weighting factors include:

- A substitution may depend on the two items; for instance, characters appearing adjacent on a keyword are more likely to be substituted for each other than those not adjacent.
- The position of the character within the identifier; that is, a difference in the first character is much more likely to be visually noticed than a difference nearer the end of the identifier[106]. 770 word reading individual
- The visual similarity between adjacent characters; for instance, the Levenstein distance between the identifier `h1tk1` and the two identifiers `__t__` and `kltfh` (based on characters) is the same. However, the identifier `__t__` is much more different visually.

Computing an identifier's Levenstein distance, based on the characters it contains, to every other identifier in a program is potentially a computationally time-consuming operation. Possible techniques for reducing this overhead include the following:

- Reduce the number of identifiers against which the Levenstein distance has to be calculated
- Maintain a dictionary of precompute information for known identifiers. An algorithm by Bunke[180] looks up the nearest neighbor in a dictionary (which needs to hold identifiers converted to some internal form) in linear time, proportional to the length of one of the two strings to be matched (but storage usage is exponential in the length of the dictionary words).
- Map the identifiers into points in a d-dimensional space such that the distances between them is preserved (and less costly to calculate). Jin, Li, and Mehrota[669] describe an algorithm that uses this mapping idea to obtain the set of pairs of identifiers whose distance is less than or equal to k. While this algorithm runs in a time proportional to the total number of identifiers, it is an approximation that does not always find all identifier pairs meeting the distance criteria.

identifier 792 guideline significant characters

- The possibility of reducing the number of identifier's against which a particular identifier needs to be compared against is discussed elsewhere.

5.1.1 Language complications

Words often have an internal structure to them, or there are conventions for using multiple words. A similarity measure may need to take a reader's knowledge of internal structure and conventions into account. Three language complications are discussed next — an example of internal word structure (affixes), spelling letter pairs, and a common convention for joining words together (people's names), along with tools for handling such constructs.

agglutinative 792 languages

- A word sometimes includes a prefix or suffix. So-called *stemming* algorithms attempt to reduce a word to its common root form. Some algorithms are rule-based, while others are dictionary-based[774] (*creation* can be reduced to *create* but *station* cannot be reduced to *state*). Comparisons of the accuracy of the algorithms has produced mixed results, each having their own advantages.[460, 605] Languages differ in the extent to which they use suffixes to create words. English is at one end of the scale, supporting few suffixes. At the other end of the scale are Hebrew and Slovene (supporting more than 5,000 suffixes); Popovic and Willett[1103] found that use of stemming made a significant difference to the performance of an information lookup system.

morpheme 792

- There appears to be patterns to the incorrect characters used in misspelled words. Kernighan, Church, and Gale[728] used the Unix `spell` program to extract 14,742 *misspelled* words from a year's worth of AP wire text (44 million words). These words were used to build four tables of probabilities, using an iterative training process. For instance, $del[x, y]/chars[x, y]$ denotes the number of times the character y is deleted when it follows the character x (in misspelled words) divided by the number of times the character y follows the character x (in all words in the text). The other tables counted insertions, substitutions, and transpositions.

- People's names and source code identifiers often share the characteristic that blocks of characters are deleted or transposed. For instance, "John Smith" is sometimes written as "J. Smith" or "Smith John", and `total_widget` might be written as `tot_widget` or `widget_total`. Searching and matching problems based on different spellings of the same person's name occur in a variety of applications and a number of algorithms have been proposed, including, `LIKEIT`[1493] and `Matchsimile`.[996]

5.1.2 Contextual factors

The context in which a letter sequence is read can affect how it is interpreted (and possibly confused with another).

- *Reading sequences of words.* For instance, in the sentence "The child fed the dack at the pond" the nonword *dack* is likely to be read as the word *duck*. Sequences of identifiers separated by other tokens occur in code and are sometimes read sequentially. The extent to which identifier spellings will cause expectations about the spelling of other identifiers is not known.

- *Paging through source code* (e.g., when in an editor). Studies[1113] have found that when asked to view rapidly presented lists, subjects tend to mistakenly perceive a nonword as a word that looks like it (the error rate for perceiving words as other words that look like them is significantly smaller).

identifier 792 visual search

- *Searching.* The issues involved in visual search for identifiers are discussed elsewhere.

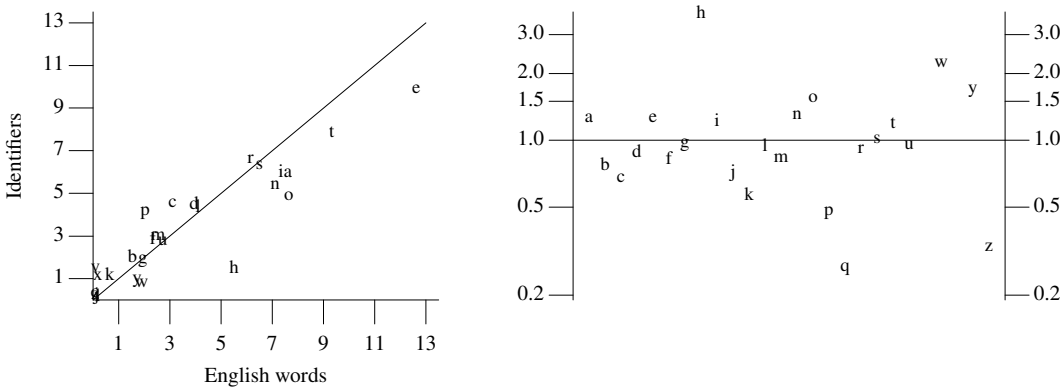

Figure 792.16: Occurrence of alphabetic letters in English text[1267] and identifier names (based on the visible form of the `.c` files; all letters mapped to lowercase). Left graph: the letter percentage occurrence as (x, y) coordinates; right graph: the ratio of dividing the English by the identifier letter frequency (i.e., letters above the line are more common in English text than in identifiers; two letters outside the range plotted are $v = 0.0588$ and $x = 0.165$).

5.2 Visual similarity

A large number of factors have been found to influence a reader's performance in visual recognition of character sequences (the special case of the character sequence representing a word is discussed elsewhere). This subsection discusses those visual factors that may cause one character sequence to be confused for another. Individual character similarity is discussed first, followed by character sequence similarity.

identifier
visual similarity
792 word
visual recognition

Readers have extensive experience in reading character sequences in at least one natural language. One consequence of this experience is that many character sequences are not visually treated as the sum of their characters. In some cases a character is made more visually prominent by the characters that surround it and in other cases it is visually hidden by these characters. Examples of these two cases include:

792 identifier
introduction

- For the first case, the *word superiority effect*. A study by Reicher[1152] showed subjects a single letter or a word for a brief period of time. They had been told that they would be required to identify the letter, or a specified letter (e.g., the third), from the word. The results showed that subjects' performance was better when the letter was contained within a word.
- For the second case, a study by Holbrook,[584] asked subjects to detect spelling errors in a 700-word story. The spelling errors were created by replacing a letter by either the letter with highest confusability, the letter with the lowest confusability, or one whose confusability was half way between the two extremes. After adjusting for letter frequency, word frequency, and perceived word similarity, the results showed a correlation between measurements of individual letter confusability and subjects' misspelling detection performance.

The following discussion assumes that all of the characters in a particular character sequence are displayed using the same font. Readers' performance has been found[1196] to be degraded when some of the characters in a word are displayed in different fonts. However, this issue is not discussed further here.

5.2.1 Single character similarity

The extent to which two characters have a similar visual appearance is affected by a number of factors, including the orthography of the language, the font used to display them, and the method of viewing them (print vs. screen). Examples of two extremes of similarity (based on commonly used fonts) are the characters `1` (one) and `l` (ell), which are very similar, and the characters `T` and `w` which are not visually similar.

character
visual similarity
792 orthography

In most cases the method used to view source code uses some form of screen. Reading from a printed listing is becoming rare. Even when a printed listing is used, it has usually been produced by a laser printer.

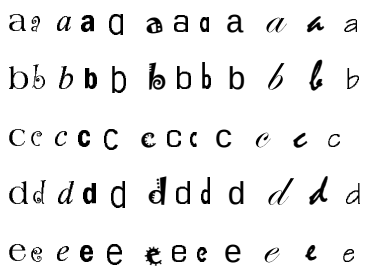

Figure 792.17: A number of different glyphs (different fonts are used) for various characters.

The character legibility issues caused by poorly maintained dot matrix or line printers are now almost a thing of the past and are not considered further here.

Before a character can be recognized, its shape has to be distinguished. The greater the visual similarity between two characters, the greater the probability that one of them will be mistakenly treated as the other. Studies of letter similarity measurement have a long history.[583, 1353] These studies have used letters only—there are no statistically significant published results that include digits or common mathematical symbols (as occur in C language source code). The raw data from these measurements is usually a two-dimensional confusion matrix, specifying the degree to which one letter has been estimated (by summing the responses over subjects) to be confusable with another one. In an attempt to isolate the different factors that contribute to this confusion matrix, a multidimensional similarity analysis is sometimes performed.

The following is a discussion of the major published studies (see Mueller et al[978] for a review). Kuennapas and Janson[782] asked subjects to judge the pairwise similarity of lowercase Swedish letters. A multidimensional similarity analysis on the results yielded nine factors: vertical linearity (e.g., *t*), roundness (e.g., *o*), parallel vertical linearity (e.g., *n*), vertical linearity with dot (e.g., *i*), roundness attached to vertical linearity (e.g., *q*), vertical linearity with crossness (e.g., *k*), roundness attached to a hook (e.g., *å*), angular open upward (e.g., *v*), zigzaggedness (e.g., *z*). Bouma[143] used Dutch subjects to produce confusion matrices for lowercase letters. The letters were viewed at distances of up to 6 meters and at angles of up to 10° from the center of the field of view. The results were found to depend on 16 different factors. Townsend[1360] used English subjects to produce confusion matrices for uppercase letters. The letters were briefly visible and in some cases included visual noise or low-light conditions (the aim was to achieve a 50% error rate).

A later study[1359] investigated the results from two individuals. Gilmore, Hersh, Caramazza, and Griffin[492] attempted to reduce the statistical uncertainty present in previous studies caused by small sample size. Each English uppercase letter was visually presented on a computer display, and analyzed by subjects a total of 1,200 times. A multidimensional similarity analysis on the published confusion matrices yielded five factors. Gervais, Harvey, and Roberts[482] attempted to fit their confusion matrix data (not published) for uppercase letters to models based on template overlap, geometric features, and spatial frequency content (Fourier transforms). They obtained a correlation of 0.7 between the data and the predictions of a model, based on spatial frequency content.

Boles and Clifford[134] produced a similarity matrix for upper- and lowercase letters viewed on a computer display (many previous studies had used letters typed on cards). A multidimensional similarity analysis on the results yielded three factors— lower- vs. uppercase, curved vs. straight lines, and acute angular vs. vertical.

Given that visual letter recognition is a learned process and that some letters occur much more frequently than others, it is possible that letter confusability is affected by frequency of occurrence. A study by Bouma[143] failed to find a frequency-of-occurrence factor in a letter's confusability with other letters.

5.2.2 Character sequence similarity

character sequence similarity

An important factor in computing character sequence similarity is a model of how people represent the

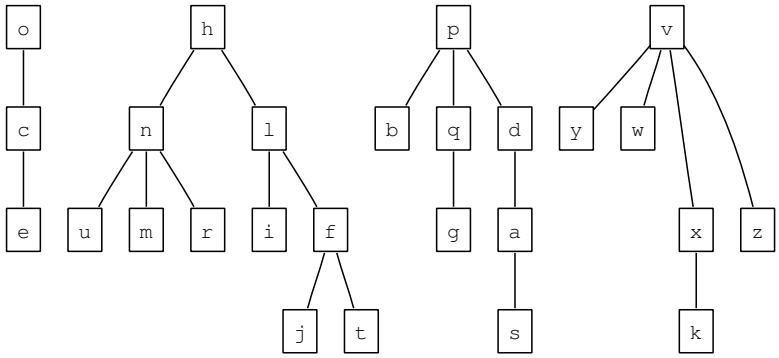

Figure 792.18: Similarity hierarchy for English letters. Adapted from *Lost reference*.[?]

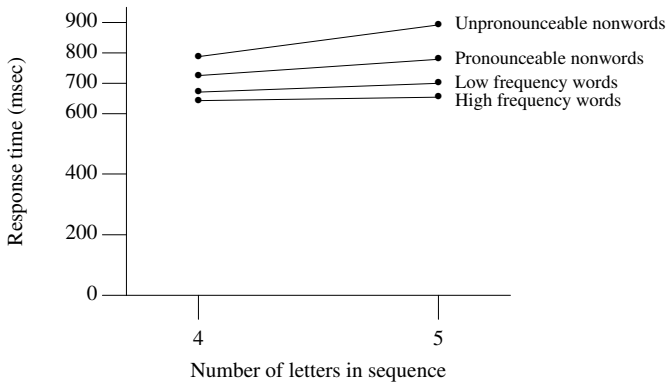

Figure 792.19: Response time to match two letter sequences as being identical. Adapted from Chambers and Foster.[214]

position of characters within a sequence. Proposed models include slot-coding (i.e., separate slots for each position-specific letter), localised context (i.e., the position of a letter with respect to its nearest neighbours), open-bigram encoding (e.g., *cl*, *ca*, *cm*, *la*, *lm*, and *am*).[328] Unfortunately researchers have only recently started to study this issue and there is not yet a consensus on the best model.

The following is a selection of studies that have investigated readers' performance with sets of character sequences that differ by one or more characters. The study by Andrews suggests that transposition may need to be included in a Levenstein distance calculation.

792 confusability
transposed-letter
792 Levenstein
distance

- A study by Chambers and Foster[214] measured response times in a simultaneous visual matching task using four types of letter sequences— high-frequency words, low-frequency words, pronounceable nonwords, unpronounceable nonwords. Subjects were simultaneously shown two letter sequences and had to specify whether they were the same or different. The results (see Figure 792.19) show the performance advantage for matching words and pronounceable nonwords. Measurements were also made when the letter sequences differed at different positions within the sequence; Table 792.15 shows the response times for various differences.

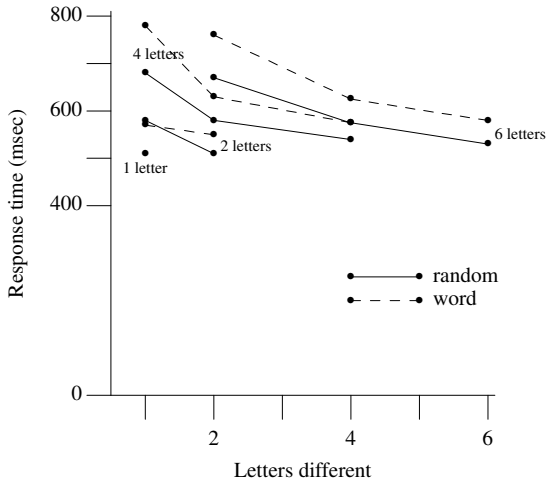

Figure 792.20: Time taken (in milliseconds) to match a pair of letter sequences as being identical— for different number of letters in the sequence and number of positions in the sequence containing a nonmatching letter. Adapted from Eichelman.[381]

Table 792.15: Response time (in milliseconds) to fail to match two letter sequences. Right column is average response time to match identical letter sequences. Columns are ordered by which letter differed between letter sequences. Adapted from Chambers and Foster.[214]

	All Letters	First Letter	Third Letter	Fifth Letter	Same Response
Words	677	748	815	851	747
Pronounceable nonwords	673	727	844	886	873
Unpronounceable nonwords	686	791	1,007	1,041	1,007

Chambers and Foster explained the results in terms of three levels of letter sequence identification: the word level, the letter cluster level, and the letter level. The higher the level at which operations are performed, the fewer are required for a fixed number of letters. The increasing response time as the differing letter moves further to the right of the word suggests a left-to-right order of processing. However, performance when all letters differ is much better than when only the first letter differs. This behavior would not occur if a strictly left-to-right comparison was performed and suggests some *whole word* processing occurs— also see Henderson.[559]

- A study by Eichelman[381] measured response times in a simultaneous visual matching task where letter sequences (either words or randomly selected) varied in the number letters that differed or in case (lower vs. upper). The results (see Figure 792.20) show how response time increases with the number of letters in a sequence and decreases as the number of letters that are different increases.

  In a second simultaneous visual matching task some letter sequences were all in uppercase, while others were all in lowercase. Subjects were told to compare sequences, ignoring letter case. The results showed that when the case used in the two letter sequences differed, the time taken to match them as being identical increased for both words and random sequences. This pattern of response is consistent with subjects performing a visual match rather than recognizing and comparing whole words. For this behavior, a change of case would not be expected to affect performance when matching words.

- Neighborhood frequency effects. A study by Grainger, O'Regan, Jacobs, and Segui[512] found an interaction (response time and error rate) between the initial eye fixation point within a word and the position of the letter differentiating that word from another (this behavior is only possible if readers have a preexisting knowledge of possible spellings they are likely to encounter, which they will have for words).

word 770
reading individual

Mr. Chips 770

- Perceptual interaction between two adjacent, briefly presented, words (as might occur for two operands in an expression when paging through source in an editor). For instance, subjects have reported the adjacent words *line* and *lace* as being *lane* or *lice*.[1399] 792 illusory conjunctions

- Transposed-letter confusability. A study by Andrews[37] found that so-called *transposed letter pair* words (e.g., *salt-slat*) affected subjects' performance in some cases (low-frequency words; non-words were not affected). A model of internal human word representation based on letters and their approximate position within a word was discussed. confusability transposed-letter

- A study by Ziegler, Rey, and Jacobs[1513] found that speed of recognition of words whose letters were not readily legible was proportional to the log of their frequency of occurrence and approximately linear on what they defined as letter confusability. The error rate for correctly identifying words was proportional to the number of orthographic neighbors of a word, and a measure of its orthographic redundancy.

5.2.2.1 Word shape

The term *whole word shape* refers to the complete visual appearance of the sequence of letters used to form a word. Some letters have features that stand out above (ascenders— *f* and *t*) and below (descenders — *q* and *p*) the other letters, or are written in uppercase. Source code identifiers may also have another shape-defining character— the underscore _. Words consisting of only uppercase letters are generally considered to have the same shape. The extent to which *whole word shape* affects visual word-recognition performance is still being debated (see Perea and Rosa[1074] for a recent discussion). In the following two studies a whole word shape effect is found in one case and not in the other. word shape

- A study by Monk and Hulme[958] asked subjects to quickly read a paragraph. As a subsidiary task they were asked to circle spelling errors in the text. The spelling errors were created by deleting or substituting a letter from some words (in some cases changing the shape of the word). The results (see Table 792.16) showed that when lowercase letters were used, a greater number of misspelled words were circled when the deletion also changed the shape of the word. When a mixture of letter cases (50% lowercase/uppercase) was used, differences in word shape were not sufficient to affect misspelling detection rates (this study has been replicated and extended[556]).

Table 792.16: Proportion of spelling errors detected (after arcsin transform was applied to the results). Adapted from Monk and Hulme.[958]

	Same Lowercase Word Shape	Different Lowercase Word Shape	Same Mixedcase Word Shape	Different Mixedcase Word Shape
Letter deleted	0.554	0.615	0.529	0.517
Letter substituted	0.759	0.818	0.678	0.680

- A study by Paap, Newsome, and Noel[1038] modified an earlier study by Haber and Schindler,[531] which had found a word shape effect. Subjects were asked to read a passage at their normal reading speed, circling any misspelled words as they read. They were told that they would be tested for comprehension at the end. Four kinds of misspellings were created. For instance, the letter *h* in *thought* was replaced by: (1) *b* (maintain shape and confusable letter), (2) *d* (maintain shape and distinct letter), (3) *n* (alter shape and confusable letter), or (4) *m* (alter shape and distinct letter). The results (see Figure 792.21) showed that many more misspellings went undetected when the letters were confusable (irrespective of word shape) than when they were distinctive (irrespective of word shape).

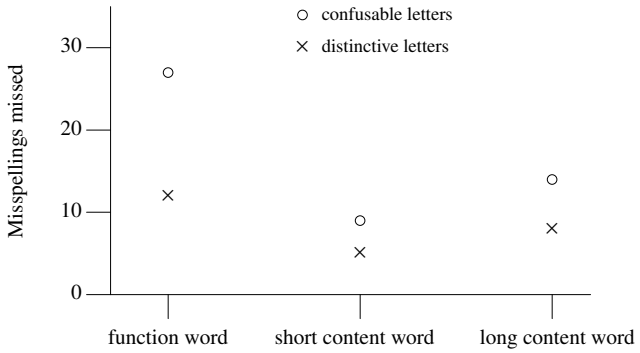

Figure 792.21: Percentage of misspellings not detected for various kinds of word. Adapted from Paap, Newsome, and Noel.[1038]

5.3 Acoustic confusability

acoustic confusability
standard 1 specifies form and interpretation
grapheme 792
phoneme 792
word 792 pronounceability

C source code is not intended to represent a spoken language. However, it is always possible to convert an identifier's character sequence to some spoken form. This spoken form may be a list of the individual characters or readers may map one or more characters (graphemes) to sounds (phonemes). This subsection does not concern itself with the pronunciation used (the issue of possible pronunciations a developer might use is discussed elsewhere), but discusses the various possibilities for confusion between the spoken form of different identifiers.

The studies discussed in this subsection used either native British or American speakers of English. It is recognized that the pattern of sounds used by different languages varies. The extent to which the results, relating to sound similarity, obtained by the studies discussed here are applicable to speakers of other languages is not known. While many of the studies on acoustic similarity use spoken material as input to subjects, not written material, most of the studies described here used written material.

A number of studies have found what has become known as the *dissimilar immunity effect*.[75] The effect is that the recall of phonologically dissimilar items on a list is not affected by the presence of similar items (i.e., recall is the same as if the items appeared in a completely dissimilar list). A recent study[409] found evidence that similar items enhanced memory for the order of dissimilar items between two similar items.

phonology 792

The first subsection discusses the issue of measuring the degree to which the pronunciations of two identifiers sound alike. This is followed by subsections discussing studies of letter acoustic confusion and memory performance for lists of words that sound alike.

5.3.1 Studies of acoustic confusion

A number of studies have investigated the acoustic confusion of letters and digits. Two of these (both using British subjects) published a confusion matrix. In the study by Conrad[268] (whose paper only contained data on a subset of the letters— see Morgan[963] for data on all letters), subjects listened to a recording of spoken letters into which some noise had been added and were asked to write down the letters they heard. The study by Hull[604] included letters and digits.

In a study by Morgan, Chambers, and Morton[964] subjects listened to a list of digits (spoken by either an American or Australian female or an English male) and after hearing the list were asked to write down the digits. A total of 558 subjects listened to and recalled 48,402 digit lists. Confusion matrices for the different speakers and the recognition and memory tasks were published.

What are the factors that affect the confusability of two letters? Both Morgan[963] and Shaw[1221] performed multidimensional scaling analysis[792.12] on the Conrad and Hull data. Morgan presented an analysis using $n = 3$, but suggested that larger values may be applicable. Shaw treated the letters phonologically, using

phonology 792

[792.12] Multidimensional scaling is a technique that attempts to place each result value in an n-dimensional space (various heuristics are used to select n, with each dimension being interpreted as a factor contributing to the final value of the result obtained).

$n = 5$ isolated phonological factors for three of the dimensions (open vs. closed vowels, vowel+consonant sound vs. consonant+vowel sound, and voiced vs. unvoiced consonants). There is significant correlation between the ordering of data points in one of the dimensions (open vs. closed vowels) and the first formant frequency of English vowels (see Cruttenden, tables 3, 4, and 5[301]). This correlation was also found by Morgan, Chambers, and Morton[964] in their study of digits.

While these results offer a possible explanation for the factors affecting letter confusion and data points from which calculations can be made, it is important to bare in mind that the pronunciation of letters will depend on a person's accent. Also, as the measurements in Cruttenden[301] show, the relative frequencies of formants (assuming this is a factor in confusability) differ between males and females.

Most identifiers contain more than one letter. A study by Vitz and Winkler[1426] found that for words the phonemic distance (a measure of the difference between two phoneme sequences) between the two words is a major factor in predicting whether people judge them to have "similarity of sound". Other factors include rhyme, alliteration, and stress.

792 word stress

A study by Bailey and Hahn[84] compared two of the main approaches to measuring phonological similarity (for the case of single syllable words), one empirically derived from measurements of confusability and the other based on a theoretical analysis of phonological features. They found that empirical confusability measurements did not provide any advantages over the theoretically based analysis.

5.3.1.1 Measuring sounds like

0 coding guidelines introduction

One of the design aims of guideline recommendations is to support automatic enforcement. In order to measure the acoustic similarity of two identifiers, it is necessary to be able to accurately convert their spellings to sound (or an accurate representation of their sound, e.g., a phonetic transcription; the issue of how people convert character sequences to sounds is discussed elsewhere) and to have a method of measuring the similarity of these two sounds. There are a number of issues that a measurement of sounds-like needs to address, including:

792 phoneme
792 characters mapping to sound

You can lead a horse to water, but a pencil must be lead. Wind the clock when the wind blows.

792 characters mapping to sound

- Developers are well aware that source code identifiers may not contain natural language words. It is likely that nonwords in identifiers will be pronounced using the grapheme-to-phoneme route (see Figure 792.3). For instance, the pronunciation of the nonword `gint` rhyming with the word `hint` rather than `pint` (of bear). A study by Monsell et al.[960] (and others) shows that readers have some control over the degree to which one naming route is preferred to another based on their expectations of the likely status of character sequences they will encounter. This suggests that a developer who expects identifiers to be nonwords may be more likely to pronounce identifiers using the grapheme-to-phoneme route. This route may, or may not, result in the generally accepted pronunciation for the word being used.
- Some identifiers contain more than one word. Readers recognize a word as a unit of sound. As such, two identifiers containing the same two words would have the same sound if those words occurred in the same order. For instance, `count_num` and `num_count` could be said to have a Levenstein distance of one based on the word as the edit unit.

A number of studies have attempted to automatically measure the sound similarity of two words (Kessler[729] provides an overview of phonetic comparison algorithms and the applications that use them), the following are some of them:

- Frisch[454] describes a method of computing a similarity metric for phonological segments (this is used to calculate a relative degree of confusability of two segments, which is then compared against English speech error data).

792 syllable

- Mueller, Seymour, Kieras and Meyer[977] defined a phonological similarity metric between two words based on a multidimensional vector of psychologically relevant (they claimed) aspects of dissimilarity. The dimensions along which the metric was calculated included the extent to which the words rhyme, the similarity of their stress patterns, and the degree to which their syllable onsets match.

792 phonology
792 syllable

- Lutz and Greene[879] describe a system that attempts to predict probable pronunciations of personal names based on language-specific orthographic rule sets. This information was used to automatically measure the phonological similarity between a name and potential matches in a database.

5.3.2 Letter sequences

Learning to read teaches people a method for mapping certain sequences of letters to sounds. Many adults have had so much practice performing this mapping task that it has become so automatic for very many sequences that the sound is heard rather than the letters seen.

A study by Lambert, Donderi, and Senders[800] asked each subject to classify 70 drug names, based on the individuals own criteria, by similarity. The results showed little correlation between these subjects' classification and a similarity measure based on counting letter trigrams common to each pair of drug names.

A study by Conrad[269] visually presented subjects with six consonants, one at a time. After seeing all the letters, subjects had to write down the recalled letters in order. An analysis of errors involving letter pairs (see Table 792.17) found that acoustic similarity (AS) was a significant factor.

Table 792.17: Classification of recall errors for acoustically similar (AS), acoustically dissimilar (AD) pairs of letters. *Semi-transpose* refers to the case where, for instance, *PB* is presented and *BV* is recalled (where *V* does not appear in the list). *Other* refers to the case where pairs are both replaced by completely different letters. Adapted from Conrad.[269]

Number Intervening Letters	Transpose (AS)	Semi-transpose (AS)	Other (AS)	Transpose (AD)	Semi-transpose (AD)	Other (AD)	Total
0	797	446	130	157	252	207	1,989
1	140	112	34	13	33	76	408
2	31	23	16	2	18	56	146
3	12	20	12	1	5	23	73
4	0	4	1	0	2	7	14
Total	890	605	193	173	310	369	2,630

5.3.3 Word sequences

As the following studies show, people recall fewer words from a list containing similar sounding words than dissimilar sounding words. The feature-based model of immediate memory[991] explains the loss of information from short-term memory in terms of interference between the items being remembered rather than their memory traces decaying over time. This model predicts that similar sounding words will interfere with each other more than dissimilar sounding words (it also accounts for the recency effect and temporal grouping). A subsequent enhancement to the model[1000] enabled it to account for the word-length effect (memory performance is worse for items that take longer to pronounce).

- A study by Baddeley[73] dramatically showed the effects of acoustic similarity on recall performance from short-term memory. Subjects were visually presented with either a list of acoustically similar words (e.g., *man*, *cab*, *can*, *cad*, *cap*, *mad*, *map*, etc.), or a list of words that were not acoustically similar (e.g., *few*, *pit*, *cow*, *pen*, *bar*, *hot*, *bun*, etc.). After a delay of zero, four, or eight seconds, during which they had to write down digits that were slowly read to them, they had to write down the presented word list. The results (see Figure 792.22) show the significant impact acoustic similarity can have on recall performance.
- A study by Daneman and Stainton[315] asked subjects to carefully read a passage (subjects were given a comprehension test) and proofread it for spelling errors. The spelling errors were either homophones (e.g., *meet* replaced by *meat*) or not (e.g., *meet* replaced by *meek*). Homophone misspellings were less likely to be detected than the non-homophone ones. A study by Van Orden[1403] asked subjects to make a semantic category decision on a visually presented word. For instance, they were told "answer yes/no if the word is a flower" and presented with either *ROSE*, *ROWS*, or *ROBS*. The results showed that subjects were significantly more likely to answer yes to words that were homophones of words that were members of the category.

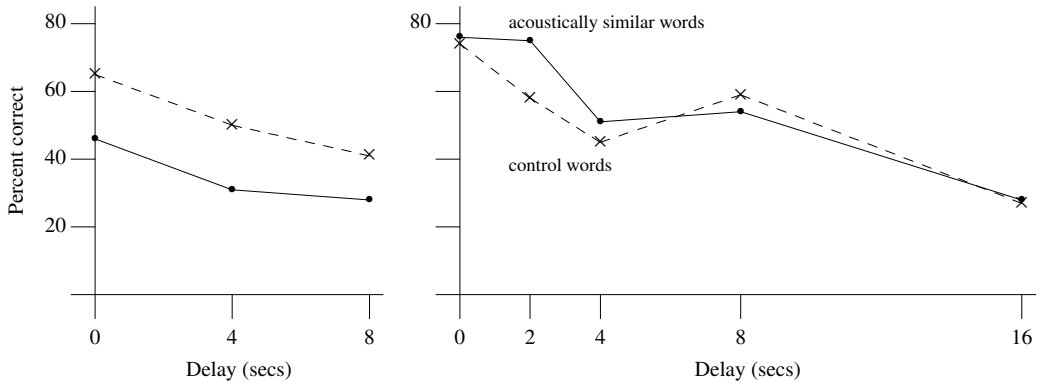

Figure 792.22: Rate of forgetting of visually presented lists of four words containing the same (solid line) or different vowels (dashed line); left graph. Rate for two lists, one containing three acoustically similar words (solid line) and the other five control words (dashed line); right graph. Adapted from Baddeley.[73]

- People do not always say the word they intended to speak. Two well-known kinds of mistake are: (1) *malapropisms*, using a word that has a similar sound but a different meaning ("the geometry of contagious countries"), and (2) *spoonerisms*, the transposition of syllables between two words (*blushing crow* instead of *crushing blow*). A study by Fay and Cutler[413] located 183 malapropisms in a collection of more than 2,000 speech errors. They found that in 99% of cases the target and erroneous word were in the same grammatical category, in 87% of cases they contained the same number of syllables, and in 98% of cases they shared the same stress pattern. 792 Spoonerisms

- *Silent* letters. Early studies[283] suggested that silent letters (i.e., not pronounced) in a word were more likely to be go unnoticed (i.e., their misspelling not detected in a proofreading task) than letters that were pronounced. Later studies[369] showed that the greater number of search errors occurred for high-frequency function words (e.g., *the*), not for content words. The search errors were occurring because of the high-frequency and semantic role played by the word, not because letters were either silent or pronounced.

- A study by Coltheart[261] found that it did not matter whether the same, visually presented, words were used on each memory trial, or different words were used every time; recall of similar sounding words was significantly lower (62–69% vs. 83–95% when recall in the correct order was required, and 77% vs. 85–96% when order-independent recall was required).

5.4 Semantic confusability

Identifier semantic confusability

Developers often intend identifier names to convey semantic information about what an identifier represents. Because of the small number of characters that are usually used, the amount of semantic information that can be explicitly specified in the name is severely limited. For this reason developers make assumptions (usually implicitly) about knowledge they share with subsequent readers. Semantic confusion occurs when a reader of the source does not meet the shared knowledge assumptions made by the creator of the identifier name.

This coding guideline section does not make any recommendations relating to semantic confusability. Given the extent to which people implicitly treat their own culture as *natural*, it is difficult to see how even detailed code reviews can reliably be expected to highlight culturally specific identifier naming assumptions made by project team members. However, the following subsections attempt to give a flavor of some of the possible confusions that might occur; the issues covered include natural language, metaphor, and category formation. 0 code reviews 792 Metaphor

This subsection primarily covers the issue from the perspective of a trying to minimise the confusion a developer may have over the semantics that might be associated with an identifier. It is possible for the

semantics associated with an identifier to be clear to a reader, but for a mistake made by the original author to cause that reader to make an incorrect decision.

operand name context

A study by Jones[686] asked subjects to parenthesize an expression, containing two binary operators, to reflect the relative precedence of the operators. The name of the middle operand was chosen to suggest that it bound to one of the operators (either the correct or incorrect one). For instance, in `a+flags&c` a reader may be influenced to believe (incorrectly) that `flags` is ANDed with `c` and the result added to `a`. The results showed that when the name of the operand matched the context of the correct operator, 76.3% of answers were correct; when the name of the operand matched the context of the incorrect operator, 43.4% of answers were correct.

5.4.1 Language

human language characteristics 792

Natural language issues such as word order, the use of suffixes and prefixes, and ways of expressing relationships, are discussed elsewhere.

In written prose, use of a word that has more than one possible meaning, *polysemy*, can usually be disambiguated by information provided by its surrounding context. The contexts in which an identifier, containing a polysemous word, occur may not provide enough information to disambiguate the intended meaning. The discussion on English prepositions provides some examples.

Prepositions 792

5.4.1.1 Word neighborhood

neighborhood identifier 792

Word neighborhood effects have been found in a number of contexts. They occur because of similarities between words that are familiar to a reader. The amount of familiarity needed with a word before it causes a neighborhood effect is not known. Studies have found that some specialist words used by people working in various fields show frequency effects. The study described next shows a word neighborhood effect— the incorrect identification of drug names.[792.13]

words domain knowledge 792

A study by Lambert, Chang, and Gupta[799] investigated drug name confusion errors. Drug names and their U.S. prescription rates were used, the assumption being that prescription rate is a good measure of the number of times subjects (forty-five licensed, practicing pharmacists) have encountered the drug name. Subjects saw a drug name for three seconds and were then asked to identify the name. The image containing each name had been degraded to a level comparable to that of a typewritten name received through a fax machine with a dirty print cartridge that was running out of ink.

The results found that each subject incorrectly identified 97 of 160 drug names (the degraded image of the drug name being responsible for the very high error rate of 60.6%). Both the frequency of occurrence of drug names and their neighborhood density were found to be significant factors in the error rate (see Figure 792.23). Neighborhood frequency was not a significant factor.

neighborhood identifier 792

An analysis of the kinds of errors made found that 234 were omission errors and 4,128 were substitution errors. In the case of the substitution errors, 63.5% were names of other drugs (e.g., *Indocin*® instead of *Indomed*®), with the remaining substitution errors being spelling-related or other non-drug responses (e.g., *Catapress* instead of *Catapres*®). Figure 792.24 shows the number of substitution errors having a given edit distance from the correct response.

All character sequences ever encountered by a reader can potentially have a word-frequency effect. The character sequences most familiar to developers are those of their native language.

6 Usability

identifier usability

Identifier usability is in the eye (and life experienced mind) of the beholder. The original author of the source, subsequent maintainers of that source, and the managers responsible for products built from the source are likely to have different reasons for reading the source and resources (time and past experience) available to them. Cognitive effort minimization and speed/accuracy trade-offs are assumed to play an important role in identifier usability. As well as discussing visual, acoustic, and semantic factors, this subsection also covers

identifier developer interaction 792

cognitive effort 0

effort vs. accuracy decision making 0

[792.13] Errors involving medication kill one person every day in the U.S., and injure more than one million every year; confusion between drug names that look and sound alike account for 15% to 25% of reported medication errors.

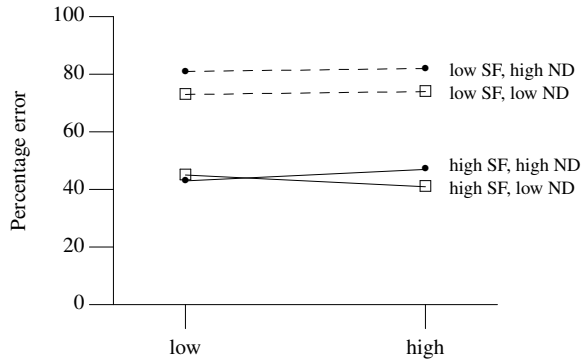

Figure 792.23: Error rate at low and high neighborhood frequency. Stimulus (drug name) frequency (SF), neighborhood density (ND). Adapted from Lambert, Chang, and Gupta.[799]

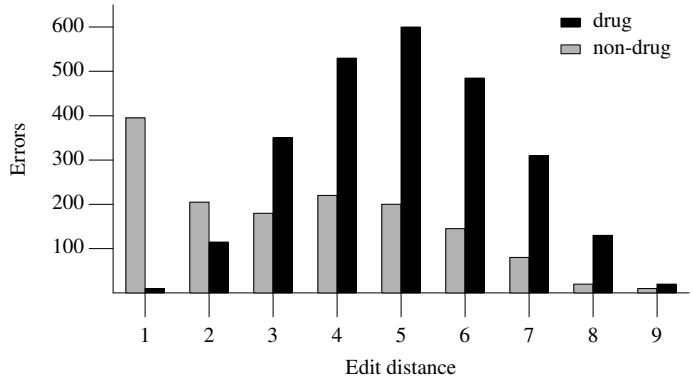

Figure 792.24: Number of substitution errors having a given edit distance from the correct response. Grey bars denote non-drug-name responses, while black bars denote responses that are known drug names. Based on Lambert, Chang, and Gupta.[799]

the use of cognitive resources, initial implementation versus maintenance costs (an issue common to all coding guideline), and typing.

0 coding guidelines importance

Management may show an interest in the spelling used for identifiers for a number of reasons. These reasons, which are not discussed further here, include:

- Some vendors provide interfaces via callable functions or accessible objects, making the names of identifiers visible to potentially millions of developers. Or, a company may maintain internal libraries that are used across many development projects (a likely visibility in the hundreds or perhaps low thousands of developers, rather than millions). In this case customer relation issues are often the most significant factor in how identifier spellings are chosen.
- Project control (or at least the appearance of), often involves the creation of identifier naming guideline documents, which are discussed elsewhere. Other forms of project control are code reviews. These reviews can affect identifier naming in code whether it is reviewed or not, people often use a different decision strategy when they know others will be evaluating their choice.

792 identifier other guideline documents
0 code reviews
0 justifying decisions

6.1 C language considerations

For the majority of identifiers, scope is the most important attribute in deciding their usage patterns:

400 scope

- *local scope.* This is the most common form of identifier usage, both in terms of number of identifiers defined (see Table 439.1) and number of occurrences in the visible source of function definitions.

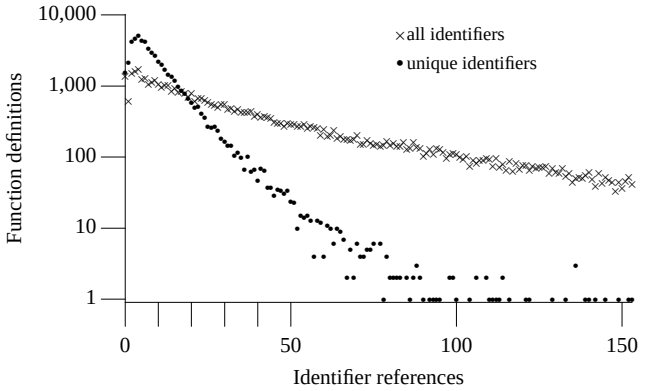

Figure 792.25: Number of identifiers referenced within individual function definitions. Based on the translated form of this book's benchmark programs.

Individual identifier usage is restricted to a relatively small subset of the source code. It is possible for local identifiers in different parts of the source code to share the same name, yet refer to different entities. Identifiers in local scope can be used and then forgotten about. Individually these identifiers may only be seen by a small number of developers, compared to those at global scope.

- *global scope.* While use of this kind of identifier may be restricted to a single source file, it often extends to the entire source code of a program. While, on average, they may be individually referenced more often than individual local identifiers, these references tend to be more widely scattered throughout the source code. Although it may be possible to use and then forget about some identifiers at global scope, it is much more likely that they will need to be recalled, or recognized, across a wider range of program source. They are also much more likely to be used by all the developers working on a project.
- *header file contents.* Over time developers are likely to learn the names of identifiers that appear in included headers. Only identifiers appearing in the most frequently read functions will be familiar. In the early stages of learning about a function, developers are likely to think of identifiers in terms of their spelling; they have yet to make automate the jump to their semantic meaning. How does this impact a reader's analysis of expressions and sequences of statements? It is likely that while being analyzed their component parts will be held in short-term memory.

expressions 940

The majority of references to identifiers occur within expressions and most declarations declare identifiers to be objects (see Table 439.1).

6.2 Use of cognitive resources

identifier cognitive resource usage
attention 0
cogni- 0
tive effort
developer 0
differences

The cognitive resources available to developers are limited. An important aspect of usability is making the optimum use of the available cognitive resources of a reader. Overloading the available resources can lead to a significant increase in the number of errors made.

Different people have different amounts of cognitive resources at their disposal. A general discussion of this issue is given elsewhere. This subsection discusses people's cognitive performance characteristics from the perspective of processing character sequences. While recognizing that differences exist, it does not discuss them further.

A study by Hunt, Lunneborg, and Lewis[608] investigated various performance differences between subjects classified as either *low verbal* or *high verbal*. The Washington Pre-College Test was used to measure verbal ability (a test similar to the Scholastic Achievement Test, SAT). In a number of experiments there was a significant performance difference between low and high verbal subjects. In some cases, differences in performance were only significant when the tests involved existing well-learned patterns. For instance, high

verbals performed significantly better than low verbals in remembering written sequences of syllables when the sequences followed English usage patterns; the performance difference was not very large when nonsense syllable sequences were used.

6.2.1 Resource minimization

identifier resource minimization
0 automatization

Minimizing the amount of resources needed to accomplish some goal is an implicit, if not explicit, human aim in most situations. Studies have found that individuals and groups of people often minimize their use of resources implicitly, without conscious effort.

792 identifier developer interaction
0 developer differences

In the context of this coding guideline resource minimization is a complex issue. The ways in which developers interact with identifiers can vary, as can the abilities (resources available) to individual developers, and management requirements target particular developers (e.g., having certain levels of experience with the source, or having particular cultural backgrounds).

Zipf's law

Zipf noticed a relationship between the frequency of occurrence of some construct, created by some operation performed by people, and the effort needed to perform them. He proposed an explanation based on the principle of least effort. What has become known as Zipf's law[1514] states a relationship between the rank and frequency of occurrence of some construct or behavior. Perhaps its most famous instantiation relates to words, $r = C/f_r$— where r is 1 for the most frequently occurring word, 2 for the second most frequently occurring, and so on; f_r is the number of times the word of rank r occurs; and C is a constant. According to this law, the second most common word occurs half as many times as the most commonly occurring word (in English this is *the*), the third most common occurs $2/3$ times as often as the second most common, and so on.

Zipf's law has been found to provide a good approximation to many situations involving a cost/effort trade-off among different items that occur with varying degrees of frequency. Further empirical studies[1115] of word usage and theoretical analyses have refined and extended Zipf's original formulation.

However, while it is possible to deduce an inverse power law relationship between frequency and rank (Zipf's law) from the principle of least effort, it cannot be assumed that any distribution following this law is driven by this principle. An analysis by Li[853] showed that words in randomly generated texts (each letter, including the space character, being randomly selected) exhibit a Zipf's law like frequency distribution.

The relatively limited selection pressure on identifier spelling (the continued existence of source code does not depend on the spelling of the identifiers it contains and developers are rarely judged by the identifier spelling they create) does not necessarily mean that identifier spellings don't evolve. A study by Kirby[738] found that languages can evolve simply through the dynamics of learning, no selection of learners (i.e., killing off those that fail to reach some minimum fitness criteria) is needed.

A plot of the rank against frequency of identifier spellings (see Figure 792.26) shows a good approximation to a straight line (the result expected from measuring behavior following Zipf's law). Your author cannot provide a reasonable explanation for this behavior.[792.14]

6.2.2 Rate of information extraction

identifier information extraction
0 developer computational power

Reading a character sequence requires identifying each of the characters. The results of a study by Miller et al. found that the amount of information, about a nonword, recalled by subjects was approximately proportional to the time interval it was visible to them. However, the unit of perception used by subjects was not the character. Subjects made use of their knowledge of native language character ordering relationships to chunk sequences of characters into larger perceptual units. A number of studies have suggested various candidates (e.g., syllables, graphemes) for the perceptual reading unit, and these are also described here.

A study by Miller, Bruner, and Postman[936] measured the amount of information subjects remembered about a briefly presented nonword. The nonwords were constructed so as to have different orders of approximation to existing English words (see Table 792.18). Subjects saw a single nonword for a duration of 10, 20, 40, 100, 200, or 500 ms. They then had to write down the letters seen and their position in the nonword (using an answer sheet containing eight blank squares).

[792.14] An explanation for why a ranking of cities by their population follows Zipf's law has been provided by Gabaix,[465] who showed it to be a statistical consequence of individual city population growth following Gibrat's law.

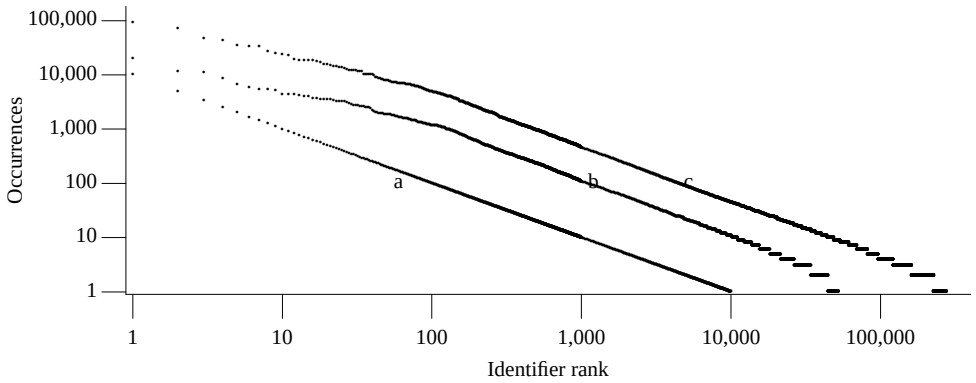

Figure 792.26: Identifier rank (based on frequency of occurrence of identifiers having a particular spelling) plotted against the number of occurrences of the identifier in the visible source of (b) Mozilla, and (c) Linux 2.4 kernel; (a) is a distribution following Zipf's law with the most common item occurring 10,000 times. Every identifier is represented by a dot. Also see Figure 1896.4.

Table 792.18: Examples of nonwords. The 0-order words were created by randomly selecting a sequence of equally probable letters, the 1-order words by weighting the random selection according to the probability of letters found in English words, the 2-order words by weighting the random selection according to the probability of a particular letter following the previous letter in the nonword (for English words), and so on. Adapted from Miller[936]).

0-order	1-order	2-order	4-order
YRULPZOC	STANUGOP	WALLYLOF	RICANING
OZHGPMTJ	VTYEHULO	RGERARES	VERNALIT
DLEGQMNW	EINOAASE	CHEVADNE	MOSSIANT
GFUJXZAQ	IYDEWAKN	NERMBLIM	POKERSON
WXPAUJVB	RPITCQET	ONESTEVA	ONETICUL
VQWVBIFX	OMNTOHCH	ACOSUNST	ATEDITOL
CVGJCDHM	DNEHHSNO	SERRRTHE	APHYSTER
MFRSIWZE	RSEMPOIN	ROCEDERT	TERVALLE

The results (see Figure 792.27) show a consistent difference among the order of approximation for all presentation times. Miller et al. proposed that subjects had a fixed rate of information intake. The performance difference occurred because the higher-order letter sequences had a lower information content for the English language speaking subjects. Had the subjects not been native English speakers, but Japanese speakers for instance, they would have had no knowledge of English letter frequency and the higher-order letter sequences would have contained just as much information as the lower-order ones.

This study (reproduced by Baddeley[74] using spoken rather than visual presentation of letters) shows that developers will need more time to process identifier spellings having a character sequence frequency distribution that does not follow that of their native language. In those cases where source is quickly scanned, a greater number of characters in a sequence (and their positions) are available for recall if they have frequency distribution of the readers' native language.

If individual characters are not the unit of perception and recall used by readers when processing words, what is? The following are a number of proposals:

- A study by Spoehr and Smith[1272] asked subjects to identify some of the letters in a briefly presented letter sequence (the subjects did not know which letters until after they had seen the letter sequence). The results showed that subjects' perceptual accuracy for a word is correlated with the number of recoding steps needed to convert it into speech. For instance, the letter sequences *LSTB*, *BLST*, *BLOST*, and *BLAST* are a sequence not matching English rules, matching English rules but omitting a vowel, a pronounceable nonword, and a word, respectively. They are reproduced correctly in 66%, 70%, 78%, and 82% of cases, respectively. The results are consistent with the letters of a word first being parsed

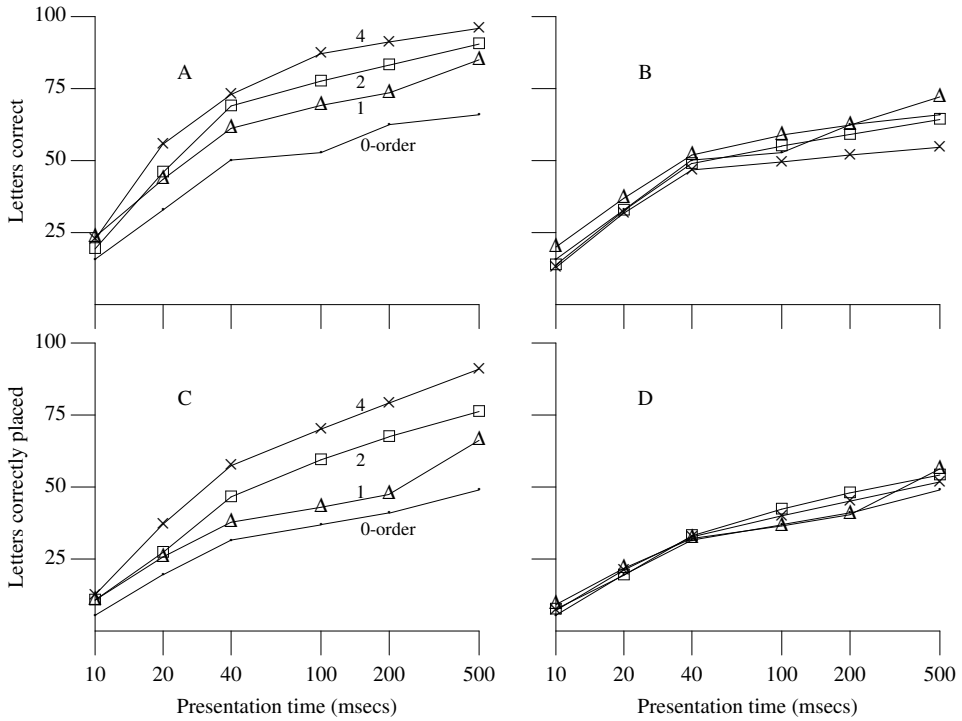

Figure 792.27: Number of correct letters regardless of position (A), and number of correct letters placed in the correct position (C). Normalizing for information content, the corresponding results are (B) and (D), respectively. Plotted lines denote 0-, 1-, 2-, and 4-order approximations to English words (see Table 792.18). Adapted from Miller, Bruner, and Postman.[936]

into syllables.

- A study by Rey, Ziegler, and Jacobs[1160] asked subjects (English and French, using their respective native language) to specify whether a letter was contained within a briefly displayed word. The results found that the response time was longer when the searched for letter was contained within a multi-letter grapheme (phoneme similarity was taken into account). These results are consistent with graphemes being the perceptual reading unit.

792 grapheme

6.2.3 Wordlikeness

The extent to which a nonword is similar to words belonging to a particular natural language is called its *wordlikeness*. Wordlikeness is a cognitive resource in that it represents a person's accumulated reading experience. Wordlikeness has a strong influence on how quickly and accurately nonwords are processed in a variety of tasks.

identifier wordlikeness

How is *wordlikeness* measured? Coleman and Pierrehumbert[253] trained a general phonological word grammar on a list of English words whose phonology was known. The result was a grammar whose transition probabilities correspond to those of English words. This grammar was used to generate a list of letter sequences and subjects were asked to judge their *wordlikeness*. The results showed that the log probability of the phonological rules used in the generation of the complete letter sequence had a high correlation with subjects' judgment of wordlikeness. A study by Frisch, Large, and Pisoni[455] replicated and extended these results.

792 phonology

A number of studies have found differences in people's performance in tasks involving words or nonwords, including:

word nonword effects

- *Visual comparison of words and nonwords.* Studies of performance in comparing two-letter sequences

792 character sequence similarity

have found that response time is faster when the letter sequence represents a word rather than a nonword.

- *Naming latency.* A study by Weekes[1451] found that naming latency for high-frequency words was not significantly affected by the number of letters (between three and six), had some affect for low-frequency words, and had a significant affect for nonwords (this study differed from earlier ones in ensuring that number of phonemes, neighborhood size, bigram frequencies, and other linguistic factors were kept the same). The error rate was not found to vary with number of letters.
- *Short-term memory span.* A study by Hulme, Maughan, and Brown[606] found that subjects could hold more words in short-term memory than nonwords. Fitting a straight line to the results, they obtained:

$$word\ span = 2.4 + 2.05 * speech\ rate \quad (792.1)$$

$$nonword\ span = 0.7 + 2.27 * speech\ rate \quad (792.2)$$

They concluded that information held in long-term memory made a contribution to the short-term memory span of that information.

Wordlikeness may involve more than using character sequences that have an n-th order approximation to the target language. For instance, readers of English have been found to be sensitive to the positional frequency of letters within a word.[902] Using an averaged count of letter digram and trigram frequencies[1265] to create nonwords does not always yield accurate approximations. Positional information of the letters within the word[1266] needs to be taken into account.

Experience shows that over time developers learn to recognize the *style* of identifier spellings used by individuals, or development groups. Like the ability to recognize the *wordlikeness* of character sequences, this is another example of implicit learning. While studies have found that training in a given application domain affects people's performance with words associated with that domain, how learning to recognize an identifier naming *style* affects reader performance is not known.

6.2.4 Memory capacity limits

identifier
STM required

This subsection discusses short-term memory limitations. Long-term memory limitations are an indirect cause of some of the usability issues discussed under other subsection headings in this usability section. The issue of some identifiers being available in LTM, or migrating to LTM during the process of comprehending source code, is not considered further here.

memory 0
developer
phonological loop

Short-term memory has a number of components, each having different capacity characteristics. The one of immediate interest here is the phonological loop, that is capable of holding approximately two seconds of sound.

Identifiers appear in a number of different source code constructs, most commonly in expressions (the contents of comments are not considered here). When reading an expression, the identifiers it contains are components of a larger whole. One method of reducing the possibility of readers exceeding their short-term memory limit when attempting to comprehend expressions is to minimize the time taken to say (the internal spoken form in a persons head) each identifier. However, short-term memory capacity is not always the main consideration in selecting an identifier spelling.

optimal 792
spelling
identifier

Measuring the amount of time occupied by the verbal form of a word in short-term memory is a nontrivial task[977] (e.g., is it the time taken to say the word in isolation, say the same word repeatedly, or say the word in the context of a list of other words; where *say* is the form spoken internally in the mind, not the spoken form that vibrates the air and can be heard by others).

Calculating the short-term memory requirements needed to hold information on words represented using a logographic writing system is more complicated than for alphabetic writing systems. A study by Hue and Erickson[603] found that literate Chinese subjects represented frequently occurring Chinese characters in verbal form, while low frequency characters were held in visual form.

logographic 792

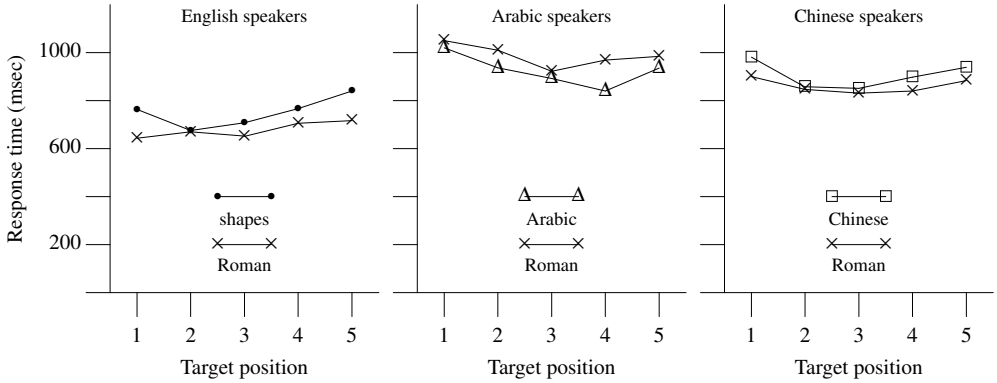

Figure 792.28: Mean response time (in milliseconds) for correct target detection as a function of the position of the match within the character sequence. Adapted from Green and Meara.[518]

6.3 Visual usability

The three main, identifier-related visual operations performed by developers— detailed reading, skimming, and searching — are discussed in the following subsections. The first subsection discusses some of the visual factors involved in extracting information from individual words. The general subject of human visual processing is discussed elsewhere.

770 vision early

6.3.1 Looking at a character sequence

In what order do people process an individual word? Do they start at the leftmost character and move their eyes successively to the right? Do they look at the middle of the word first and progressively work outwards? Do they look at the start and end of the word first, before looking at the rest of the word, or some other order of processing the character sequence?

- A study by Green and Meara[518] investigated the effects of orthography on visual search. Subjects (native English, Spanish, Arabic, or Chinese speakers) were asked to search for a character (Roman letter, Arabic character, or Chinese logograph) in a sequence of five characters (of the same kind). None of the results showed any trade-off between speed and accuracy (which varied between 5–8%). The results (see Figure 792.28) for English and Spanish speakers were very similar— an upward sloping *M* response curve when searching letters and a *U* response curve when searching shapes (with the response slowing as the match position moves to the right). For Arabic speakers there was a *U* response curve for both Arabic and Roman characters (with the response slowing as the match position moved to the left; Arabic is read right-to-left). For Chinese speakers there was a *U* response curve for both Chinese and Roman characters (there was no left or right position dependency).

  792 orthography

  An earlier study[519] comparing the performance of English children and adults found that performance improved with age and that left-to-right processing became more established with age.

- A study by Chitiri and Willows[230] compared how readers of English and Greek paid attention to different parts of a word. Greek primarily uses inflections to denote semantic and syntactic relationships. For instance, one or more characters at the end of a noun can indicate gender, number (singular, plural), and the case (nominative, genitive, accusative, vocative). These letters at the end of a word carry important information, and it is to be expected that experienced readers of Greek will have learned to pay more attention to the ends of words than readers of languages that are not so inflective, such as English. The results showed that Greek readers tended to pay more attention to the ends of words than English readers.

  identifiers Greek readers

- A study by James and Smith[664] asked subjects to search a string of letters for a designated letter. The results showed that for words, in certain cases, vowels were located more quickly than consonants

(there was no difference in performance for nonwords). It was proposed that the difference in performance was caused by the position of vowels in words being more predictable than consonants in English. Subjects were using their knowledge of English spelling to improve their search performance. Searching words in all uppercase or all lowercase did not affect the results.[663]

- A review by Lukatela and Turvey[873] discussed research involving Serbo-Croatian readers. This language has two alphabets, one based on a Cyrillic alphabet and the other on a Roman one, and before the breakup of Yugoslavia schoolchildren in the eastern half of the country learned the Cyrillic alphabet first, followed by the Roman; this order was reversed for schoolchildren in the western half of the country. Some letters were common to both alphabets but had different pronunciations in each. For instance, *potop* could be pronounced */potop/*, */rotop/*, */potor/*, or */rotor/* (two of which represented words— *deluge* in the Roman form, or *rotor* in the Cyrillic form).

- A study by Herdman, Chernecki, and Norris[566] measured subjects' response time and error rate when naming words presented in either lowercase or cAsE aLtErNaTeD form. The words also varied in being either high/low frequency or having regular/irregular spellings. Case alternation slowed response time by approximately 10%. However, it almost doubled the error rate for regularly spelled words (1.8% vs. 3.5% for high-frequency and 5.3% vs. 8.5% for low-frequency) compared to use of lowercase. The cAsE aLtErNaTiOn used in this study is probably more extreme than that usually seen in identifier spellings. As such, it might be considered an upper bound on the performance degradation to be expected when case alternation is used in identifier spelling. A study by Pring[1124] investigated subjects' performance when presented with words using different case. Subjects saw letter sequences such as *CHurCH* and *ChuRCH*. The results showed an increase in error rate (4.4% vs. 2.7%) when a difference in case occurred across grapheme boundaries (a British English speaker might divide *CHURCH* into the graphemes *CH*, *UR*, and *CH*). No difference was found in the error rate for nonwords.

grapheme 792

6.3.2 Detailed reading

Several studies[733] have found that people read prose written using lowercase letters more quickly (approximately 7%) than prose written using uppercase letters. There are a number of reasons for this, including: (1) when proportional spacing is used, a greater number of lowercase characters, compared to uppercase, fall within the visual field allowing larger chunks to be processed per saccade;[108] (2) words appearing in lowercase have a more distinctive shape to them, which is information that enables readers to make more accurate guesses about the identity of a word; and (3) readers have had more practice reading lowercase.

Studies of subjects' eye movements while reading have found that irregular or salient letter sequences at the beginning of a word[610, 1431] cause the eye's initial landing position to be closer to the beginning of the word. However, the initial landing position was not affected by having the salient letters (those needed to disambiguate a word from other words) in the second half of a long word (Finnish words containing 10 to 13 characters).[611] Both of these findings are consistent with the Mr. Chips model of eye movement. Word predictability has been found to have little influence on the initial landing position.[1148]

Mr. Chips 770

There are many differences between reading prose and reading source code. For instance, prose often has a narrative style that allows readers to progress through the material sequentially, while source code rarely has a narrative type and readers frequently have to refer back to previously read material. Whether these constant interruptions reduce the performance advantage of lowercase letters is not known. The extent to which any of these letter–case performance factors affect source code reading performance is not known.

6.3.3 Visual skimming

visual skimming

The number of characters in each identifier that appear in the visible source affects the visual appearance of any construct that contains it. As Figure 792.29 shows, the use of relatively long identifiers can affect the visual layout of constructs that reference them. The layout issues associated with this kind of usage are discussed elsewhere.

expression 940 visual layout
declaration 1348 visual layout
statement 1707 visual layout

```
#include <string.h>

#define MAXIMUM_CUSTOMER_NUMBER_LENGTH 13
#define VALID_CUSTOMER_NUMBER           0

   for (customer_number_index=0; customer_number_index < customer_number_length; customer_number_index++)
      {
      if ((possibly_valid_customer_number[customer_number_index] < '0') ||
          (possibly_valid_customer_number[customer_number_index] > '9'))
         {
         *customer_number_status=INVALID_CUSTOMER_NUMBER;
         }
      }
   }
}
```

Figure 792.29: Example of identifier spellings containing lots of characters. Based on an example from Laitinen.[795]

6.3.4 Visual search

identifier visual search

The commonly chosen, by readers, method of locating occurrences of an identifier in the code visible on a display is visual search. Given such behavior, visual search usability might be defined in terms of selecting an identifier spelling that minimize the probability of a search failing to locate an instance of the searched-for target identifier, or incorrectly classifying an instance as the target.

While there have been a considerable number of studies[1046] investigating visual search, most have involved searching for objects of different shapes and colors rather than words.

Visually source code appears as an ordered sequence of lines. In many cases a complete declaration or statement appears on a single line. The reason for searching the source and the kind of information required can affect what is considered to be the best search strategy; for instance, skimming the characters in a similar order to the one used during detailed reading, scanning down the left edge of the source looking for an assigned-to object, or looking at conditional expressions to see where an object is tested. Your author does not know of any studies that have investigated this issue. The following discussion therefore has to been based primarily on studies using character sequences from other task domains:

- A study by Vartabedian[1412] investigated search times for words presented on a CRT display. Subjects were asked to locate a word among a list of 27 words (either all lowercase or all uppercase) arranged as three columns of nine rows (not forming any meaningful phrases or sentences). The average search time was less (approximately 13%) for the uppercase words.
- A study by Phillips[1084] investigated the effect of letter case in searching for words on paper maps. The results showed that performance was best when the words consisted of an uppercase letter followed by lowercase letters (all uppercase resulted in the worst performance). A second study[1085] investigated the eye fixations used in searching for words in maplike visual displays. The order in which subjects fixated words and the duration of the fixation was measured. The visual similarity between the word

being searched for and the other words was varied (e.g., common initial letter, same word shape based on ascenders and descenders, and word length). The results showed that differences in these visual attributes did not affect eye movements— subjects tended to fixate a word, then a word close to it, and so on. (Some subjects worked from the top-down in a zigzag fashion, others worked clockwise or anti-clockwise around the display.) The duration of the fixation was affected by the similarity of the word being searched for. Objects of similar size and color to words were fixated less often than words, unless the resemblance was very close.

- A study by Flowers and Lohr[431] asked subjects to search for words consisting of either familiar English three-letter words or nonword trigrams with similar features in a display. The time taken, and error rate, for subjects to specify whether a word was or was not present in a display was measured. Distractor words with high similarity to the searched-for word were created by permuting the letters in that word (e.g., *BOY*, *BYO*, *OBY*, *OYB*, and *YBO*). Medium-similarity distractor words contained one letter that was the same as the searched-for word and low-similarity shared no letters. The results showed a significant difference in speed of search with high-similarity nonword distractors. In this case word searches were 30% to 50% faster than nonword searches. This performance difference dropped to 10% to 20% when the distractors were medium-similarity nonwords. There was little difference in performance when the distractors had low similarity or were words. The error rates were not found to be dependent on the distractors.

- A study by Karlin and Bower[713] investigated whether subjects could categorize a word semantically before they precisely identified the word. The time taken and error rate for subjects to specify whether a word was or was not present in a display was measured. The searched-for word either belonged to the same category as the other words displayed, or to a different category. For instance, the name of a color, say *PINK*, might be displayed with the names of other colors or the names of trees. The results showed that as the number of distractor words increased subjects increased their use of category information to improve search time performance (searching for a word in a different category was nearly a third faster when searching among six items than when it was in the same category). The error rates were not found to be category-dependent. Karlin and Bower proposed that comparison involved two kinds of tests, performed in parallel— a categorization test and a perceptual feature test. In those cases where a comparison requires a lot of perceptual resources because two items are perceptually similar, the categorization test may complete first. Flowers and Lohr explained their results in terms of categories, words, and nonwords. Searching for a word amongst nonword distractors that share the same letters imposes a high perceptual load because of overlap of features, and the categorization comparison completes first. When the distractors share a single letter, the difference is less pronounced.

When searching for an identifier, it is possible that mistakes will be made (either failing to locate an identifier that is present, or incorrectly matching the wrong identifier). The issue of identifier confusability is discussed elsewhere.

identifier confusability 792

6.4 Acoustic usability

A number of factors contribute toward the acoustic usability of a character sequence. Memory and confusability acoustic factors are discussed in earlier subsections. Here, generating a pronunciation for a character sequence and meanings suggested by sounds (phonetic symbolism) are discussed.

phoneme 792

Phonological codes (the basic sounds of a language) have been found to play an important role in accessing the semantic information associated with words written in nonlogographic scripts (some researchers believe they are obligatory,[433, 1403] while others believe there is a single mechanism, e.g., connectionist models[1094]). It was once thought that, because of their pictorial nature, logographs did not evoke phonological codes in readers. Studies[1330] have found that phonographic codes also play a role in reading logographic scripts.

logographic 792

6.4.1 Pronounceability

word pronounceability

All character sequences can be pronounced in that the individual characters can be pronounced one at a time.

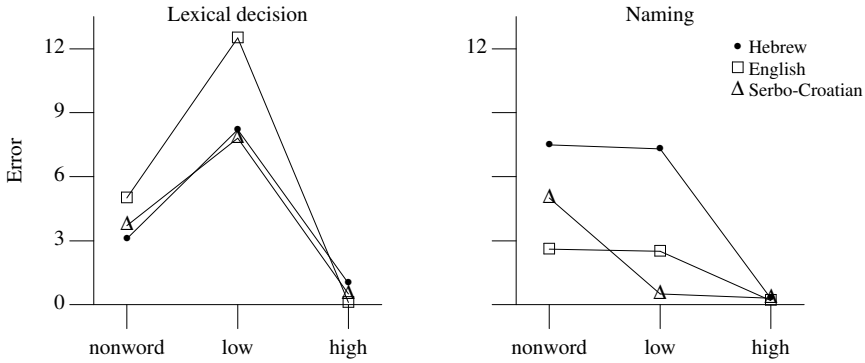

Figure 792.30: Error (as a percentage of responses) for naming and lexical decision tasks in Hebrew, English, and Serbo-Croatian using high/low frequency words and nonwords. Adapted from Frost, Katz, and Bentin.[457]

The term *pronounceable* is commonly applied to character sequences that are wordlike and can be converted to a spoken form using the grapheme-to-phoneme conventions of a natural language familiar to the reader. In some languages (e.g., Japanese kana and Greek) virtually any combination of characters is pronounceable. This is because each character represents an individual sound that is not significantly affected by adjacent the characters.

792 identifier wordlikeness

'Twas brillig, and the slithy toves Did gyre and gimble in the wabe: All mimsy were the borogoves, And the mome raths outgrabe. Lewis Carroll

In this subsection pronounceability is measured in terms of the ease with which a reader is able to convert a sequence of characters to a spoken form (pronounceability could also be defined in terms of minimizing information content). Whether the spoken form used by the reader is the one intended by the author of the source code is not of concern here.

Abbreviating words removes what appear to be redundant characters. However, these characters are needed by readers if they are to recognize the graphemes their prior experience has trained them to expect (unless the reader recognizes the abbreviation and internally uses the word it represents). Abbreviations thus reduce pronounceability.

792 characters mapping to sound
792 identifier information extraction
792 abbreviating identifier

Experience shows that developers use a number of techniques to generate a spoken representation of character sequences. In some cases the sounds of the individual characters are used. In other cases developers mentally add characters (vowels and sometimes consonants) to what would otherwise be a nonpronounceable nonword (for abbreviations this is often the unabbreviated word); the sound used evolves over time, particularly when the character sequence is used in a spoken form between developers. Some developers simply take pleasure in inventing sounds for character sequences.

- A study by Frost, Katz, and Bentin[457] investigated the influence orthographic depth had on visual word recognition. Subjects were native speakers of Hebrew (a very deep orthography), Serbo-Croatian (a very shallow orthography), and English (an orthography somewhere between the two). The tasks involved word naming or making a word/nonword lexical decision and the response times and error rates were measured. The results were consistent with the idea that readers of shallow orthographies generate the pronunciation directly from the words, while for readers of deeper orthographies it is derived from an internal lexicon. The error rates are shown in Figure 792.30

  792 orthography

  Brain imaging studies[1063] have found that Italian speakers (shallow orthography) activate different parts of their brain while reading compared to English speakers (deep orthography).

- A study by Lange and Content[808] analyzed the grapheme-to-phoneme correspondence of French words. (The results confirmed the view that this was quite predictable; phoneme to grapheme correspondence was not analyzed and is considered to be much less predictable.) They then used the results of this analysis to measure French speakers' performance when reading words aloud. The selected words had either low/high grapheme frequency (number of occurrences in the corpse, independent of phoneme mapping) or low/high grapheme entropy (a measure of the number of different phonemes,

and their frequency, a particular grapheme could be mapped to). They found that time to name a word and error rate did not vary significantly with grapheme frequency. However, there was a significant difference in error rate (but not time to name the word) when comparing words with a low/high grapheme entropy. This provided experimental evidence that more naming errors are made for words containing graphemes having many possible pronunciations than those having fewer possible pronunciations.

- A study by Rey, Jacobs, Schmidt-Weigand, and Ziegler[1159] asked subjects to identify words (using matching native English and French words and subjects) containing five letters. These five-letter words contained either three, four, or five phonemes (e.g., for English: TEETH */tiT/*, BLEAT */blit/*, or BLAST */bl#st/* respectively). Subjects' response time and error rate were measured. The results showed that subjects' performance improved (slightly faster response time and decreased error rate) as the number of phonemes increased (except for high-frequency French words). A study by Rastle and Coltheart[1145] found the same behavior for nonwords in both their DRC model of word naming and human subjects. The results from the DRC model suggested that reader expectations were causing the difference in performance. As each letter was successively processed, readers used it and previous letters to create a phoneme. In many cases these phonemes contained a small number of letters (perhaps just one) and readers started processing based on an expected common case. For instance, the letter *P* often represents the phoneme */p*; however, the following letter may create a multi-letter phoneme, and the previous processing on creating a pronunciation needs to be partially undone and processing started again (e.g., when the letter *P* is followed by *H*, the phoneme */f/* needs to be used). In the preceding studies it is not that the five phoneme letter sequences are processed more quickly, but that the three phoneme sequences are significantly slowed by additional cycles of processing, undoing, and reprocessing.

Word recognition 792
models of

- A study by Stanovich and Bauer[1284] showed that the regularity of spelling-to-sound correspondence affected performance; for instance, the regular pronunciation of *_INT* occurs in *MINT*, *HINT*, *DINT*, and an irregular pronunciation in *PINT*. Their study showed that regularity had some impact on the time taken to name a word (552 ms vs. 570 ms) and on a lexical decision task (623 ms vs. 645 ms).
- A study by Stone, Vanhoy, and Orden[1303] showed that not only did spelling-to-sound regularity (feed-forward consistent) affect performance, but sound-to-spelling regularity (feedback consistency) was also a factor. Visual word perception is a two-way street. For instance, the sound */_ip/* can have either of the spellings that occur in *HEAP* and *DEEP*. The results showed, in a lexical decision task, an error rate of 3.9% for feedback-consistent and 9.8% for feedback-inconsistent words. There was no difference in error rate for nonwords.

6.4.1.1 Second language users

The following discussion and studies are based on having English as the second language. The results point to the conclusion that encoding strategies used by a person in their first language are transferred to English. This behavior can result in a different phonological encoding being formed, compared to the set of encodings likely to be used by native English speakers, when an unknown character sequence is encountered. The issue of pronouncing characters unfamiliar to the reader is discussed elsewhere.

phonology 792
reading 792
characters
unknown to reader

- A study by Holm and Dodd[587] investigated how phonological awareness skills acquired while learning to read and write a first language were transferred to learning to read and write a second language. The subjects were students at an Australian university who had first learned to read and write their native language in China, Hong Kong, Vietnam, and Australia. The characters learned by the Chinese and Hong Kong subjects were the same— logographs representing a one-syllable morpheme. The Vietnamese and Australian subjects had been taught using an alphabetic writing system, where a mapping to phonemes existed. As an aid to the teaching of reading and writing, China introduced an alphabetic system using Latin symbols called *pinyin* in 1959. No such system had been used by the subjects from Hong Kong. One of the tasks involved creating spoonerisms from pairs of written

Spoonerisms

words (e.g., *dark ship* ⇒ *shark dip*). This task requires segmenting words based on phonological rules not letter rules. The results of the study showed that the performance of Hong Kong subjects was significantly worse than the other subjects in these kinds of phonological-based tasks. While they were proficient readers and writers of English, they had no ability to associate a written word with its pronunciation sound unless they had previously been told of the association. Holm and Dodd compared the performance of the Hong Kong students with phonological dyslexics that have been documented in the research literature. Interviews with the Chinese subjects found that one of the strategies they used was to "thinking how to write the word in pinyin". Some of the Hong Kong students reported being able to recognize and use written words by looking up their definitions in a dictionary. However, on hearing one of these words in a lecture, they were not able to make the association to the written form they had previously encountered unless they saw it written down (e.g., in the notes written by the student sitting next to them in class). The results of this study showed that for some developers identifier pronounceability is not an issue because they don't pronounce them.

- A study by Koda[754] investigated the impact of subjects' first language (Arabic, English, Japanese, or Spanish; who had had at least six years of English instruction) on their phonological encoding strategies for various kinds of character sequences. Subjects were shown five character sequences followed by a probe (one of the five character sequences). They had to specify which character sequence followed the probe. The character sequences were either phonologically similar English nonwords, phonologically dissimilar but visibly similar English nonwords, unpronounceable sequence of letters, pronounceable Japanese Kanji (logographs that were either visually similar or dissimilar), unpronounceable Japanese Kanji, or Sanskrit (a logography unfamiliar to all subjects). The results showed that subjects, independent of language background, performed better when phonologically dissimilar English pronounceable nonwords were used (phonological similarity causes interference in working memory) and the performance of Japanese subjects was not significantly affected by the use of unpronounceable English nonwords. The results from the Japanese lists showed that performance among the three non-Japanese subjects did not differ significantly. There was no significant difference between any group of subjects on the Sanskrit lists.

  792 acoustic confusability

- A study by Furugori[464] found that the typical spelling mistakes of Japanese users of English reflected the lack of differentiation, made in Japanese, of some English phonemes (e.g., Japanese has no */θ/* phoneme as in *th*ink, which is heard as */s/*, leading to *thunderstorm* being spelled *sanderstorm*).

6.4.2 Phonetic symbolism

identifier phonetic symbolism

Studies have found that native speakers of English have the ability to guess the meanings of words from unfamiliar languages with greater than chance probability. For instance, a study by Brown, Black, and Horowitz[171] asked subjects (English speakers unfamiliar with the other languages used in the study) to match English antonyms against the equivalent Chinese, Czech, and Hindi pairs of words (58.9%, 53.7%, and 59.6% pairs were correctly matched, respectively). It has been proposed that there exists a universal phonetic symbolism. This proposal implies that sounds tend to have intrinsic symbolic connotations that are shared by humans and that traces of these sound-to-meaning linkages survive in all natural languages.

792 antonym

A study by Koriat[764] found that the stronger a subject's feeling of knowing for a particular antonym pair, the higher the probability of their match being correct (English antonyms were required to be matched against their Thai, Kannada, and Yoruba equivalents).

0 feeling of knowing

The symbolism commonly associated with certain word sounds has been known about for many years; for instance, that words with *K* or *P* sounds are funny (chicken, pickle, cucumber, and porcupine). Advertisers also make use of the sound of a word when creating names for new products. A study by Schloss[1201] showed that 27% of the top 200 brands of 1979 began with *C*, *P*, or *K*; 65% began with *A*, *B*, *C*, *K*, *M*, *P*, *S*, or *T* (with less than a 5% probability of this occurring by chance).

A study by Magnus[886] looked at monosyllabic words in English. The results showed that words containing a given consonant fell within much narrower semantic domains than would be expected if there were no

correlation between phonology and semantics. The term *phonesthemes* was defined to refer to a sound sequence and a meaning with which it is frequently associated. An example of a phonestheme is the English */gl/* in initial position being associated with indirect light.

Table 792.19: Words that make up 19 of the 46 words beginning with the English */gl/* of the monomorphemic vocabulary (Note: The others are: globe, glower, glean, glib, glimmer, glimpse, gloss, glyph, glib, glide, glitter, gloss, glide, glissade, glob, globe, glut, glean, glimmer, glue, gluten, glutton, glance, gland, glove, glad, glee, gloat, glory, glow, gloom, glower, glum, glade, and glen). Adapted from Magnus.[886]

Concept Denoted	Example Words
Reflected or indirect light	glare, gleam, glim, glimmer, glint, glisten, glister, glitter, gloaming, glow
Indirect use of the eyes	glance, glaze(d), glimpse, glint
Reflecting surfaces	glacé, glacier, glair, glare, glass, glaze, gloss

Magnus also asked subjects (predominantly English speakers responding to a Web survey) to provide definitions for made-up words. For many of the words the particular definitions provided where limited to a small number of semantic domains, often with two domains accounting for more than half of the definitions.

6.5 Semantic usability (communicability)

Identifier semantic usability

A commonly specified coding guideline recommendation is that *meaningful* identifiers be used. This subsection discusses the topic of shared semantic associations (the sharing is treated as occurring between the original creator of an identifier spelling and subsequent readers of it), a more technical way of saying *meaningful*.

semantic networks 792

Developers have an existing semantic net in their head, which maps between character sequences and various kinds of information. This net has been continually building up since they first started to learn to read and write (as such, very little of it is likely to be directly related to any computer-related applications or software development). This existing semantic net is of major significance for several reasons, including:

- Making use of existing knowledge enables a small amount of information (an identifier's spelling) to represent a much larger amount of information. However, this is only possible when the original author and the reader share the same associations (or at least the ones they both consider applicable to the circumstances) for the same character sequences.
- Creating new memories is a time-consuming and error-prone process; making use of existing ones can be more efficient.

implicit learning 0

- A large amount of the information that it contains is not explicitly available. Developers often apply it without consciously being aware of the extent to which their decisions are driven by culturally (in its broadest sense) specific learning.

Given the current state of knowledge about the kinds of semantic associations made by groups of people working in a common field, even predicting how developers educated in the same culture might communicate effectively with each other is very difficult, if not impossible. Predicting how developers educated in different cultures might communicate, via identifier spellings, creates even more layers of uncertainty.

However impossible prediction might be at the time of writing, it is a problem that needs to be addressed. The following subsections discuss some of the issues.

6.5.1 Non-spelling related semantic associations

The need to recall information about an identifier is often prompted by its being encountered while reading the source. (A developer may ask another developer for information on an identifier and provide a spoken rendition of its spelling, but this usage is much less common.) The context in which the identifier occurs can often be used to deduce additional information about it. For instance, the identifier is a typedef name (it occurs in a list of declaration specifiers), it has arithmetic type (it occurs as the operand of a binary

multiplication operator), or designates an array or function (it occurs immediately to the left of a particular kind of bracket).

Although often providing important information to readers of the source, these nonspelling-related semantic associations are not discussed further here.

6.5.2 Word semantics

What does it mean to know a word? Richards[1161] gave the following answer, which has been very influential in the field of vocabulary acquisition:

1. The native speaker of a language continues to expand his vocabulary in adulthood, whereas there is comparatively little development of syntax in adult life.
2. Knowing a word means knowing the degree of probability of encountering that word in speech or print. For many words, we also *know* the sort of words most likely to be found associated with the word.
3. Knowing a word implies knowing the limitations imposed on the use of the word according to variations of function and situation.
4. Knowing a word means knowing the syntactic behavior associated with that word.
5. Knowing a word entails knowledge of the underlying form of a word and the derivatives that can be made from it.
6. Knowing a word entails knowledge of the network of associations between that word and the other words in language.
7. Knowing a word means knowing the semantic value of a word.
8. Knowing a word means knowing many of the different meanings associated with the word.

The following discussion involves what was once thought to be a semantic effect on word naming performance— *imagineability*. Subsequent studies have shown that age of acquisition is the primary source of performance difference. This work is discussed here because many sources cite imagineability effects as a word-handling performance issue. A study by Strain, Patterson, and Seidenberg[1304] asked subjects to read aloud words that varied across high/low frequency, regular/irregular spelling–sound correspondence, and high/low imagineability (as judged by 40 members of staff at the author's workplace; examples of high imagineability included *corkscrew* and *sparkling*, while words with low imagineability included *naive* and *presumption*). The results showed that on one case (low-frequency, irregular spelling–sound correspondence low imagineability) the error rates were significantly higher (14–19% vs. 0–3%) than the other cases. It was proposed that the semantic clues provided by imagineability provide a performance benefit that is only significant when processing irregularly spelled low frequency words. However, a later study by Monaghan and Ellis[955] also took a words age of acquisition into account. The results showed that age of acquisition had a significant effect on word naming performance. Once this effect was taken into account the apparent effects of imagineability disappeared. It was pointed out that words learned early in life tend to be less abstract than those learned later. It is age of acquisition that is the primary effect.

792 age of acquisition

6.5.3 Enumerating semantic associations

semantic associations enumerating

How can the semantic associations evoked by a word be enumerated? One method is to enumerate the list of words that are considered to be related, or similar, to it. To this end this subsection discusses some of the algorithms that have been proposed for measuring the semantic relatedness, or similarity, of two words. It is based on the review by Budanitsky.[177] To quote from its opening sentence "Is *first* related to *final*? Is *hair* related to *comb*? Is *doctor* related to *hospital* and, if so, is the connection between them stronger than that between *doctor* and *nurse*?"

The methods of measuring similarity proposed by researchers can be broadly divided into two groups. The context-free methods do not consider the context in which the two words occur. Some compendium of words (e.g., a dictionary or thesaurus) is used to provide the base information. The context-sensitive methods consider the context in which the two words are used.

6.5.3.1 Human judgment

word similarity human judgment

One way to obtain a list of words associated with a particular word is human judgment. Studies of human semantic memory, by cognitive psychologists, often make use of word association norms. However, most of these studies use a small set of words. For instance, a study by Burke, Peters, and Harrold[183] measured associations for 113 words using 80 young (mean age 21.7) and 80 older (mean age 71.6) subjects. There have been two studies, using English speakers, that have collected associations for a large number of words.

A long-term study (it started in 1973) by Nelson, McEvoy, and Schreiber[1006] created the University of South Florida word association, rhyme, and word fragment norm database by collating the nearly three-quarters of a million responses to 5,019 stimulus words from more than 6,000 subjects. Subjects (students at the university) were given lists of words (approximately 100 in a booklet, with 25–30 per page) and asked to write the first word that came to mind that was meaningfully related or strongly associated to each of these words. For example, given *book*, they might write *read*.

Nelson et al. compared their results with those obtained by Kiss, Armstrong, Milroy, and Piper[740] in the UK. They found substantial differences between the results and suggested that these were caused by cultural differences between Florida and the UK. For example, the most frequent responses of the Florida subjects to the word *apple* were *red* and *orange* (the fruit), with *tree* and *pie* being given relatively infrequently.

A study by Steyvers[1298] used the Nelson et al. word association data to build a *Word Association Space* (which was claimed to have psychological relevance). The results showed that this space was a good predictor of similarity rating in recognition memory, percentage correct responses in cued recall, and intrusion rates in free recall.

6.5.3.2 Context free methods

The advantage of using existing sources of word associations, such as dictionaries, is the large amount of information they provide about general word associations. The disadvantages with using these sources of information is that the word associations they contain may not include specific, technical uses of words or even have some of the words being analyzed. The availability of large volumes of written text on the Internet has shown that the primary definitions given to words in dictionaries are often not the definitions commonly used in this material (although publishers are starting to produce dictionaries[257] based on measurements of common word usage). Also a human-written dictionary in computer readable form may not be available (the calculations for the original thesaurus study[965] were done by hand because online material was not available to the authors).

The following are some of the studies that have used context-free methods:

- A study by Kozima and Furugori[769] used a subset of the *Longman Dictionary of Contemporary English*[867] (*LDOCE*) to build a semantic network. This dictionary uses a small (2,851 words) vocabulary to express the meanings of all the other words (more than 56,000) it defines.[792.15] This semantic network was used to calculate the similarity between words using spreading activation. Later work by Kozima and Ito[770] made context-sensitive measurements by performing what they called *adaptive scaling of the semantic space*. They gave the example of *{car, bus}* having the context *vehicle* and being closely associated with *taxi*, *railway*, *airplane*, and so on, while *{car, engine}* had the context *components of a car* and were closely associated with *tire*, *seat*, *headlight*, and so on. A change of context usually resulted in a change of distance between the same word pair.
- Ellman[386] created a tool to detect lexical chains (constructs used in calculating text similarity) in large texts, with the intent of extracting a representation of its meaning. Various kinds of semantic relations between the words classified in *Roget's Thesaurus* (a thesaurus is intended as an aid in finding words that best express an idea or meaning, while a dictionary explains the meaning of words) were used to compute lexical chains between pairs of words appearing in the texts.

[792.15] This feature, along with the publisher making it available to researchers for a small fee, has made LDOCE widely used by language researchers.

6.5.3.3 Semantic networks

semantic networks

A semantic network consists of a set of nodes with connections, and arcs, between them. The nodes representing concepts and the arcs denoting relationships between the nodes (concepts) they connect.

WordNet

WordNet[792.16][416] is a semantic network whose design was inspired by current psycholinguistic theories of human lexical memory. It organizes English nouns, verbs, adjectives, and adverbs into synonym sets (synsets), each expressing one underlying lexical concept (see Table 792.20). Edmonds[377] provides a detailed discussion (and a computational model) of the fine-grained meanings of near synonyms and the differences between them. For instance, all of the WordNet noun synsets are organized into hierarchies. At the top of the hierarchies are the following nine abstract concepts called *unique beginners*:

792 synonym

Table 792.20: WordNet 2.0 database statistics.

Part of Speech	Unique Strings	Synsets	Total Word-sense Pairs
Noun	114,648	79,689	141,690
Verb	11,306	13,508	24,632
Adjective	21,436	18,563	31,015
Adverb	4,669	3,664	5,808
Total	152,059	115,424	203,145

- Entity— that which is perceived or known or inferred to have its own physical existence (living or nonliving)
- Psychological feature— a feature of the mental life of a living organism
- Abstraction— a general concept formed by extracting common features from specific examples
- State— the way something is with respect to its main attributes: *the current state of knowledge*, *his state of health*, *in a weak financial state*
- Event— something that happens at a given place and time
- Act, human action, human activity— something that people do or cause to happen
- Group, grouping— any number of entities (members) considered as a unit
- Possession— anything owned or possessed
- Phenomenon— any state or process known through the senses rather than by intuition or reasoning

The arcs between nouns in synsets are defined by the following relations:

- Antonym— the *complement* relation; words of opposite meaning (e.g., hot-cold)
- Holonymy— the *has a* relation, the opposite of meronymy

antonym

- Hypernymy— the *is a* relation (e.g., plant is a hypernym of tree)
- Hyponymy— the *subsumes* relation, the inverse of hypernymy
- Meronymy— relationship between objects where one is a part of the other (e.g., sleeve is a meronym of coat, dress, or blouse)
- Synonym— word with the same, or nearly the same meaning

synonym

Steyvers and Tenenbaum[1300] investigated the graph theoretic properties of the semantic networks created by WordNet, *Roget's Thesaurus*, and the associative word lists built by Nelson et al. The results showed that they had a small world[25] structure.

[792.16] Probably the most well-known semantic network in linguistics, and it is available for download from the internet.

6.5.3.4 Context sensitive methods

The attributes associated with an unknown word can often be inferred from the context in which it occurs; for instance, the paragraph: "A bottle of tezgüino is on the table. Everybody likes tezgüino. Tezgüino makes you drunk. We make tezgüino out of corn." suggests that *tezgüino* is an alcoholic drink made from corn mash.

Context-sensitive methods obtain their information directly from a corpus of written material. These methods all assume the words occur in text written in a natural language. As such, they are not directly applicable to identifiers in source code. However, they do provide a possible mechanism for automatically obtaining word similarity information for specialist domains (e.g., by processing books and papers dealing with those domains).

The advantages of context-sensitive methods are that they are not limited to the words appearing in some predefined source of information and because the needed information is automatically extracted from a corpus they are sensitive to the associations made. The disadvantage of this method is that the corpus may not contain sufficient occurrences of particular words for an accurate evaluation of their associations to be calculated.

latent semantic analysis

One of the most widely discussed context-sensitive methods is *Latent Semantic Analysis*, LSA.[802] The underlying idea is that the sum of all the contexts in which a given word does and does not appear provides a set of mutual constraints that determines the similarity of meanings of words and sets of words to each other. The process of extracting relations between words starts with a matrix, where each row stands for a unique word and each column stands for a context (which could be a sentence, paragraph, etc.). Each matrix cell holds a count of the number of times the word it represents occurs in the context it represents. Various mathematical operations are performed (to the uninitiated these seem completely disconnected from the problem at hand and for this reason are not described here) on the matrix to yield results (each word is mapped to a vector in an n-dimensional space, where n is usually around 300, and the similarity between two words is calculated from cosine of the angle between their respective vectors) that have been found to effectively model human conceptual knowledge in a growing number of domains.

morphology 792

LSA takes no account of word order ("dog bites man" and "man bites dog" are treated the same way), syntactic relations (no syntactic parsing of the text is performed), or morphology (*fast* and *faster* are treated as different words). This eliminates many of the practical difficulties experienced by other methods. This simplicity, along with the quality of its results has made LSA a popular choice for information-retrieval problems.

An obvious way to try to improve the quality of word similarity measures is to take their syntactic relationships into account. Lin[856] proposed a similarity measure that takes the grammatical relationship between the two words into account. The raw data from which this word information is extracted is a list of sentences. These sentences are broken down into dependency triples, consisting of two words and the grammatical relationship between them, within the sentence. For instance, the triples for the sentence "I have a brown dog" are: (*have* subj *I*), (*I* subj-of *have*), (*dog* obj-of *have*), (*dog* adj-mod *brown*), (*brown* adj-mod-of *dog*), (*dog* det *a*), (*a* det-of *dog*), given two words w and $w^{'}$, and the relation r. The similarity between two words is based on the amount of information contained in the commonality between them, divided by the amount of information in the description of them, and the amount of information, I, contained in the dependency tuple $\parallel w, r, w^{'} \parallel$ is given by:

$$I(w,r,w^{'}) = \log(\frac{\parallel w,r,w^{'} \parallel \times \parallel *,r,* \parallel}{\parallel w,r,* \parallel \times \parallel *,r,w^{'} \parallel}) \tag{792.3}$$

where $*$ matches all words.

Lin obtain his sentences from various online newspapers (a total of 64 million words). An English language parser extracted 56.5 million dependency triples, 8.7 million being unique. There were 5,469 nouns, 2,173 verbs, and 2,632 adjectives/adverbs occurring more than 100 times.

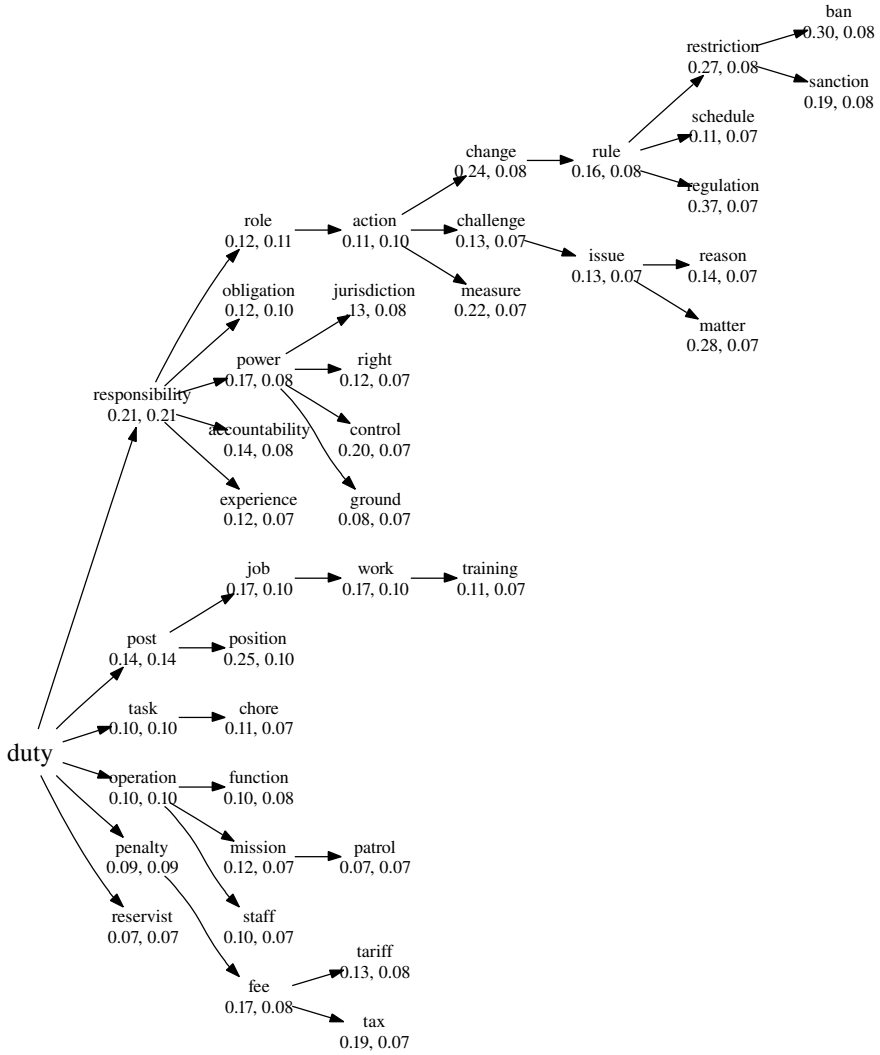

Figure 792.31: Semantic similarity tree for *duty*. The first value is the computed similarity of the word to its parent (in the tree), the second value its similarity to *duty*. Adapted from Lin.[856]

6.5.4 Interperson communication

Identifier spellings provide a delayed, one-way form of human communication. The original author decides on a spelling to use, often with the intent of it denoting meaningful information, and sometime later a second person reads it (code reviews offer an opportunity for other developers to perform the role of future readers, 0 code reviews but they are not usually held for this purpose). This form of communication is significantly different from the collaborative process that underlies most human communication. For instance, a study by Clark and Wilkes-Gibbs[244] showed how two people work together in the creation of agreed-on references (to complex shapes). The results also found that the number of words used decreased over successive trials (rearranging square and triangular paper cards to form complex shapes) as subject pairs learned from each other.

The writers and readers of source code rarely get to take part in a collaborative communications process with each other. Furthermore, the original author may not even have other human readers in mind, when deciding on an identifier spelling. Authors may see themselves as communicating with the computer or communicating with themselves at some future date.

The following two subsections discuss the evolution of terminology groups by use in communicating among themselves and some of the issues involved in two people reaching the same conclusions about the semantic associations of a word or phrase.

6.5.4.1 Evolution of terminology

All but the smallest software development project will have more than one person working on it, although each particular piece of source code often has a single person working on it. While in many cases the number of people who actually write significant amounts of source is usually only a fraction of the total number of people on the project, there is invariably a set of linguistic conventions (including a terminology) that evolves and is shared by a large percentage of the members of a project.

The characteristics of the evolution of linguistic conventions that occur in groups are of interest to the extent that they affect the performance of subsequent readers of the source.

A study by Garrod and Doherty[473] investigated the establishment of linguistic conventions in two different kinds of groups. Two people had to work together to solve a maze game in which the information needed was distributed between them (the only way of communicating the needed information was by questioning and answering each other; responses were recorded by the experimenter). In one group (five pairs) the same two people always worked together, while in the other group everybody (10 people) eventually got to be paired with everybody else in the group. Each subject played nine 10-minute games with the maze randomly generated for each game.

The results showed that isolated pairs of subjects had much higher levels of inter-speaker coordination (measured by categorizing each information exchange that took place between subjects while solving a particular maze, and counting the exchanges in each category) compared to the community pairs during the first few games. However, by the time six games had been played, this situation had reversed, with the community pairs having significantly more inter-speaker coordination.

The way in which the two groups coordinated their descriptions differed. The isolated pairs used descriptions that were specific to a particular position in the solution and specific to themselves. Once the community pairs became established through overlapping interactions, they began to coordinate as a group. The constraints on their descriptions became global ones that apply to communities in general (i.e., they were not able to make use of special cases previously agreed to between two individuals).

If the behavior seen in the Garrod and Doherty study also occurs in development groups, it is to be expected that groups of one or two developers are likely to evolve terminology that is much more tightly bound to their mutually agreed-on way of thinking than larger groups of developers.

6.5.4.2 Making the same semantic associations

The semantic usability of an identifier's spelling might be judged by the degree to which the semantic associations it creates reduces the effort needed to comprehend source code containing it. A randomly selected identifier spelling is extremely unlikely to create semantic associations having this property. Selecting an identifier's spelling to create the necessary associations is the solution. However, the decision on the spelling to use is judged by the semantic associations created in the original author's mind at the time it is selected. It cannot be assumed that the semantic associations of the original author are the ones most relevant to subsequent readers. This subsection discusses some of the issues involved.

Both the authors and readers of an identifier's spelling will make assumptions about how it is to be interpreted.

- *Authors* of source code will make assumptions about the thought process of subsequent readers. Explicit assumptions made might include: degree of familiarity with application domain (e.g., to simplify their task the original authors may have specified to management that competent people need to be hired and then proceed to work on the basis that this requirement will be met), or that they have read the documentation. Implicit assumptions might include: culture (no thought given to alternative cultures), degree of familiarity with the application domain (e.g., is familiar with certain terms such as

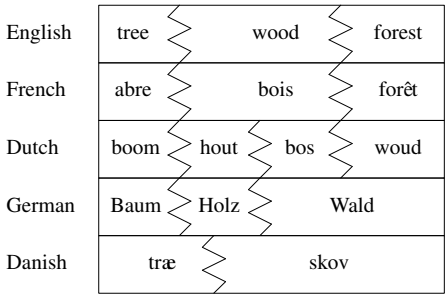

Figure 792.32: The relationship between words for tracts of trees in various languages. The interpretation given to words (boundary indicated by the zigzags) in one language may overlap that given in other languages. Adapted from DiMarco, Hirst, and Stede.[359]

overload, *spill* and abbreviations such as *fft*, *cse*, *sql*), or education of the reader (e.g., familiarity with mathematics to a certain level).

- *Readers* of the source code will make assumptions about the intent of the original author. An explicit assumption might be *trusting* the original author (e.g., "the software has been working well"). The reader may have limited time available and trust may seem like the best way of reducing the time they need to invest; whether this trust is justified is not the issue here. The implicit assumptions might include: the reader and author sharing common ground, that the original author had intentions about the identifiers used in a particular section of source (original authors are often seen as mythological figures; it is possible that no particular interpretation was intended), and degree of familiarity with the application domain.

Given the many different kinds of assumptions that different developers may make, people might wonder how readers can be expected to obtain helpful semantic information from identifier spellings. The answer is that often they aren't. There are two routes by which different people might arrive at similar semantic interpretations for an identifier's spelling:

1. *Shared knowledge.* Shared knowledge may occur through culture, natural language usage, or specific learning experiences. An example of where differences in shared knowledge produce differences in performance is the treatment of time in English and Mandarin Chinese. English predominantly treats time as if it were horizontal (e.g., "ahead of time", "push back the deadline"), while Mandarin often, but not always, treats it as being vertical (an English example of vertical treatment is "passes down the generations").[1208] A study by Boroditsky[140] found that English subjects responded more quickly (by approximately 10%) to a question about dates (e.g., "Does March come before April?") if the previous question they had answered had involved a horizontal scenario (e.g., "X is ahead of Y") than if the previous question had involved a vertical scenario (e.g., "X is below Y"). These results were reversed when the subjects were Mandarin speakers and the questions were in Mandarin.
2. *Shared behavior.* Possible shared behaviors include effort minimization, universal grammar, and universal category formation. An example of how shared behavior can affect people's communication was shown by the results of a study by Beun and Cremers.[118] They gave pairs of subjects, a builder and an instructor, the task of building a replica of a building that was only visible to the instructor. The two subjects were seated at a table and could speak to each other and could see each others' hands, but there was no other mode of communication. A pile of blocks of different colors, shapes, and sizes, only visible to the builder, were provided. The block building had to be done on a plate visible to both subjects. Both subjects spoken conversation and hand gestures were recorded. The behavior predicted by Beun and Cremers is based on the *principle of minimal cooperative effort*, where the speaker and

addressee not only try to say as little as possible together, they also try to do as little as possible. For instance, what features of an object should be used in a description? This principle suggests that people will prefer absolute (e.g., *black* or *square*) rather than relative (e.g., *darkest*, *longest*) features. This is because absolute features only require one object to be taken into account, while relative features requires comparison against other objects. The results found that 63% of referential acts used absolute features only, 19% used a combination of absolute and relative features, and 1% used relative features only. A pointing action, with the hands, was used in 18% of cases. The study also found evidence for several other hypotheses derived from this principle, including: (1) if the target object is inherently salient within the domain of conversation, reduced information is used; and (2) if the target object is located in the current focus area, only information that distinguishes the object from other objects in the focus area is used.

6.6 Abbreviating

abbreviating identifier

Developers sometimes form an identifier by abbreviating the words of a descriptive phrase or sentence (e.g., `first_elem_ptr` might be derived from *a pointer to the first element of an array*). While the words in a phrase or complete sentence are rarely abbreviated in everyday life, continued use may result in a multiword phrase eventually being replaced by an acronym (e.g., *Light Amplification by Stimulated Emission of Radiation* became *LASER* and eventually *laser*). For this reason, there does not appear to be any published research on the creation of abbreviations from multi-word phrases.

This subsection discusses the issues associated with shortening the words (it is not unknown for single words to be shortened) used to create an identifier (the issue of source filename abbreviations is discussed elsewhere). The following are some of the issues associated with using shortened forms:

file name 108 abbreviations

- Shortening is likely to change the amount of cognitive resources needed by readers of the source to process an identifier containing them. This is because abbreviation changes the distribution of character sequences, with infrequent or never-seen character pairs occurring more often. It may also remove any obvious grapheme-to-phoneme mapping, making it harder to create a pronunciation

word 792 pronounceability

- Fewer characters means less effort is needed to type the character sequence denoting an identifier
- Reducing the number of characters in an identifier can simplify the visual organization of source code (i.e., by removing the need needing to split an expression or statement over more than one line)
- While some abbreviations may have semantic associations for the original developer, these are often not understood or are forgotten by subsequent readers of the source. Such identifier spellings are then treated as a random sequence of characters

Word shortening can be studied by asking people to create shortened forms of words and phrases;[579, 1308] by analyzing the shortened forms occurring in prose,[1273] source code,[796] speech,[204] or from a purely information content point of view.[145] These studies investigated the form of the abbreviations created, not the circumstance under which people decide to create or use an abbreviation. A number of commonly occurring patterns to the shortened forms have been found, including:

- Vowel deletion— sometimes known as *contraction* (e.g., *search*⇒`srch` and *pointer*⇒`pntr`)
- Truncation of trailing characters (e.g., *audit* ⇒ `aud` and *catalog* ⇒ `cat`)
- A combination of vowel removal and truncation (e.g., *pointer*⇒`ptr` and *temporary*⇒`tmp`)
- Using the first letter of each word (e.g., *customer query number*⇒`cqn` and *first in first out* ⇒ `fifo`)
- Phonetic abbreviations— simply changing one grapheme to another that represents the same phoneme (e.g., *ph*⇒*f*) or digits may be used (e.g., *straight*⇒*str8*)

These abbreviations may in turn be concatenated together to create specialized instances (e.g., `tmp_cqn`, `cat_pntr`, and `srch4cqn`).

An abbreviation is generally a meaningless sequence of characters unless readers can decode it to obtain the original word. A study by Ehrenreich and Porcu[379] found that readers' performance in reconstructing the original word was significantly better when they knew the rules used to create the abbreviation (81–92% correct), compared to when the abbreviation's rules were not known (at best 62% after six exposures to the letter sequences). In practice imposing a fixed set of word abbreviation rules on the world's software developers is not realistic. Imposing a fixed set of abbreviation rules on the developers within a single development group is a realistic possibility, given automated checking to ensure conformance. However, calculating the likely cost/benefit of imposing such a set of rules is very difficult and these coding guidelines do not discuss the issue further.

The widespread use of phonetic abbreviations is relatively new. The growth in online chat forums and the use of text messaging via mobile phones has significantly increased the number of people who use and understand their use. The extent to which this user population intersects the set of creators of identifier spellings also continues to grow. Some people find this use of abbreviations irritating and irresponsible. These coding guidelines take the position that all character sequences should be judged on their ability to communicate information to the reader. Your author has not been able to find any published studies of the use of phonetic abbreviations and they are not discussed further here.

A study by Frost[456] investigated subjects' performance in reading words with missing vowels. The subjects were experienced readers of Hebrew, a language in which words are usually written with the vowels omitted. The time taken to name words was found to vary linearly with the number of vowels omitted. Missing vowels had no effect on lexical decision performance. One point to note is that there was only one word corresponding to each letter sequence used in the study. It is not known how reader performance would vary if there was more than one word matching a vowel-free written form.

The results of two studies asking people to abbreviate the words and phrases they were given showed a number of common points. The common methods used to create abbreviations were the first four of those listed above. Even the shortest words usually had more than one abbreviation (mean of 3.35 in Hodge et al. and 5.73 in Streeter et al), with the average number of abbreviations per word increasing with word length (mean of 6.0 in Hodge et al. and 18.0 in Streeter et al). The most common algorithm used for shorter words was vowel deletion, while longer words tended to be truncated. Streeter et al point out that vowel deletion requires producing the whole word and then deleting the vowels, an effort-prone and time-consuming task for long words (small words probably being handled as a single *chunk*). In the case of polysyllabic words truncation produces short abbreviations, which are easy to produce and only require a single change to the word output strategy (cut it short).

- A study by Hodge and Pennington[579] asked subjects to create a personal (one they might use for their own private writing) and a general (one that could be understood by other people) abbreviation from words containing between four and nine letters. The results for the personal abbreviations paralleled those of the general abbreviations. Male subjects made greater use of vowel removal for the longer words than female subjects (who preferred truncation for longer words). The percentage of the original word's letters used in the abbreviation decreased with word length (from 70–75% for shorter words to 58–65% for longer words). The abbreviations of more frequent words contained fewer letters than less frequent words. A separate group of subjects were given the abbreviations created by the first group and asked to reconstruct the original words. The mean reconstruction rate at all word lengths was 67%.

  792 word frequency

- A study by Streeter, Ackroff, and Taylor[1308] investigated the rules used by people to create abbreviations. Subjects were asked to produce "good abbreviations" for 81 computer command names and arguments (e.g., *move* and "usage billing number"). Analysis of the results was based on the number of syllables in a word (between one and four) or the input containing multiple words. The resulting abbreviations were compared against those produced by a variety of algorithms. The performance of the different algorithms varied with the number of syllables (see Figure 792.33).

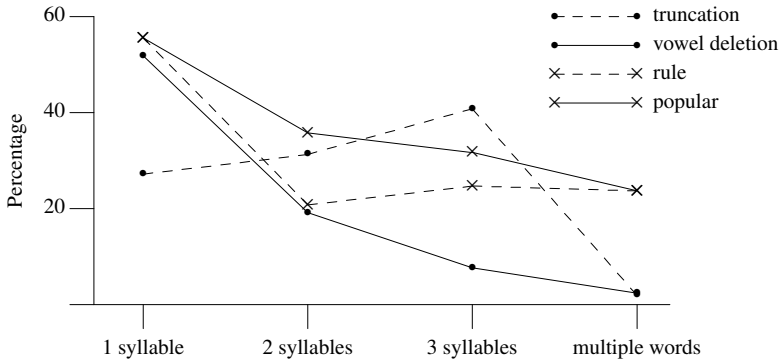

Figure 792.33: Percentage of abbreviations generated using each algorithm. The *rule* case was a set of syllable-based rules created by Streeter et al.; the *popular* case was the percentage occurrence of the most popular abbreviation. Based on Streeter, Ackroff, and Taylor.[1308]

A second group of subjects were asked to learn word/abbreviation pairs. The abbreviations used were those generated by the first group of subjects. The abbreviations used were either the most popular one chosen for a word, or the one obtainable by following the Streeter et al. rules. When given the word and asked for the abbreviation, mean recall performance was 54% correct for the popular abbreviations and 70% for the rule abbreviations (recall rate decreased in both cases as the number of syllables increased, although both were more than 90% for multiple words). Another two experiments, using randomly chosen English words, paralleled the procedure in the first two experiments. However, after learning word/abbreviation pairs, subjects were asked to recall the word when given the abbreviation (mean recall performance was 62.6% correct for the popular abbreviations and 46.7% for the rule abbreviations, with recall rate slowly decreasing in both cases as the number of syllables increased).

An alternative approach to predicting use of abbreviation strategies was studied by Carter and Clopper.[204] Words are abbreviated in both spoken and written forms— for instance, *rhinoceros* ⇒ *rhino* and *telephone* ⇒ *phone*. Subjects were asked to listen to a series of words. After each word, they had to speak the word and then produce a *reduced* spoken form (they were reminded that most of the words would not normally be reduced in everyday speech).

Table 792.21: The syllable most likely to be omitted in a word (indicated by the × symbol) based on the number of syllables (*syl*) and the position of the primary, (*pri*) stressed syllable. Adapted from Carter and Clopper.[204]

Syllables in Word and Primary Stress Position	Syllable(s) 1	Omitted 2	Most 3	Often 4
2syl–1pri		×	–	–
2syl–2pri	×		–	–
3syl–1pri		×	×	–
3syl–2pri	×			–
3syl–3pri		×	×	–
4syl–1pri		×		
4syl–2pri			×	×
4syl–3pri	×	×		×

Carter and Clopper drew three conclusions from the results (see Table 792.21):

1. the stressed syllable is nearly always preserved,
2. the initial syllable is preserved more often than omitted, and
3. only when the final syllable of a two syllable word contains the stress is that syllable preserved more often than it is omitted.

A study by Bourne and Ford[145] investigated word abbreviation from an information content point of view. They looked at thirteen different algorithms capable of reducing an arbitrary word to a predefined number of letters. Algorithm quality was measured by the ability to map different words to different abbreviations. The consistently best algorithm dropped every second letter (this rule was applied iteratively on the successively shorter letter sequences until the desired number of characters was obtained) and appended a check letter (algorithmically derived from the discarded letters). While this algorithm might be of interest when automatically generating identifier spellings, we are only interested in human-created spellings here.

The following studies investigated the interpretation of existing abbreviations in various contexts:

- Sproat, Black, Chen, Kumar, Ostendorf, and Richards[1273] give a detailed discussion of the issues involved in converting what they call *nonstandard* words to spoken words (in the context of text to speech synthesis). What appears to be an abbreviation may actually be a nonstandard word. For instance, `Article_IV` is probably pronounced "article four", `Henry_IV` is pronounced as "Henry the fourth", while `IV_drip` is probably pronounced "I V drip".
- Laitinen, Taramaa, Heikkilä, and Rowe[796] built a tool, `InName`, to *disabbreviate* source code. `InName` used a simple grammar to describe the components of an identifier spelling. This broke the spelling into short letter sequences which were assumed to be either abbreviations of words or words (e.g., `boOffsetMeasDone` ⇒ `bo`, `Offset`, `Meas`, `Done`). A relatively small dictionary of around 1,000 entries was used to detect words, plus a list of 300 common abbreviations (e.g., len ⇒ length, curr ⇒ current). A GUI interface highlighted an abbreviated name and listed possible nonabbreviated forms (e.g., `tmpnamelen` ⇒ `temporary_name_length`). The user could accept one of the suggested forms or type in their own choice. The results of not abbreviating five applications are shown in Table 792.22.

Table 792.22: Five different applications (A–E) unabbreviated using `InName`, by five different people. Application C had many short names of the form `i`, `m`, `k`, and `r2`. Adapted from Laitinen.[796]

Application	A	B	C	D	E
Source lines	12,075	6,114	3,874	6,420	3,331
Total names	1,410	927	439	740	272
Already acceptable	5.6	3.1	8.7	9.3	11.0
Tool suggestion used	42.6	44.7	35.3	46.8	41.5
User suggestion used	39.6	29.3	15.0	30.7	43.8
Skipped or unknown names	12.2	22.9	41.0	13.2	3.7
User time (hours)	11	5	4	4	3

- A study by Cutler and Carter[304] found that 85% of English lexical words (i.e., excluding function words) begin with a strong syllable. They proposed that such a strategy simplified the problem listeners faced in identifying the start of words in continuous speech.
- A study by Anquetil and Lethbridge[48] investigated the abbreviations used to name files (this is discussed elsewhere). 108 file name abbreviations

6.7 Implementation and maintenance costs

Encoding information in the sequence of characters forming an identifier's spelling sounds attractive and this usage often occurs in automatically generated code. However, human-written code is invariably maintained by humans and a number of possible human-related factors ought to be taken into account. While it might not yet be possible to obtain reliable figures on these costs, the main ones are listed here for future reference, including:

- Keeping the information up-to-date during source code maintenance and updates.
- The cost of new readers learning to interpret the encoding used.

- The probability of correctly interpreting the character sequences used. For instance, a numeric value may indicate some maximum value, but this maximum may be the largest representable value (a representation attribute) or the largest value an object is expected to hold (an application attribute).
- The cost of processing the character encoding when reading source. (It took developers many years of practice to achieve fluency in reading text in their native language and they are likely to require practice at decoding identifier spellings before they can read them as fluently.)

The only information likely to be needed every time the identifier is read is the semantics of what it denotes. Experience suggests that this information rarely changes during the development and maintenance of a program.

6.8 Typing mistakes

typing mistakes

A summary of the results of typing studies would include two factors of relevance to this identifier guidelines section. Hitting a key adjacent to the correct one is the largest single contributor (around 35%) to the number of typing mistakes made by people. Performance is affected by the characteristics of the typists native written language (word frequency and morphology).

morphology 792

Researchers studying typing often use skilled typists as subjects (and build models that mimic such people[1188]). These subjects are usually asked to make a typewritten copy of various forms of prose— the kind of task frequently performed by professional typists, the time taken and errors made being measured. Software developers are rarely skilled typists and rarely copy from written material. (It is often created in the developer's head on the fly, and a theory of developer typing performance would probably need to consider these two processes separately.)

These coding guidelines assume that developers' typing mistakes will follow the same pattern as those of typists, although the level of performance may be lower. It is also assumed that the primary input device will be a regular-size keyboard and not one of those found on mobile computers.[882]

- A study by Shaffer and Hardwick[1216] asked qualified touch typists to type text, the characteristics of which varied. The five different kinds of text were: Prose, an article on gardening; Word, a random arrangement of the words in the previous article; Syllable, obtained by shuffling the spaces between the words of the article into syllable boundaries within the words; First-order, random letter strings having the same distribution of letters as the article; and Zero-order, random letter strings with all letters being equally probable.

Table 792.23: Distribution of mistakes for each kind of text. Unparenthesized values are for subjects who made fewer than 2.5% mistakes, and parenthesized values for subjects who made 2.5% or more mistakes. Omission— failing to type a letter; response— hitting a key adjacent to the correct one; reading— mistakes were those letters that are confusable visually or acoustically; context — transpositions of adjacent letters and displacements of letters appearing within a range of three letters left or right of the mistake position; random— everything else. When a mistake could be assigned to more than one category, the category appearing nearer the top of the table was chosen. Adapted from Shaffer.[1216]

Kind of mistake	Prose	Word	Syllable	First Order	Zero Order	Total
Omission	19 (21)	11 (23)	24 (36)	15 (46)	34 (82)	103 (208)
Response	19 (25)	31 (38)	27 (53)	32 (43)	108 (113)	217 (272)
Reading	3 (2)	2 (0)	8 (15)	14 (20)	20 (41)	47 (78)
Context	19 (27)	19 (17)	34 (30)	56 (51)	46 (40)	174 (165)
Random	3 (5)	2 (6)	4 (11)	13 (15)	22 (41)	44 (78)
Total	63 (80)	65 (84)	97 (145)	130 (175)	230 (317)	585 (801)

The results (see Table 792.23) show that hitting a key adjacent to the correct one was the largest single contributor (around 35%) to the number of mistakes. Surprisingly, both the number of mistakes and typing rate were the same for prose and random word ordering. Text containing words created using purely random letter sequences had the highest rate of typing mistakes (and the slowest typing

rate), almost twice that of text created using the distribution of letters found in English. Shaffer and Hardwick performed a second experiment to investigate the reasons for the significant difference in typing performance when first- or zero-order words were used. Was it caused by a decline in syllable-like sequences in the words because of fewer vowels, or because of an increase in the less frequently used letters of the alphabet? Every letter of the alphabet was used 10 times to create passages of 52 five-letter words and 16 fifteen-letter words (plus a single 20-letter word). For one set of passages the letters in each word were randomly selected; in the other set an attempt was made to create words containing readable syllables (e.g., *spowd*, *throx*).

Table 792.24: Mean response time per letter (in milliseconds). Right half of the table shows mean response times for the same subjects with comparable passages in the first experiment. Adapted from Shaffer.[1216]

	Syllable	Random		First Order	Zero Order
5-letter	246	326	Fixed	236	344
15-letter	292	373	Random	242	343

The only results reported (see Table 792.24) were response times for letters typed, not the number of mistakes. These results show that performance for text containing words having readable syllables was significantly better than words having a random sequence of letters. Since both passages contained the same number of occurrences of each letter, the difference was not caused by a decrease in the number of vowels or an increase in the number of infrequently used letters. Performance was slower for the passage containing longer words.

- A study by Gentner, Larochelle, and Grudin[481] also found that rate of typing was affected by letter digraph frequency and word frequency in the typist's natural language (they did not measure error mistake rates). The position of the digraph within the word and syllable boundaries had a smaller affect on performance.
- A study by Schoonard and Boies[1203] taught subjects to use abbreviations for commonly occurring words (so-called *short-type*; the intent being to increase typing performance by having the word processor used automatically expand the abbreviations). The results showed an average short-type detection rate of 93.2% (of those possible) and that typing rate (in characters per second) was not affected by use of short-type (error rates were only given for short-type). Developers often abbreviate words when creating identifier names (but editors rarely expand them).

0 people
error rates
792 abbreviating
identifier

- Studies have analyzed the mistakes made by each finger of each hand. Software developers rarely touch type, often using a few fingers from each hand. While *Stewardesses* may be the longest English word touch typed with the left hand only, most developers are likely to use fingers from the right hand. For this reason these studies are not considered applicable here.

6.9 Usability of identifier spelling recommendations

The computational resources needed to rapidly check a character sequence against a list of several million character sequences is well within the capabilities of computers used for software development today. However, the cost of maintaining an up to-date list of identifiers currently used within a software product under active development can be a non-trivial task and may result in developers having to wait for a relatively long period of time for a proposed choice of identifier spelling to be checked against existing identifier spellings. One way of reducing the identifier database maintenance resources required is to reduce the number of identifiers that need to be checked. All identifiers have attributes other than their spelling (they all exist in some name space and scope, have a linkage and some have a type), and it might be possible to take advantage of the consequences of an identifier having these attributes; for instance:

identifier
guideline significant characters

438 name space
400 scope
420 linkage
472 types

- If the identifier `X_1` is not visible at the point in the source where a developer declares and uses the identifier `X_2`, a reference to `X_2` mistyped as `X_1` will result in a translator diagnostic being issued.

400 visible
identifier

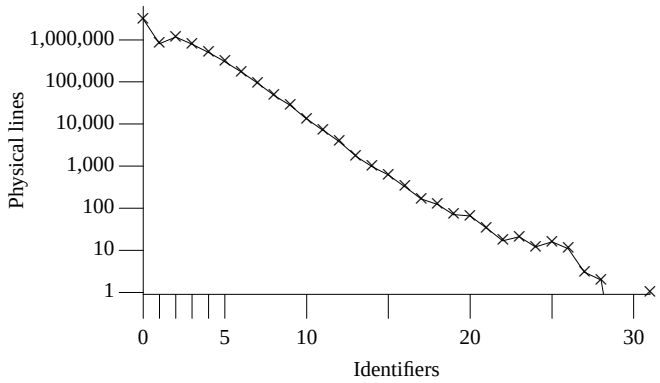

Figure 792.34: Number of physical lines containing a given number of identifiers. Based on the visible form of the `.c` files.

name space 438

- If the identifiers `X_1` and `X_2` are in different name spaces, a mistyped reference to one can never result in a reference to the other.
- If the identifiers `X_1` and `X_2` are objects or functions having incompatible types, a mistyped reference to one, which refers to the other, is likely to result in a translator diagnostic being issued.

Mistyping an identifier only becomes a fault if the usage does not cause a diagnostic to be issued by a translator. (A developer who visually confuses two identifiers can create a fault that does not generate a translator diagnostic by writing code that makes use of incorrect identifier information without directly referencing the confused identifiers.)

While modifications to existing source may not result in new identifiers being declared, it is possible for the C language attributes of an existing identifier to be changed. Experience suggests that modifications rarely change an identifier's name space, but that changes of scope or linkage (which controls visibility) is relatively common; for instance, moving the declaration of an identifier from block scope to file scope or changing its linkage from internal to external (experience suggests that these changes rarely occur in the other direction). Changes to the type of an object might include a change of integer type or new members being added to the structure type it has.

scope 410
overlapping

This usage pattern suggests the following deviation:

Dev 792.3

Every identifier need only be compared against every other identifier in the same name space in the visible source of a program.

Semantics

An identifier is a sequence of nondigit characters (including the underscore _, the lowercase and uppercase Latin letters, and other characters) and digits, which designates one or more entities as described in 6.2.1. 793

Commentary

A restatement of information given in the Syntax clause.

C90

Explicit support for other characters is new in C99.

Lowercase and uppercase letters are distinct. 794

Commentary

The reason the standard needs to explicitly specify that lowercase and uppercase letters are distinct is because in many computer languages they are not. In some tokens lowercase and uppercase letters may not be treated as being distinct.

1911 header name significant characters

Other Languages

Some languages (e.g., Ada, Fortran, Lisp, and Pascal) support the use of lowercase letters in an identifier, but treat them as being equivalent to their corresponding uppercase letters. Java and Modula-2 treat lower- and uppercase letters as being distinct.

Coding Guidelines

The visual similarity of these letters is discussed elsewhere.

792 character visual similarity

---

795 There is no specific limit on the maximum length of an identifier.

Commentary

The standard does specify a minimum limit on the number of characters a translator must consider as significant. Implementations are free to ignore characters once this limit is reached. The ignored characters do not form part of another token. It is as if they did not appear in the source at all.

282 internal identifier significant characters
283 external identifier significant characters

C90

The C90 Standard does not explicitly state this fact.

Other Languages

Few languages place limits on the maximum length of an identifier that can appear in a source file. Like C, some specify a lower limit on the number of characters that must be considered significant.

Coding Guidelines

Using a large number of characters in an identifier spelling has many potential benefits; for instance, it provides the opportunity to supply a lot of information to readers, or to reduce dependencies on existing reader knowledge by spelling words in full rather than using abbreviations. There are also potential costs; for instance, they can cause visual layout problems in the source (requiring new-lines within an expression in an attempt to keep the maximum line length within the bounds that can be viewed within a fixed-width window), or increase the cognitive effort needed to visually scan source containing them.

The length of an identifier is not itself directly a coding guideline issue. However, length is indirectly involved in many identifier memorability, confusability, and usability issues, which are discussed elsewhere.

792 identifier syntax

Usage

The distribution of identifier lengths is given in Figure 792.7.

---

796 Each universal character name in an identifier shall designate a character whose encoding in ISO/IEC 10646 falls into one of the ranges specified in annex D.[60)]

identifier UCN

Commentary

Using other UCNs results in undefined behavior (in some cases even using these UCNs can be a constraint violation). These character encodings could be thought of as representing letters in the specified national character set.

816 UCNs not basic character set

C90

Support for universal character names is new in C99.

Other Languages

The ISO/IEC 10646 standard is relatively new and languages are only just starting to include support for the characters it specifies. Java specifies a similar list of UCNs.

28 ISO 10646

Common Implementations

A collating sequence may not be defined for these universal character names. In practice a lack of a defined collating sequence is not an implementation problem. Because a translator only ever needs to compare the spelling of one identifier for equality with another identifier, which involves a simple character-by-character comparison (the issue of the ordering of diacritics is handled by not allowing them to occur in an identifier).

Support for this functionality is new and the extent to which implementations are likely to check that UCN values fall within the list given in annex D is not known.

Coding Guidelines

The intended purpose for supporting universal character names in identifiers is to reduce the developer effort needed to comprehend source. Identifiers spelled in the developer's native tongue are more immediately recognizable (because of greater practice with those characters) and also have semantic associations that are more readily brought to mind.

ISO 10646 28 The ISO 10646 Standard does not specify which languages contain the characters it specifies (although it does give names to some sets of characters that correspond to a language that contains them). The written form of some human languages share common characters; for instance, the characters *a* through *z* (and their orthography 792 uppercase forms) appear in many European orthographies. The following discussion refers to using UCNs from more than one human language. This is to be taken to mean using UCNs that are not part of the written form of the native language of the developer (the case of developers having more than one native language is not considered). For instance, the character *a* is used in both Swedish and German; the character û is used in Swedish, but not German; the character ß is used in German but not Swedish. Both Swedish and German developers would be familiar with the character *a*, but the character ß would be considered foreign to a Swedish developer, and the character û foreign to the German.

Some coding guideline documents recommend against the use of UCNs. Their use within identifiers can increase the portability cost of the source. The use of UCNs is an economic issue; the potential cost of not permitting their use in identifiers needs to be compared against the potential portability benefits. (Alternatively, the benefits of using UCNs could be compared against the possible portability costs.)

Given the purpose of using UCNs, is there any rationale for identifiers to contain characters from more than one human language? As an English speaker, your author can imagine a developer wanting to use an English word, or its common abbreviation, as a prefix or suffix to an identifier name. Perhaps an Urdu speaker can imagine a similar usage with Urdu words. The issue is whether the use of characters in the same identifier from different human languages has meaning to the developers who write and maintain the source.

Identifiers very rarely occur in isolation. Should all the identifiers in the same function, or even source file, only contain UCNs that form the set of characters used by a single human language? Using characters from different human languages when it is possible to use only characters from a single language, potentially increases the cost of maintenance. Future maintainers are either going to have to be familiar with the orthography and semantics of the two human languages used or spend additional time processing instances of identifiers containing characters they are not familiar with. However, in some cases it might not be possible to enforce a *single human language* rule. For instance, a third-party library may contain callable functions whose spellings use characters from a human language different from that used in the source code that contains calls to it.

Support for the use of UCNs in identifiers is new in C99 (and other computer languages) and at the time of this writing there is almost no practical experience available on the sort of mistakes that developers make with them.

The initial character shall not be a universal character name designating a digit. 797

Commentary

identifier 792 syntax The terminal *identifier-nondigit* that appears in the syntax implies that the possible UCNs exclude the digit characters. Also the list given in annex D does not include the digit characters. This means that an identifier containing a UCN designating a digit in any position results in undefined behavior.

The syntax for constants does not support the use of UCNs. This sentence, in the standard, reminds implementors that such usage could be supported in the future and that, while they may support UCN digits within an identifier, it would not be a good idea to support them as the initial character. 822 constant syntax

Table 797.1: The Unicode digit encodings.

Encoding Range	Language	Encoding Range	Language
0030–0039	ISO Latin-1	0BE7–0BEF	Tamil (has no zero)
0660–0669	Arabic–Indic	0C66–0C6F	Telugu
06F0–06F9	Eastern Arabic–Indic	0CE6–0CEF	Kannada
0966–096F	Devanagari	0D66–0D6F	Malayalam
09E6–09EF	Bengali	0E50–0E59	Thai
0A66–0A6F	Gurmukhi	0ED0–0ED9	Lao
0AE6–0AEF	Gujarati	FF10–FF19	Fullwidth
0B66–0B6F	Oriya digits		

C++

This requirement is implied by the terminal non-name used in the C++ syntax. Annex E of the C++ Standard does not list any UCN digits in the list of supported UCN encodings.

Other Languages

Java has a similar requirement.

Coding Guidelines

The extent to which different cultural conventions support the use of a digit as the first character in an identifier is not known to your author. At some future date the Committee may chose to support the writing of integer constants using UCNs. If this happens, any identifiers that start with a UCN designating a digit are liable to result in syntax violations. There does not appear to be a worthwhile benefit in a guideline recommendation dealing with the case of an identifier beginning with a UCN designating a digit.

Example

```
1  int \u1f00\u0ae6;
2  int \u0ae6;
```

---

798 An implementation may allow multibyte characters that are not part of the basic source character set to appear in identifiers; identifier multibyte character in

Commentary

Prior to C99 there was no standardized method of representing nonbasic source character set characters in the source code. Support for multibyte characters in string literals and constants was specified in C90; some implementations extended this usage to cover identifiers. They are now officially sanctioned to do this. Support for the ISO 10646 Standard is new in C99. However, there are a number of existing implementations that use a multibyte encoding scheme and this usage is likely to continue for many years. The C committee recognized the importance of this usage and do not force developers to go down a UCN-only path. 28 ISO 10646

The standard says nothing about the behavior of the **__func__** reserved identifier in the case when a function name is spelled using wide characters. 810 __func__

C90

This permission is new in C99.

C++

translation phase 1 116

The C++ Standard does not explicitly contain this permission. However, translation phase 1 performs an implementation-defined mapping of the source file characters, and an implementation may choose to support multibyte characters in identifiers via this route.

Other Languages

While other language standards may not mention multibyte characters, the problem they address is faced by implementations of those languages. For this reason, it is to be expected that some implementations of other languages will contain some form of support for multibyte characters.

Coding Guidelines

universal character name syntax 815

UCNs may be the preferred, C Standard way, of representing nonbasic character set characters in identifiers. However, developers are at the mercy of editor support for how they enter and view characters that are not in the basic source character set.

---

which characters and their correspondence to universal character names is implementation-defined. 799

Commentary

Various national bodies have defined standards for representing their national character sets in computer files. While ISO 10646 is intended to provide a unified standard for all characters, it may be some time before existing software is converted to use it.

ISO 10646 28

Common Implementations

It is common to find translators aimed at the Japanese market supporting JIS, shift-JIS, and EUC encodings (see Table 243.3). These encoding use different numeric values than those given in ISO 10646 to represent the same national character.

When preprocessing tokens are converted to tokens during translation phase 7, if a preprocessing token could be converted to either a keyword or an identifier, it is converted to a keyword. 800

Commentary

The Committee could have created a separate name space for keywords and allowed developers to define identifiers having the same spelling as a keyword. The complexity added to a translator by such a specification would be significant (based on implementation experience for languages that support this functionality), while a developer's inability to define identifiers having these spellings was considered a relatively small inconvenience.

C90

This wording is a simplification of the convoluted logic needed in the C90 Standard to deduce from a constraint what C99 now says in semantics. The removal of this C90 constraint is not a change of behavior, since it was not possible to write a program that violated it.

C90 6.1.2

Constraints

In translation phase 7 and 8, an identifier shall not consist of the same sequence of characters as a keyword.

Other Languages

Some languages allow keywords to be used as variable names (e.g., PL/1), using the context to disambiguate intended use.

---

footnote 60

60) On systems in which linkers cannot accept extended characters, an encoding of the universal character name may be used in forming valid external identifiers. 801

Commentary

This is really an implementation tip for translators. The standard defines behavior in terms of an abstract machine that produces external output. The tip given in this footnote does not affect the conformance status of an implementation that chooses to implement this functionality in another way. The only time such a mapping might be visible is through the use of a symbolic execution-time debugging tool, or by having to link against object files created by other translators.

C90

Extended characters were not available in C90, so the suggestion in this footnote does not apply.

215 extended characters

Other Languages

Issues involving third-party linkers are common to most language implementations that compile to machine code. Some languages, for instance Java, define the characteristics of an implementation at translation and execution time. The Java language specification goes to the extreme (compared to other languages) of specifying the format of the generated file object code file.

Common Implementations

There is a long-standing convention of prefixing externally visible identifier names with an underscore character when information on them is written out to an object file. There is little experience available on implementation issues involving UCNs, but many existing linkers do assume that identifiers are encoded using 8-bit characters.

Coding Guidelines

The encoding of external identifiers only needs to be considered when interfacing to, or from code written in another language. Cross-language interfacing is outside the scope of these coding guidelines.

---

802 For example, some otherwise unused character or sequence of characters may be used to encode the **\u** in a universal character name.

Commentary

Some linkers may not support an occurrence of the backslash (\) character in an identifier name. One solution to this problem is to create names that cannot be declared in the source code by the developer; for instance, by deleting the \ characters and prefixing the name with a digit character.

Common Implementations

There are no standards for encoding of universal character names in object files. The requirement to support this form of encoding is too new for it to be possible to say anything about common encodings.

---

803 Extended characters may produce a long external identifier.

Commentary

Here the word *long* does not have any special meaning. It simply suggests an identifier containing many characters.

282 internal identifier significant characters

Implementation limits

---

804 As discussed in 5.2.4.1, an implementation may limit the number of significant initial characters in an identifier;

Implementation limits

Commentary

This subclause lists a number of minimum translation limits

276 translation limits

C90

The C90 Standard does not contain this observation.

C++

2.10p1 *All characters are significant.*[20)]

C identifiers that differ after the last significant character will cause a diagnostic to be generated by a C++ translator.

Annex B contains an informative list of possible implementation limits. However, " . . . these quantities are only guidelines and do not determine compliance.".

---

the limit for an *external name* (an identifier that has external linkage) may be more restrictive than that for an *internal name* (a macro name or an identifier that does not have external linkage). 805

Commentary

external 283 identifier significant characters

External identifiers have to be processed by a linker, which may not be under the control of a vendor's C implementations. In theory, any tool that performs the linking process falls within the remit of the C Committee. However, the Committee recognized that, in practice, it is not always possible for translator vendors to supply their own linker. The limitations of existing linkers needed to be factored into the limits specified in the standard.

internal 282 identifier significant characters

Internal identifiers only need to be processed by the translator and the standard is in a strong position to specify the behavior.

Other Languages

Most other language implementations face similar problems with linkers as C does. However, not all language specifications explicitly deal with the issue (by specifying the behavior). The Java standard defines a complete environment that handles all external linkages.

Coding Guidelines

What are the costs associated with a change to the linkage of an identifier during program maintenance, from internal linkage to external linkage? (Experience shows that identifier linkage is rarely changed from external to internal?)

external 283 identifier significant characters identifier 792 number of characters

In most cases implementations support a sufficiently large number of significant characters in an external name that a change of identifier linkage makes no difference to its significant characters (i.e., the number of characters it contains falls inside the implementation limit). In those cases where a change of identifier linkage results in some of its significant characters being ignored, the affect may be benign (there is no other identifier defined with external linkage whose name is the same as the truncated name) or results in undefined behavior (the program defines two identifiers with external linkage with the same name).

external 1818 linkage exactly one external definition

The number of significant characters in an identifier is implementation-defined. 806

Commentary

internal 282 identifier significant characters

Subject to the minimum requirements specified in the standard.

C++

2.10p1 *All characters are significant.*[20)]

References to the same C identifier, which differs after the last significant character, will cause a diagnostic to be generated by a C++ translator.

There is also an informative annex which states:

Annex Bp2

Number of initial characters in an internal identifier or a macro name [1024]

Number of initial characters in an external identifier [1024]

Other Languages

Some languages require all characters in an identifier to be significant (e.g., Java, Snobol 4), while others don't (e.g., Cobol, Fortran).

Common Implementations

It is rare to find an implementation that does not meet the minimum limits specified in the standard. A few translators treat all identifiers as significant. Most have a limit of between 256 and 2,000 significant characters. The POSIX standard requires that any language that binds to its API needs to support 14 significant characters in an external identifier.

Coding Guidelines

While the C90 minimum limits for the number of significant characters in an identifier might be considered unacceptable by many developers, the C99 limits are sufficiently generous that few developers are likely to complain.

Automatically generated C source sometimes relies on a large number of significant characters in an identifier. This can occur because of the desire to simplify the implementation of the generator. Character sequences in different offsets within an identifier might be reserved for different purposes. Predefined default character sequence is used to pad the identifier spelling where necessary.

As the following example shows, it is possible for a program's behavior to change, both when the number of significant identifiers is increased and when it is decreased.

```
1  /*
2   * Yes, C99 does specify 64 significant characters in an internal
3   * identifier.  But to keep this example within the page width
4   * we have taken some liberties.
5   */
6
7  extern float _________1_________2_________3___bb;
8
9  void f(void)
10 {
11 int _________1_________2_________3___ba;
12
13 /*
14  * If there are 34 significant characters, the following operand
15  * will resolve to the locally declared object.
16  *
17  * If there are 35 significant characters, the following operand
18  * will resolve to the globally declared object.
19  */
20 _________1_________2_________3___bb++;
21 }
22
23 void g(void)
24 {
25 int _________1_________2_________3___aa;
26
27 /*
28  * If there are 34 significant characters, the following operand
29  * will resolve to the globally declared object.
30  *
31  * If there are 33 significant characters, the following operand
32  * will resolve to the locally declared object.
33  */
```

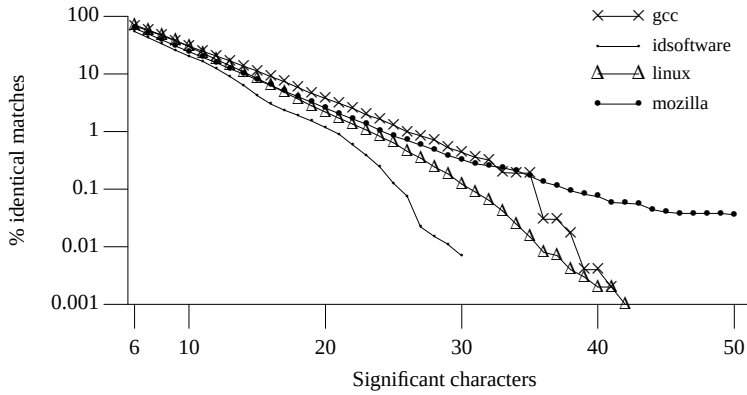

Figure 806.1: Occurrence of unique identifiers whose significant characters match those of a different identifier (as a percentage of all unique identifiers in a program), for various numbers of significant characters. Based on the visible form of the `.c` files.

```
34  __________1_________2_________3___bb++;
35  }
```

The following issues need to be addressed:

- All references to the same identifier should use the same character sequence; that is, all characters are intended to be significant. References to the same identifiers that differ in nonsignificant characters need to be treated as faults.
- Within how many significant characters should different identifiers differ? Should identifiers be required to differ within the minimum number of significant characters specified by the standard, or can a greater number of characters be considered significant?

reading 770 kinds of
identifiers 792 Greek readers
word 770 reading individual

Readers do not always carefully check all characters in the spelling of an identifier. The contribution made by characters occurring in different parts of an identifier will depend on the pattern of eye movements employed by readers, which in turn may be affected by their reasons for reading the source, plus cultural factors (e.g., direction in which they read text in their native language, or the significance of word endings in their native language). Characters occurring at both ends of an identifier are used by readers (at least native English- and French-speaking ones) when quickly scanning text.

Cg 806.1 When performing similarity checks on identifiers, all characters shall be considered significant.

Any identifiers that differ in a significant character are different identifiers. 807

Commentary

In many cases different identifiers also denote different entities. In a some cases they denote the same entity (e.g., two different typedef names that are synonyms for the type **`int`**).

Other Languages

This statement is common to all languages (but it does not always mean that they necessarily denote different entities).

Coding Guidelines

Identifiers that differ in a single significant character may be considered to be

- different identifiers by a translator, but considered to be the same identifier by some readers of the source (because they fail to notice the difference).
- the same identifiers by a translator (because the difference occurs in a nonsignificant character), but considered to be different identifiers by some readers of the source (because they treat all characters as being significant).
- identifiers by both a translator and some readers of the source.

The possible reasons for readers making mistakes are discussed elsewhere, as are the guideline recommendations for reducing the probability that these developer mistakes become program faults.

0 developer errors
792 identifier filtering spellings

Example

```
1  extern int e1;
2  extern long e1;
3  extern int a_longer_more_meaningful_name;
4  extern int a_longer_more_meeningful_name;
5  extern int a_meaningful_more_longer_name;
```

808 If two identifiers differ only in nonsignificant characters, the behavior is undefined.

Commentary

While the obvious implementation strategy is to ignore the nonsignificant characters, the standard does not require implementations to use this strategy. To speed up identifier lookup many implementations use a hashed symbol table— the hash value for each identifier is computed from the sequence of characters it contains. Computing this hash value as the characters are read in, to form an identifier, saves a second pass over those same characters later. If nonsignificant characters were included in the original computed hash value, a subsequent occurrence of that identifier in the source, differing in nonsignificant characters, would result in a different hash value being calculated and a strong likelihood that the hash table lookup would fail.

Developers generally expect implementations to ignore nonsignificant characters. An implementation that behaved differently because identifiers differed in nonsignificant characters might not be regarded as being very user friendly. Highlighting misspellings that occur in nonsignificant characters is not always seen in a positive light by some developers.

C++

In C++ all characters are significant, thus this statement does not apply in C++.

Other Languages

Some languages specify that nonsignificant characters are ignored and have no effect on the program, while others are silent on the subject.

Common Implementations

Most implementations simply ignore nonsignificant characters. They play no part in identifier lookup in symbol tables.

Coding Guidelines

The coding guideline issues relating to the number of characters in an identifier that should be considered significant are discussed elsewhere.

792 identifier guideline significant characters

809 **Forward references:** universal character names (6.4.3), macro replacement (6.10.3).

6.4.2.2 Predefined identifiers

Semantics

__func__ The identifier **__func__** shall be implicitly declared by the translator as if, immediately following the opening brace of each function definition, the declaration 810

```
static const char __func__[] = "function-name";
```

appeared, where *function-name* is the name of the lexically-enclosing function.[61)]

Commentary

Implicitly declaring **__func__** immediately after the opening brace in a function definition means that the first, developer-written declaration within that function can access it. Giving **__func__** static storage duration enables its address to be referred to outside the lifetime of the function that contains it (e.g., enabling a call history to be displayed at some later stage of program execution). This is not a storage overhead because space needs to be allocated for the string literal denoted by **__func__**. The **const** qualifier ensures that any attempts to modify the value cause undefined behavior. The identifier **__func__** has an array type, and is not a string literal, so the string concatenation that occurs in translation phase 6 is not applicable.

translation phase 6 135

This identifier is useful for providing execution trace information during program testing. Developers who make use of UCNs may need to ensure that the library they use supports the character output required by them:

```
#include <stdio.h>

void \u30CE(void)
{
printf ("Just entered %s\n", __func__);
}
```

identifier multibyte character in 798

The issue of wide characters in identifiers is discussed elsewhere.

Which function name is used when a function definition contains the **inline** function specifier? In:

```
#include <stdio.h>

inline void f(void)
{
printf("We are in %s\n", __func__);
}

int main(void)
{
f();
printf("We are in %s\n", __func__);
}
```

the name of the function `f` is output, even if that function is inlined into `main`.

C90

Support for the identifier **__func__** is new in C99.

C++

Support for the identifier **__func__** is new in C99 and is not available in the C++ Standard.

Common Implementations

A translator only needs to declare **__func__** if a reference to it occurs within a function. An obvious storage saving optimization is to delay any declaration until such time as it is known to be required. Another optimization is for the storage allocated for **__func__** to exactly overlay that allocated to the string literal. Allocating storage for a string literal and copying the characters to the separately allocated object it initializes is not necessary when that object is defined using the **const** qualifier. `gcc` also supports the built-in form **__FUNCTION__**.

Example

Debugging code in functions can provide useful information. But when there are lots of functions, the quantity of useless information can be overwhelming. Controlling which functions are to output debugging information by using conditional compilation requires that code be edited and the program rebuilt.

The names of functions can be used to dynamically control which functions are to output debugging information. This control not only reduces the amount of information output, but can also reduce execution time by orders of magnitude (output can be a resource-intense operation).

flookup.h

```
typedef struct f__rec {
                      char *func_name;
                      _Bool enabled;
                      struct f__rec *next;
                      } func__list;

extern _Bool func_lookup(func__list *, char *);

/*
 * Use the name of the function to control whether debugging is
 * switched on/off.  lookup is only called the first time this code
 * is executed, thereafter the value f___l->enabled can be used.
 */
#define D_func_trace(func_name, code)  {           \
                 static func__list * f___l = NULL; \
                 if (f___l ? f___l->enabled : lookup(&f___l, func_name)) \
                    {code}                                               \
                 }
```

flookup.c

```
#include <stdbool.h>

#include "flookup.h"

/*
 * A fixed list of functions and their debug mode.
 * We could be more clever and make this a list which
 * could be added to as a program executes.
 */
static struct {
              char *func_name;
              _Bool enabled;
              func__list *traces_seen;
              } lookup_table[] = {
                                  "abc", true, NULL,
                                  NULL, false, NULL
                                  };

_Bool func_lookup(func__list *f_list, char *f_name)
{
/*
 * Loop through lookup_table looking for a match against f_name.
 * If a match is found, add f_list to the traces_seen list and
 * return the value of enabled for that entry.
 */
}

void change_enabled_setting(char *f_name, _Bool new_enabled)
{
/*
 * Loop through lookup_table looking for a match against f_name.
 * If a match is found, loop over its traces_seen list setting
```

```
33    * the enabled flag to new_enabled.
34    *
35    * This function can switch on/off the debugging output from
36    * any registered function.
37    */
38   }
```

This name is encoded as if the implicit declaration had been written in the source character set and then translated into the execution character set as indicated in translation phase 5. 811

Commentary

translation phase 5 133

Having the name appearing as if in translation phase 5 avoids any potential issues caused by macro names defined with the spelling of keywords or the name **__func__**. It also enables a translator to have an identifier name and type predefined internally, ready to be used when this reserved identifier is encountered. Translation phase 5 is also where characters get converted to their corresponding members in the execution character set, an essential requirement for spelling a function name. In many implementations the function name written to the object file, or program image, is different from the one appearing in the source. This translation phase 5 requirement ensures that it is not any modified name that is used.

program image 141

Example

```
1   #include <stdio.h>
2
3   #define __func__ __CNUF__
4   #define __CNUF__ "g"
5
6   void f(void)
7   {
8   /*
9    * The implicit declaration does not appear until after preprocessing.
10   * So there is no declaration 'static const char __func__[] = "f";'
11   * visible to the preprocessor (which would result in __func__ being
12   * mapped to __CNUF__ and "f" rather than "g" being output).
13   */
14  printf("Name of function is %s\n", __CNUF__);
15  }
```

EXAMPLE Consider the code fragment: 812

```
#include <stdio.h>
void myfunc(void)
{
        printf("s\n", __func__);
        /* ... */
}
```

Each time the function is called, it will print to the standard output stream:
myfunc

Commentary

This assumes that the standard output stream is not closed (in which case the behavior would be undefined).

Forward references: function definitions (6.9.1). 813

814 61) Since the name **__func__** is reserved for any use by the implementation (7.1.3), if any other identifier is explicitly declared using the name **__func__**, the behavior is undefined. footnote 61

Commentary

The name is reserved because it begins with two underscores. The fact that the standard defines an interpretation for this name in the identifier name space in block scope does not give any license to the developer to use it in other name spaces or at file scope. This name is still reserved for use in other name spaces and scopes.

C90

Names beginning with two underscores were specified as reserved for any use by the C90 Standard. The following program is likely to behave differently when translated and executed by a C99 implementation.

```
1  #include <stdio.h>
2
3  int main(void)
4  {
5  int __func__ = 1;
6
7  printf("d\n", __func__);
8  }
```

C++

Names beginning with __ are reserved for use by a C++ implementation. This leaves the way open for a C++ implementation to use this name for some purpose.

6.4.3 Universal character names

815 universal character name syntax

universal-character-name:
    \u *hex-quad*
    \U *hex-quad hex-quad*
hex-quad:
    hexadecimal-digit hexadecimal-digit
        hexadecimal-digit hexadecimal-digit

Commentary

It is intended that this syntax notation not be visible to the developer,when reading or writing the source code that contains instances of this construct. A *universal-character-name* aware editor being used to display the ISO 10646 character represented by the numeric value specified by the *hex-quad* sequence value. Without such editor support, the whole rationale for adding these characters to C, allowing developers to read and write identifiers in their own language, is voided.

C90

Support for this syntactic category is new in C99.

Other Languages

Java calls this lexical construct a *UnicodeInputCharacter* (and does not support the \U form, only the \u one).

Coding Guidelines

It is difficult to imagine developers regularly using UCNs with an editor that does not display UCNs in some graphical form. A guideline recommending the use of such an editor would not be telling developers anything they did not already know.

A number of theories about how people recognize words have been proposed. One of the major issues yet 792 Word recognition models of

to be resolved is the extent to which readers make use of *whole word* recognition versus mapping character sequences to sound (phonological coding). Support for UCNs increases the possibility that developers will encounter unfamiliar characters in source code. The issue of developer performance in handling unfamiliar characters is discussed elsewhere.

reading 792 characters unknown to reader

Example

```
#define foo(x)

void f(void)
{
foo("\\u0123") /* Does not contain a UCN. */
foo(\\u0123);  /* Does contain a UCN. */
}
```

Constraints

UCNs not basic character set

A universal character name shall not specify a character whose short identifier is less than 00A0 other than 0024 (`$`), 0040 (`@`), or 0060 (`‘`), nor one in the range D800 through DFFF inclusive.[62)] 816

Commentary

ISO 10646 28

The ISO 10646 Standard defines the ranges 00 through 01F, and 07F through 09F, as the 8-bit control codes (what it calls *C0* and *C1*). Most of the UCNs with values less than 00A0 represent characters in the basic source character set. The exceptions listed enumerate characters that are in the Ascii character set, but not in the basic source character set. The ranges 0D800 through DBFF and 0DC00 through 0DFFF are known as the surrogate ranges. The purpose of these ranges is to allow representation of rare characters in future versions of the Unicode standard.

This constraint means that source files cannot contain the UCN equivalent for any members of the basic source character set.

Rationale

UCNs are not permitted to designate characters from the basic source character set in order to permit fast compilation times for C programs. For some real world programs, compilers spend a significant amount of time merely scanning for the characters that end a quoted string, or end a comment, or end some other token. Although, it is trivial for such loops in a compiler to be able to recognize UCNs, this can result in a surprising amount of overhead.

A UCN is constrained not to specify a character short identifier in the range 0000 through 0020 or 007F through 009F inclusive for the same reason: this avoids allowing a UCN to designate the newline character. Since different implementations use different control characters or sequences of control characters to represent newline, UCNs are prohibited from representing any control character.

C++

2.2p2 *If the hexadecimal value for a universal character name is less than 0x20 or in the range 0x7F–0x9F (inclusive), or if the universal character name designates a character in the basic source character set, then the program is ill-formed.*

The range of hexadecimal values that are not permitted in C++ is a subset of those that are not permitted in C. This means that source which has been accepted by a conforming C translator will also be accepted by a conforming C++ translator, but not the other way around.

Other Languages

Java has no such restrictions on the hexadecimal values.

Common Implementations

Support for UCNs is new in C99. It remains to be seen whether translator vendors decide to support any UCN hexadecimal value as an extension.

Example

```
1  \u0069\u006E\u0074 glob; /* Constraint violation. */
```

Description

817 Universal character names may be used in identifiers, character constants, and string literals to designate characters that are not in the basic character set.

Commentary

UCNs may also appear in comments. However, comments do not have a lexical structure to them. Inside a comment character, sequences starting with \u are not treated as UCNs by a translator, although other tools may choose to do so, in this context. The mapping of UCNs in character constants and string literals to the execution character set occurs in translation phase 5.

The constraint on the range of values that a UCN may take prevents them from being used to represent keywords.

816 UCNs not basic character set

C++

The C++ Standard also supports the use of universal character names in these contexts, but does not say in words what it specifies in the syntax (although 2.2p2 comes close for identifiers).

Other Languages

In Java, *UnicodeInputCharacters* can represent any character and is mapped in lexical translation step 1. It is possible for every character in the source to appear in this form. The mapping only occurs once, so \u005cu005a becomes \u005a, not Z (005c is the Unicode value for \ and 005a is the Unicode character for Z).

Coding Guidelines

UCNs in character constants and string literals are used to represent characters that are output when a program is executed, or in identifiers to provide more readable source code. In the former case it is possible that UCNs from different natural languages will need to be represented. In the latter case it might be surprising if source code contained UCNs from different languages. This usage is a complex one involving issues outside of these coding guidelines (e.g., configuration management and customer requirements) and your author has insufficient experience to know whether any guideline recommendations might be worthwhile.

Some of the coding guideline issues relating to the use of characters outside of the basic execution character set are discussed elsewhere.

238 multibyte character source contain

Example

```
1  #include <wchar.h>
2
3  int \u0386\u0401;
4  wchar_t *hello = "\u05B0\u0901";
```

Semantics

short identifier

The universal character name \U*nnnnnnnn* designates the character whose eight-digit short identifier (as specified by ISO/IEC 10646) is *nnnnnnnn*.[63)] 818

Commentary

The standard specifies how UCNs are represented in source code. A development environment may chose to provide, to developers, a visible representation of the UCN that matches the glyph with the corresponding numeric value in ISO 10646. The ISO 10646 BNF syntax for short identifiers is:

ISO 10646 short identifier

```
{ U | u } [ {+}(xxxx | xxxxx | xxxxxx) | {-}xxxxxxxx ]
```

where x represents a hexadecimal digit.

Other Languages

Java does not support eight-digit universal character names.

Coding Guidelines

external identifier 283
significant characters

This form of UCN counts toward a greater number of significant characters in identifiers with external linkage and therefore is not the preferred representation. However, the developer may not have any control over the method used by an editor to represent UCNs. Given that characters from the majority of human languages can be represented using four-digit short identifiers, eight-digit short identifiers are not likely to be needed. If the development environment offers a choice of representations, use of four-digit short identifiers is likely to result in more significant characters being retained in identifiers having external linkage.

Similarly, the universal character name \u*nnnn* designates the character whose four-digit short identifier is *nnnn* (and whose eight-digit short identifier is 0000*nnnn*). 819

Commentary

It was possible to represent all of the characters specified by versions 1 and 2 of the Unicode-sponsored character set using four-digit short identifiers. Version 3 introduced characters whose representation value requires more than four digits.

Other Languages

Java only supports this form of four-digit universal character names.

footnote 62

62) The disallowed characters are the characters in the basic character set and the code positions reserved by ISO/IEC 10646 for control characters, the character DELETE, and the S-zone (reserved for use by UTF-16). 820

Commentary

basic character set 215

Requiring that characters in the basic character set not be represented using UCN notation helps guarantee that existing tools (e.g., editors) continue to be able to process source files.

The control characters may have special meaning for some tools that process source files (e.g., a communications program used for sending source down a serial link).

C++

The C++ Standard does not make this observation.

footnote 63

63) Short identifiers for characters were first specified in ISO/IEC 10646–1/AMD9:1997. 821

Commentary

This amendment appeared eight years after the first publication of the C Standard (which was made by ANSI in 1989).

6.4.4 Constants

822 constant syntax

```
constant:
        integer-constant

        floating-constant
        enumeration-constant
        character-constant
```

Commentary

A *constant* differs from a *constant-expression* in that it consists of a single token. The term *literal* is often used by developers to refer to what the C Standard calls a *constant* (technically the only literals C contains are string literals). There is a more general usage of the term *constant* to mean something whose value does not change. What the C Standard calls a *constant-expression* developers often shorten to *constant*.

1322 constant expression syntax

895 string literal syntax

C++

> *21) The term "literal" generally designates, in this International Standard, those tokens that are called "constants" in ISO C.*

Footnote 21

The C++ Standard also includes *string-literal* and *boolean-literal* in the list of literals, but it does not include enumeration constants in the list of literals. However:

> *The identifiers in an* `enumerator-list` *are declared as constants, and can appear wherever constants are required.*

7.2p1

The C++ terminology more closely follows common developer terminology by using *literal* (a single token) and *constant* (a sequence of operators and literals whose value can be evaluated at translation time). The value of a literal is explicit in the sequence of characters making up its token. A constant may be made up of more than one token or be an identifier. The operands in a constant have to be evaluated by the translator to obtain its result value. C uses the more easily confused terminology of *integer-constant* (a single token) and *constant-expression* (a sequence of operators, *integer-constant* and *floating-constant* whose value can be evaluated at translation time).

Other Languages

Languages that support types not supported by C (e.g., instance sets) sometimes allow constants having these types to be specified (e.g., in Pascal `['a', 'd']` represents a set containing two characters). Fortran supports complex literal constants (e.g., `(1.0, 2.0)` represents the complex number $1.0 + 2.0i$)

Many languages do not support (e.g., Java until version 1.5) some form of *enumeration-constant*.

Coding Guidelines

Constants are the mechanism by which numeric values are written into source code. The term *constant* is used because the numeric values do not change during program execution (and are known at translation time;

although in some cases a person reading the source may only know that the value used will be one of a list of possible values because the definition of a macro may be conditional on the setting of some translation time option— for instance, `-D`).

macro 1931 object-like

The use of constants in source code creates a number of possible maintenance issues, including:

- A constant value, representing some quantity, often needs to occur in multiple locations within source code. Searching for and replacing all occurrences of a particular numeric value in the code is an error prone process. It is not possible, for instance, to know that all `15`s occurring in the source code have the same semantic association and some may need to remain unchanged. (Your author was once told by a developer, whose source contained lots of `15`s, that the UK government would never change value-added tax from 15%; it is now 17.5%.)
- On encountering a constant in the source, a reader usually needs to deduce its semantic association (either in the application domain or its internal algorithmic function). While its semantics may be very familiar to the author of the source, the association between value and semantics may not be so readily made by later readers.
- A cognitive switch may need to be made because of the representation used for the constant (e.g., floating point, hexadecimal integer, or character constant).

cognitive 0 switch

symbolic name

One solution to these problems is to use an identifier to give a symbolic name[822.1] to the constant, and to use that symbolic name wherever the constant would have appeared in the source. Changes to the value of the constant can then be made by a single modification to the definition of the identifier and a well-chosen name can help readers make the appropriate semantic association. The creation of a symbolic name provides two pieces of information:

1. *The property represented by that symbolic name.* For instance, the maximum value of a particular type (`INT_MAX`), whether an implementation supports some feature (`__STDC_IEC_559__`), a means of specifying some operation (`SEEK_SET`), or a way to obtain information (`FE_OVERFLOW`).
2. *A method of operating on the symbolic name to access the property it represents.* For instance, arithmetic operations (`INT_MAX`), testing in a conditional preprocessing directive (`__STDC_IEC_559__`), passing as an argument to a library function (`SEEK_SET`); passing as an argument to a library function, possibly in combination with other symbolic names (`FE_OVERFLOW`).

INT_MAX 318 2015
__STDC_IEC_559__ macro

Operating on symbolic names involves making use of representation information. (Assignment, or argument passing, is the only time that representation might not be an issue.) The extent to which the use of representation information will be considered acceptable will depend on the symbolic name. For instance, `FE_OVERFLOW` appearing as the operand of a bitwise operator is to be expected, but its appearance as the operand of an arithmetic operator would be suspicious.

The use of symbolic names is rarely seen by developers, as applying to all constants that occur in source code. In some cases the following are claimed:

- The constants are so sufficiently well-known that there is no need to give them a name.
- The number of occurrences of particular constants is not sufficient to warrant creating a name for them.
- Operations involving some constant values occur so frequently that their semantic associations are obvious to developers; for instance, assigning `0` or adding `1`.

It is true that not all numeric values are meaningless to everybody. A few values are likely to be universally known (at least to Earth-based developers). For instance, there are 60 seconds in a minute, 60 minutes in an

[822.1] In some cases the linguistically more correct terminology would be *iconic name*.

hour, and 24 hours in a day. The value 24 occurring in an expression involving time is likely to represent hours in a day. Many values will only be well known to developers working within a given application domain, such as atomic physics (e.g., the value 6.6261E-34). Between these extremes are other values; for instance, 3.14159 will be instantly recognized by developers with a mathematics background. However, developers without this background may need to think about what it represents. There is the possibility that developers who have grown up surrounded by other mathematically oriented people will be completely unaware that others do not recognize the obvious semantic association for this value.

A constant having a particular semantic association may only occur once in the source. However, the issue is not how many times a constant having a particular semantic association occurs, but how many times the particular constant value occurs. The same constant value can appear because of different semantic associations. A search for a sequence of digits (a constant value) will locate all occurrences, irrespective of semantic association.

While an argument can always be made for certain values being so sufficiently well-known that there is no benefit in replacing them by identifiers, the effort/time taken in discussions on what values are sufficiently well-known to warrant standing on their own, instead of an identifier, is likely to be significantly greater than the sum total of all the extra one seconds, or so, taken to type the identifier.

The constant values 0 and 1 occur very frequently in source code (see Figure 825.1). Experience suggests that the semantic associations tend to be that of assigning an initial value in the case of 0 and accessing a preceding or following item in the case of 1. The coding guideline issues are discussed in the subsections that deal with the different kinds of constants (e.g., integer, or floating).

What form of definition should a symbolic name denoting constant value have? Possibilities include the following:

- *Macro names.* These are seen by developers as being technically the same as constants in that they are replaced by the numeric value of the constant during translation (there can also be an unvoiced bias toward perceived efficiency here).

- *Enumeration constants.* The purpose of an enumerated type is to associate a list of constants with each other. This is not to say the definition of an enumerated type containing a single enumeration constant should not occur, but this usage would be unusual. Enumeration constants share the same unvoiced developer bias as macro names— perceived efficiency.

517 enumeration
set of named constants

- *Objects initialized with the constant.* This approach is advocated by some coding guideline documents for C++. The extent to which this is because an object declared with the **const** qualifier really is constant and a translator need not allocate storage for it, or because use of the preprocessor (often called the C preprocessor, as if it were not also in C++) is frowned on in the C++ community and is left to the reader to decide.

The enumeration constant versus macro name issue is discussed in detail elsewhere.

517 enumeration
set of named constants

What name to choose? The constant 6.6261E-34 illustrates another pitfall. Planck's constant is almost universally represented, within the physics community, using the letter *h* (sometimes with embellishments, e.g., $\hbar$). A developer might be tempted to make use of this idiom to name the value, perhaps even trying to find a way of using UCNs to obtain the appropriate h. The single letter h probably gives no more information than the value. The name PLANCK_CONSTANT is self-evident. The developer attitude— anybody who does not know what 6.6261E-34 represents has no business reading the source— is not very productive or helpful.

Table 822.1: Occurrence of different kinds of constants (as a percentage of all tokens). Based on the visible form of the `.c` and `.h` files.

Kind of Constant	`.c` files	`.h` files
character-constant	0.16	0.06
integer-constant	6.70	20.79
floating-constant	0.02	0.20
string-literal	1.02	0.74

Constraints

constant representable in its type

The value of a constant shall be in the range of representable values for its type. 823

Commentary

constant 824 type determined by form and value

This is something of a circular definition in that a constant's value is also used to determine its type. The lexical form of a constant is also a factor in determining which of a number of possible types it may take. An unsuffixed constant that is too large to be represented in the type **`long long`**, or a suffixed constant that is larger than the type with the greatest rank applicable to that suffix, violates this requirement (unless there is some extended integer type supported by the implementation into whose range the value falls).

It can be argued that all floating constants are in range, if the implementation supports $\pm\infty$.

enumeration constant 1440 representable in int

There is a similar constraint for enumeration constants

C++

The C++ Standard has equivalent wording covering *integer-literals* (2.13.1p3) *character-literals* (2.13.2p3) and *floating-literals* (2.13.3p1). For *enumeration-literals* their type depends on the context in which the question is asked:

7.2p4 *Following the closing brace of an* `enum-specifier`*, each enumerator has the type of its enumeration. Prior to the closing brace, the type of each enumerator is the type of its initializing value.*

7.2p5 *The underlying type of an enumeration is an integral type that can represent all the enumerator values defined in the enumeration.*

Other Languages

Most languages have a similar requirement, even those supporting a single integer or floating type.

Common Implementations

Some implementations use the string-to-integer conversions provided by the library, while others prefer the flexibility (and fuller control of error recovery) afforded by specially written code. Parker[1055] describes the minimal functionality required.

Example

```
1  char ch = '\0\0\0\0y';
2
3  float f_1 = 1e99999999999999999999999999999999999999999999999;
4  float f_2 = 0e99999999999999999999999999999999999999999999999;
5  float f_3 = 1e-99999999999999999999999999999999999999999999999; /* Approximately zero. */
6  float f_4 = 0e-99999999999999999999999999999999999999999999999; /* Exact zero. */
7
8  short s_1 = 99999999999999999999999999999999999999999999999;
9  short s_2 = 99999999999999999999 / 99999999999999999999;
```

The integer constant 10000000000000000000L would violate this constraint on an implementation that represented the type **long long** in 64 bits. The use of an L suffix precludes the constant being given the type **unsigned long long**.

Semantics

824 Each constant ~~has a type, determined by its form and value, as detailed later.~~ shall have a type and the value of a constant shall be in the range of representable values for its type.

constant type determined by form and value

Commentary

Just as there are different floating and integer object types, the possible types that constants may have is not limited to a single type.

836 integer constant possible types

It is a constraint violation for a constant to occur during translation phrase 7 without a type.

136 translation phase 7

The requirement that a constant be in the range of representable values for its type is a requirement on the implementation.

841 integer constant no type

The wording was changed by the response to DR #298.

C++

The type of an integer literal depends on its form, value, and suffix. 2.13.1p2

The type of a floating literal is ***double*** *unless explicitly specified by a suffix. The suffixes* `f` *and* `F` *specify* ***float****, the suffixes* `l` *and* `L` *specify* ***long double****.* 2.13.3p1

There are no similar statements for the other kinds of literals, although C++ does support suffixes on the floating types. However, the syntactic form of string literals, character literals, and boolean literals determines their type.

Coding Guidelines

The type of a constant, unlike object types, can vary between implementations. For instance, the integer constant 40000 can have either the type **int** or **long int**. The suffix on the integer constant 40000u only ensures that it has one of the listed unsigned integer types. The coding guideline issues associated with the possibility that the type of a constant can vary between implementations is discussed elsewhere.

835 integer constant type first in list

long-long-suffix: one of
                ll  LL
```

Commentary

translation phase 7 (136)

constant expression syntax (1322)

Integer constants are created in translation phase 7 when the preprocessing tokens *pp-number* are converted into tokens denoting various forms of *constant*. *Integer-constant*s always denote positive values. The character sequence `-1` consists of the two tokens `{-}` `{1}`, a constant expression.

An *integer-suffix* can be used to restrict the set of possible types the constant can have, it also specifies the lowest rank an integer constant may have (which for *ll* or *LL* leaves few further possibilities). The *U*, or *u*, suffix indicates that the integer constant is unsigned.

All translation time integer constants are nonnegative. The character sequence `-1` consists of the token sequence unary minus followed by the *decimal-constant* `1`. Support for translation time negative constants in the lexical grammar would create unjustified complexity by requiring lexers to disambiguate binary from unary operators uses in, for instance: `X-1`.

C90

Support for *long-long-suffix* and the nonterminal *hexadecimal-prefix* is new in C99.

C++

The C++ syntax is identical to the C90 syntax.

Support for *long-long-suffix* and the nonterminal *hexadecimal-prefix* is not available in C++.

Common Implementations

Some implementations specify that the suffix *0b* (or *0B*) denotes an integer constant expressed in binary notation. Over the years the C Committee received a number of requests for such a suffix to be added to the C Standard. The Committee did not see sufficient utility for this suffix to be included in C99. The C embedded systems TR specifies *h* and *H* to denote the types **short frac** or **short accum**, and one of *k*, *K*, *r*, and *R* to denote a fixed-point type.

Embedded C TR (18)

The IBM ILE C compiler[617] supports a packed decimal data type. The suffix *d* or *D* may be used to specify that a literal has this type. Microsoft C supports the suffixes *i8*, *i16*, *i32*, and *i64* denoting integer

constants having the types **byte** (an extension), **short**, **int**, and **__int64**, respectively.

Other Languages

Although Ada supports integer constants having bases between 1 and 36 (e.g., 2#1101 is the binary representation for 10#13), few other languages support the use of suffixes. Ada also supports the use of underscores within an *integer-constant* to make the value more readable.

Coding Guidelines

A study by Brysbaert[174] found that the time taken for a person to process an Arabic integer between 1 and 99 was a function of the logarithm of its magnitude, the frequency of the number (based on various estimates of its frequency of occurrence in everyday life; see Dorogovtsev et al[367] for measurements of numbers appearing in web pages), and sometimes the number of syllables in the spoken form of the value. Subject response times varied from approximately 300 ms for values close to zero, to approximately 550 ms for values in the nineties.

Experience shows that the *long-suffix* `l` is often visually confused with the *nonzero-digit* `1`.[825.1]

Cg 825.1 If a *long-suffix* is required, only the form `L` shall be used.

Cg 825.2 If a *long-long-suffix* is required, only the form `LL` shall be used.

As previously pointed out, constants appearing in the visible form of the source often signify some quantity with real world semantics attached to it. However, uses of the integer constants 0 and 1 in the visible source often have no special semantics associated with their usage. They also represent a significant percentage of the total number of integer constants in the source code (see Figure 825.1). The frequency of occurrence of these values (most RISC processors dedicate a single register to permanently hold the value zero) comes about through commonly seen program operations. These operations include: code to count the number of occurrences of entities, or that contain loops, or index the previous or next element of an array (not that 0 or 1 could not also have similar semantic meaning to other constant values).

822 constant syntax

A blanket requirement that all integer constants be represented in the visible source by symbolic names fails to take into account that a large percentage of the integer constants used in programs have no special meaning associated with them. In particular the integer constants 0 and 1 occur so often (see Figure 825.1) that having to justify why each of them need not be replaced by a symbolic name would have a high cost for an occasional benefit.

Rev 825.3 No integer constant, other than 0 and 1, shall appear in the visible source code, other than as the sole preprocessing token in the body of a macro definition or in an enumeration definition.

Some developers are sloppy in the use of integer constants, using them where a floating constant was the appropriate type. The presence of a period makes it explicitly visible that a floating type is being used. The general issue of integer constant conversions is discussed elsewhere.

835.2 integer constant with suffix, not immediately converted

Example

The character sequence `123xyz` is tokenized as {`123xyz`}, a *pp-number*. This is not a valid integer constant.

927 pp-number syntax

Usage

Having some forms of constant tokens (also see Figure 842.1) follow Benford's law[574] would not be surprising because the significant digits of a set of values created by randomly sampling from a variety of

integer constant usage

[825.1] While the visual similarity between alphabetic letters has been experimentally measured your author is not aware of any experiment that has measured the visually similarity of digits with letters.

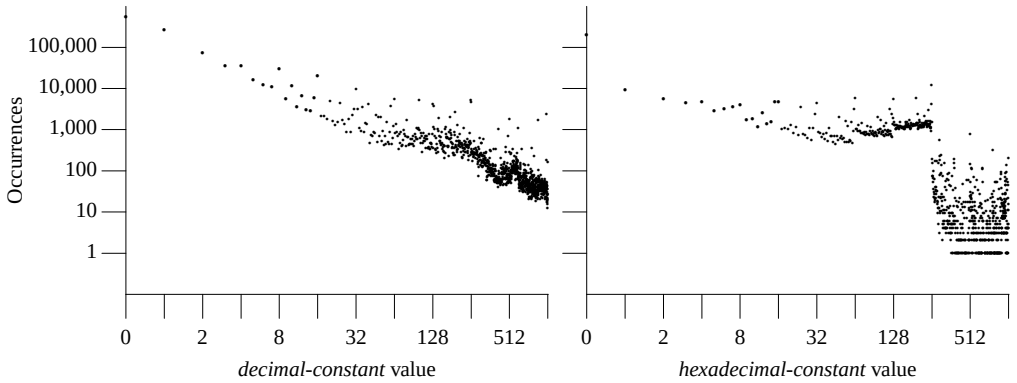

Figure 825.1: Number of integer constants having the lexical form of a *decimal-constant* (the literal 0 is also included in this set) and *hexadecimal-constant* that have a given value. Based on the visible form of the .c and .h files.

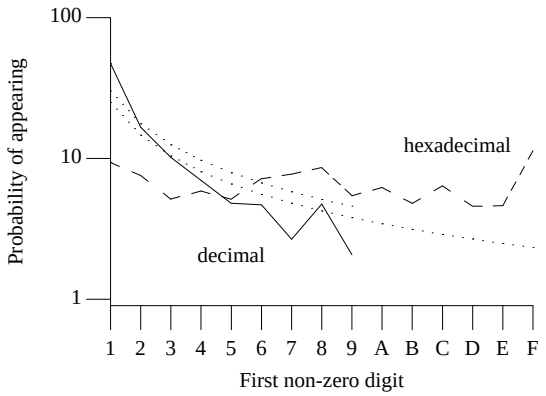

Figure 825.2: Probability of a *decimal-constant* or *hexadecimal-constant* starting with a particular digit; based on .c files. Dotted lines are the probabilities predicted by Benford's law (for values expressed in base 10 and base 16), i.e., $\log(1 + d^{-1})$, where d is the numeric value of the digit.

different distributions converges to a logarithmic distribution (i.e., Benford's law).[573] While the results for *decimal-constant* (see Figure 825.2) may appear to be a reasonable fit, applying a chi-squared test shows the fit to be remarkably poor (χ^2 = 132,398). The first nonzero digit of *hexadecimal-constant*s appears to be approximately evenly distributed.

Table 825.1: Occurrence of various kinds of *integer-constant*s (as a percentage of all integer constants; note that zero is included in the *decimal-constant* count rather than the *octal-constant* count). Based on the visible form of the .c and .h files.

A study by Pollmann and Jansen[1101] analyzed occurrences of related pairs of numerals (e.g., "two or three books") in written (Dutch) text. They found that pairs of numerals often followed what they called *ordering rules*, which were (for the number pair x and y):

- x has to be smaller than y
- x or y has to be *round* (i.e., *round* numbers include the numbers 1 to 20 and the multiples of five)
- the difference between x and y has to be a favorite number. (These include: $10^n \times (1, 2, ½, \text{or } ¼)$ for any value of n.)

Description

826 An integer constant begins with a digit, but has no period or exponent part. integer constant

Commentary

A restatement of information given in the Syntax clause.

827 It may have a prefix that specifies its base and a suffix that specifies its type.

Commentary

A suffix need not uniquely determine an integer constants type, only the lowest rank it may have. There is no suffix for specifying the type **int**, or any integer type with rank less than **int** (although implementations may provide these as an extension).

The base document did not specify any suffixes; they were introduced in C90. 1 base document

Other Languages

A few other languages also support some kind of suffix, including C++, Fortran, and Java.

Coding Guidelines

terminology integer constant

Developers do not normally think in terms of an integer constant having a prefix. The term *integer constant* is often used to denote what the standard calls a *decimal constant*, which corresponds to the common case. When they occur in source, both octal and hexadecimal constants are usually referred to by these names, respectively. The benefits of educating developers to use the terminology *decimal constant* instead of *integer constant* are very unlikely to exceed the cost.

---

decimal constant

A decimal constant begins with a nonzero digit and consists of a sequence of decimal digits. 828

Commentary

A restatement of information given in the Syntax clause.

Coding Guidelines

The constant 0 is, technically, an octal constant. Some guideline documents use the term decimal constant in their wording, overlooking the fact that, technically, this excludes the value 0. The guidelines given in this book do not fall into this trap, but anybody who creates a modified version of them needs to watch out for it.

---

octal constant

An octal constant consists of the prefix **0** optionally followed by a sequence of the digits **0** through **7** only. 829

Commentary

A restatement of information given in the Syntax clause. An octal constant is a natural representation to use when the value held in a single byte needs to be displayed (or read in) and the number of output indicators (or input keys) is limited (only eight possibilities are needed). For instance, a freestanding environment where the output device can only represent digits. The users of such input/output devices tend to be technically literate.

Other Languages

A few other languages (e.g., Java and Ada) support octal constants. Most do not.

Common Implementations

K&R C supported the use of the digits 8 and 9 in octal constants (support for this functionality was removed during the early evolution of C[1180] although some implementations continue to support it[600, 1075]). They represented the values 10 and 11, respectively.

Coding Guidelines

Octal constants are rarely used (approximately 0.1% of all *integer-constant*s, not counting the value 0). There seem to be a number of reasons why developers occasionally use octal constants:

- A long-standing practice that arguments to calls to some Unix library functions use octal constants to indicate various attributes (e.g., `open(file, O_WRONLY, 0666)`). The introduction, by POSIX in 1990, of identifiers representing these properties has not affected many developers' coding habits. The value 0666, in this usage, could be said to be treated like a symbolic identifier.
- Cases where it is sometimes necessary to think of a bit pattern in terms of its numeric value. Bit patterns are invariably grouped into bytes, making hexadecimal an easier representation to manipulate (because its visual representation is easily divisible into bytes and half bytes). However, mental arithmetic involving octal digits is easier to perform than that with hexadecimal digits. (There are fewer items of information that need to be remembered and people have generally automated the processing of digits, but conscious effort is needed to map the alphabetic letters to their numeric equivalents.)
- The values are copied from an external source; for instance, tables of measurements printed in octal.

escape sequence 873 octal digits

There are no obvious reasons for recommending the use of octal constants over decimal or hexadecimal constants (there is a potential advantage to be had from using octal constants).

830 A hexadecimal constant consists of the prefix **0x** or **0X** followed by a sequence of the decimal digits and the letters **a** (or **A**) through **f** (or **F**) with values 10 through 15 respectively.

hexadecimal constant

Commentary

A restatement of information given in the Syntax clause. A hexadecimal constant provides a natural way of denoting a value, occupying one or more 8-bit bytes, when its underlying representation is of interest. Each digit in a hexadecimal constant represents four binary digits, a nibble.

Other Languages

Many languages support the representation of hexadecimal constants in source code. The prefix character *$* (not available in the C basic source character set) is used almost as often, if not more so, than the *0x* form of prefix.

Coding Guidelines

In many cases a hexadecimal constant is not thought about, by developers, in terms of being a number but as representing a pattern of bits (perhaps even having an internal structure to it). For instance, in a number of applications objects and constants have values that are more meaningfully thought about in terms of powers of two rather than powers to ten. In such cases a constant appearing in the source as a hexadecimal constant is more easily appreciated (in terms of the sums of the powers of two involved and by which powers of two it differs from other constants) than if expressed as a decimal constant.

825 integer constant usage

Measurements of constant use in source code show that usage patterns for hexadecimal constants are different from decimal constants. The probability of a particular digit being the first nonzero digit in a hexadecimal constant is roughly constant, while the probability distribution of this digit in a decimal constant decreases with increasing value (a ch-squared analysis gives a very low probability of it matching Benford's law). Also the sequence of value digits in a *hexadecimal-constant* (see Table 830.1) almost always exactly corresponds to the number of nibbles in either a character type, **short**, **int**, or **long**.

0 automatization

A study by Logan and Klapp[863] used *alphabet arithmetic* (e.g., $A + 2 = C$) to investigate how extended practice and rote memorization affected automaticity. For inexperienced subjects who had not memorized any addition table, the results showed that the time taken to perform the addition increased linearly with the value of the digit being added. This is consistent with subjects counting through the letters of the alphabet to obtain the answer. With sufficient practice subjects performance not only improved but became digit-independent. This is consistent with subjects recalling the answer from memory; the task had become automatic.

The *practice* group of subjects were given a sum and had to produce the answer. The *memorization* group of subjects were asked to memorise a table of sums and there answers, (e.g., $A + 2 = C$). In both cases the results showed that performance was proportional to the number of times each question/answer pair had been encountered, not the total amount of time spent.

Arithmetic involving hexadecimal constants differs from that involving decimal constants in that developers will have had much less experience in performing it. The results of the Logan and Klapp study show that the only way for developers to achieve the same level of proficiency is to commit the hexadecimal addition table to memory. Whether the cost of this time investment has a worthwhile benefit is unknown.

Table 830.1: Occurrence of *hexadecimal-constant*s containing a given number of digits (as a percentage of all such constants). Based on the visible form of the `.c` files.

Digits	Occurrence	Digits	Occurrence	Digits	Occurrence	Digits	Occurrence
0	0.003	5	0.467	10	0.005	15	0.000
1	1.092	6	0.226	11	0.001	16	0.209
2	59.406	7	0.061	12	0.001		
3	1.157	8	2.912	13	0.000		
4	34.449	9	0.010	14	0.000		

Semantics

The value of a decimal constant is computed base 10; 831

Commentary

C supports the representation of constants in the base chosen by evolution on planet Earth.

that of an octal constant, base 8; 832

Commentary

unsigned 593
integer types
object representation

The C language requires the use of binary representation for the integer types. The use of both base 8 and base 16 visual representations of binary information has been found to be generally more efficient, for people, than using a binary representation. Developers continue to debate the merits of one base over another. Both experience with using one particular base and the kind of application domain affect preferences.

that of a hexadecimal constant, base 16. 833

Commentary

The correct Latin prefix is *sex*, giving *sexadecimal*. It has been claimed that this term was considered too racey by IBM who adopted *hexadecimal* (*hex* is the equivalent Greek prefix, the Latin *decimal* being retained) in the 1960s to replace it (the term was used in 1952 by Carl-Eric Froeberg in a set of conversion tables).

The lexically first digit is the most significant. 834

Commentary

The Arabic digits in a constant could be read in any order. In Arabic, words and digits are read/written right-to-left (least significant to most significant in the case of numbers). The order in which Arabic numerals are written was exactly copied by medieval scholars, except that they interpreted them using the left-to-right order used in European languages.

integer constant type first in list

The type of an integer constant is the first of the corresponding list in which its value can be represented. 835

Commentary

translation phase 136
7

This list only applies to those *pp-numbers* that are converted to *integer-constant* tokens as part of translation phase 7. Integer constants in **#if** preprocessor directives always have type `intmax_t`, or `uintmax_t` (in C90 they had type **long** or **unsigned long**).

Other Languages

In Java integer constants have type **int** unless they are suffixed with *l*, or *L*, in which case they have type **long**. Many languages have a single integer type, which is also the type of all integer constants.

Coding Guidelines

The type of an integer constant may depend on the characteristics of the host on which the program executes and the form used to express its value. For instance, the integer constant 40000 may have type **int** or **long int** (depending on whether **int** is represented in more than 16 bits, or in just 16 bits). The hexadecimal constant 0x9C40 (40000 decimal) may have type **int** or **unsigned int** (depending on the whether **int** is represented in more than 16 bits, or in just 16 bits).

object 480.1
int type only

For objects having an integer type there is a guideline recommending that a single integer type always be used (the type **int**). However, integer constants never have a type whose rank is less than **int** and so the developer issues associated with the integer promotions do not apply. It makes no sense for a coding guideline to recommend against the use of an *integer-constant* whose value is not representable in the type **int** (a developer is unlikely to use such a value without the application requiring it).

The possibility that the type of an integer constant can vary between implementations and platforms creates a portability cost. There is also the potential for incorrect developer assumptions about the type of an

integer constant, leading to additional maintenance costs. The specification of a guideline recommendation is complicated by the fact that C does not support a suffix that specifies the type **int** (or its corresponding unsigned version). This means it is not possible to specify that a constant, such as 40000, has type **int** and expect a diagnostic to appear when using a translator that gives it the type **long**.

Cg 835.1 An unsuffixed *integer-constant* having a value greater than 32767 shall be treated, for the purposes of these guideline recommendations, as if its lexical included a suffix specifying the type **int**.

An integer constant containing a suffix is generally taken as a statement of intent by the developer. A suffixed integer constant that is immediately converted to another type is suspicious.

Cg 835.2 An integer constant containing a suffix shall not be immediately converted to another type.

Dev 835.2 The use of a macro defined in a system header may be immediately cast to another type.

Dev 835.2 The use of a macro defined in a developer written system header may be immediately cast to another type, independent of how the macro is implemented.

Dev 835.2 The body of a macro may convert, to an integer type, one of the parameters of that macro definition.

Dev 835.2 If the range of values supported by the type **unsigned short**, or **unsigned char**, is the same as that supported by **unsigned int**, an integer constant containing an unsigned suffix may be converted to those types.

Is there anything to be gained from recommending that integer constants less than 32767 be suffixed rather than implicitly converted to another type? The original type of such an integer constant is obvious to the reader and a conversion to a type for which the standard provides a suffix will not change its value; the real issue is developer expectation. Expectation can become involved through the semantics of what the constant represents. For instance, a program that manipulates values associated with the ISO 10646 Standard may store these values in objects that always have type **unsigned int**. This usage can lead to developers learning (implicitly or explicitly) that objects manipulating these semantic quantities have type **unsigned int**, creating an expectation that all such quantities have this type. Expectations on the sign of an operand can show up as a difference between actual and expected behavior; for instance, the following expression checks if any bits outside of the least significant octet are set: `~F00_char > 0x00ff`. It only works if the left operand has an unsigned type. (If it has a signed type, setting the most significant bit will cause the result to be negative.) If the identifier `F00_char` is a macro whose body is a constant integer having a signed type, developer expectations will not have been met.

0 implicit learning

In those cases where developers have expectations of an operand having a particular type, use of a suffix can help ensure that this expectation is met. If the integer constant appears in the visible source at the point its value is used, developers can immediately deduce its type. An integer constant in the body of a macro definition or as an argument in a macro invocation are the two circumstances where type information is not immediately apparent to readers of the source. (The integer constant is likely to be widely separated from its point of use in an expression.)

The disadvantage of specifying a suffix on an integer constant because of the context in which it is used is that the applicable type may change. The issues involved with implicit conversion versus explicit conversion are discussed elsewhere. An explicit cast, using a typedef name rather than a suffix, is more flexible in this regard.

654 implicit conversion

Use of a suffix not defined by the standard, but provided by the implementation, is making use of an extension. Does this usage fall within the guideline recommendation dealing with use of extensions, or is it sufficiently useful that a deviation should be made for it? Suffixes are a means for the developer to specify type information on integer constants. Any construct that enables the developer to provide more information

95.1 extensions cost/benefit

is usually to be encouraged. While there are advantages to this usage, at the time of this writing insufficient experience is available on the use of suffixes to know whether the advantages outweigh the disadvantages. A deviation against the guideline recommendation might be applicable in some cases.

Dev 95.1 Any integer constant suffix supported by an implementation may be used.

Table 835.1: Occurrence of *integer-constant*s having a particular type (as a percentage of all such constants; with the type denoted by any suffix taken into account) when using two possible representations of the type **int** (i.e., 16- and 32-bit). Based on the visible form of the `.c` and `.h` files.

Type	16-bit **int**	32-bit **int**
int	94.117	99.271
unsigned int	3.493	0.414
long	1.805	0.118
unsigned long	0.557	0.138
other-types	0.029	0.059

integer constant possible types

Suffix	Decimal Constant	Octal or Hexadecimal Constant
none	**int** **long int** **long long int**	**int** **unsigned int** **long int** **unsigned long int** **long long int** **unsigned long long int**
u or **U**	**unsigned int** **unsigned long int** **unsigned long long int**	**unsigned int** **unsigned long int** **unsigned long long int**
l or **L**	**long int** **long long int**	**long int** **unsigned long int** **long long int** **unsigned long long int**
Both **u** or **U** and **l** or **L**	**unsigned long int** **unsigned long long int**	**unsigned long int** **unsigned long long int**
ll or **LL**	**long long int**	**long long int** **unsigned long long int**
Both **u** or **U** and **ll** or **LL**	**unsigned long long int**	**unsigned long long int**

Commentary

The lowest rank that an integer constant can have is type **int**. This list contains the standard integer types only, giving preference to these types. Any supported extended integer type is considered if an appropriate type is not found from this list.

C90

The type of an integer constant is the first of the corresponding list in which its value can be represented. Unsuffixed decimal: ***int****,* ***long int****,* ***unsigned long int****; unsuffixed octal or hexadecimal:* ***int****,* ***unsigned int****,* ***long int****,* ***unsigned long int****; suffixed by the letter* `u` *or* `U`*:* ***unsigned int****,* ***unsigned long int****; suffixed by the letter* `l` *or* `L`*:* ***long int****,* ***unsigned long int****; suffixed by both the letters* `u` *or* `U` *and* `l` *or* `L`*:* ***unsigned long int****.*

Support for the type **long long** is new in C99.

The C90 Standard will give a sufficiently large decimal constant, which does not contain a *u* or *U* suffix— the type **unsigned long**. The C99 Standard will never give a decimal constant that does not contain either of these suffixes— an unsigned type.

Because of the behavior of C++, the sequencing of some types on this list has changed from C90. The following shows the entries for the C90 Standard that have changed.

Suffix	Decimal Constant
none	**int** **long int** **unsigned long int**
l or **L**	**long int** **unsigned long int**

Under C99, the none suffix, and *l* or *L* suffix, case no longer contain an unsigned type on their list.

A decimal constant, unless given a *u* or *U* suffix, is always treated as a signed type.

C++

2.13.1p2

If it is decimal and has no suffix, it has the first of these types in which its value can be represented: ***int***, ***long int****; if the value cannot be represented as a* ***long int****, the behavior is undefined. If it is octal or hexadecimal and has no suffix, it has the first of these types in which its value can be represented:* ***int***, ***unsigned int***, ***long int***, ***unsigned long int****. If it is suffixed by* u *or* U*, its type is the first of these types in which its value can be represented:* ***unsigned int***, ***unsigned long int****. If it is suffixed by* l *or* L*, its type is the first of these types in which its value can be represented:* ***long int***, ***unsigned long int****. If it is suffixed by* ul, lu, uL, Lu, Ul, lU, UL, *or* LU*, its type is* ***unsigned long int****.*

The C++ Standard follows the C99 convention of maintaining a decimal constant as a signed and never an unsigned type.

The type **long long**, and its unsigned partner, is not available in C++.

There is a difference between C90 and C++ in that the C90 Standard can give a sufficiently large decimal literal that does not contain a *u* or *U* suffix— the type **unsigned long**. Neither the C++ or C99 Standard will give a decimal constant that does not contain either of these suffixes— an unsigned type.

Other Languages

In Java hexadecimal and octal literals always have a signed type and denote a negative value if the high-order bit, for their type, is set. The literal 0xcafebabe has decimal value -889275714 and type **int** in Java, and decimal value 3405691582 and type **unsigned int** or **unsigned long** in C.

---

837 If an integer constant cannot be represented by any type in its list, it may have an extended integer type, if the extended integer type can represent its value.

Commentary

For an implementation to support an integer constant which is not representable by any standard integer type, requires that it support an extended integer type that can represent a greater range of values than the types **long long** or **unsigned long long**.

C90

Explicit support for extended types is new in C99.

C++

The C++ Standard allows new object types to be created. It does not specify any mechanism for giving literals these types.

A C translation unit that contains an integer constant that has an extended integer type may not be accepted by a conforming C++ translator. But then it may not be accepted by another conforming C translator either. Support for the construct is implementation-defined.

Other Languages

Very few languages explicitly specify potential implementation support for extended integer types.

Common Implementations

integer constant syntax 825

In some implementations it is possible for an integer constant to have a type with lower rank than those given on this list.

Coding Guidelines

extensions cost/benefit 95.1

Source containing an integer constant, the value of which is not representable in one of the standard integer types, is making use of an extension. The guideline recommendation dealing with use of extensions is applicable here. If it is necessary for a program to use an integer constant having an extended integer type, the deviation for this guideline specifies how this usage should be handled. The issue of an integer constant being within the range supported by a standard integer type on one implementation and not within range on another implementation is discussed elsewhere.

integer constant greater than 32767 835.1

If all of the types in the list for the constant are signed, the extended integer type shall be signed. 838

Commentary

This is a requirement on the implementation. This requirement applies to the standard integer types. By requiring that any extended integer type follow the same rule, the standard is preserving the idea that decimal constants are signed unless they contain an unsigned suffix. All of the types in the list are signed if the lexical representation is a decimal constant without a suffix, or a decimal constant whose suffix is not *u* or *U*.

If all of the types in the list for the constant are unsigned, the extended integer type shall be unsigned. 839

Commentary

This is a requirement on the implementation. The types in the list are all unsigned if the integer constant contains a *u* or *U* suffix.

If the list contains both signed and unsigned types, the extended integer type may be signed or unsigned. 840

Commentary

Both signed and unsigned types only occur if octal or hexadecimal notation is used, and no *u* or *U* suffix appears in the constant. There is no requirement on the implementation to follow the signed/unsigned pattern seen for the standard integer types when octal and hexadecimal notation is used for the constants.

integer constant no type

If an integer constant cannot be represented by any type in its list and has no extended integer type, then the integer constant has no type. 841

Commentary

Consider the token 100000000000000000000 in an implementation that supports a 64-bit two's complement **long long**, and no extended integer types. The numeric value of this token outside of the range of any integer type supported by the implementation and therefore it has no type.

This sentence was added by the response to DR #298.

6.4.4.2 Floating constants

```
floating-constant:
                decimal-floating-constant
                hexadecimal-floating-constant
decimal-floating-constant:

                hexadecimal-digit-sequence .
binary-exponent-part:
                p sign_opt digit-sequence
                P sign_opt digit-sequence
hexadecimal-digit-sequence:
                hexadecimal-digit
                hexadecimal-digit-sequence hexadecimal-digit
floating-suffix: one of
                f  l  F  L
```

Commentary

The majority of *floating-decimal-constant*s do not have an exact binary representation. For instance, if FLOAT_RADIX is 2 then only 4% of constants having two digits after the decimal point can be represented exactly (i.e., those ending .00, .25, .50, and .75).

Unlike an *integer-suffixe*, a *floating-suffix* specifies the actual type, not the lowest rank of a set

of types (not that floating-point types have rank).

Hexadecimal floating constants were introduced to remove the problems associated with translators incorrectly mapping character sequences denoting decimal floating constants to the internal representation of floating numbers used at execution time. The potential mapping problems only apply to the significand, so a decimal representation can still be used for the exponent (requiring a hexadecimal representation for the exponent would have made it harder for human readers to quickly gauge the magnitude of a constant and created a lexical ambiguity, e.g., would the character sequence `p0x1f` be interpreted as ending in the *floating-suffix* `f` or not).

The exponent is always required for the hexadecimal notation, unlike decimal floating constants, otherwise, the translator would not be able to resolve the ambiguity that occurs when a `f`, or `F`, appears as the last character of a preprocessing token. For instance, `0x1.f` could mean `1.0f` (the `f` interpreted as a suffix indicating the type float) or `1.9375` (the `f` being interpreted as part of the significand value).

The *hexadecimal-floating-constant* `0x1.FFFFFEp128f` does not represent the IEC 60559 single-format NaN. It overflows to an infinity in the single format.

C90

Support for *hexadecimal-floating-constant* is new in C99. The terminal *decimal-floating-constant* is new in C99 and its right-hand side appeared on the right of *floating-constant* in the C90 Standard.

C++

The C++ syntax is identical to that given in the C90 Standard.

Support for *hexadecimal-floating-constant* is not available in C++.

Other Languages

Support for *hexadecimal-floating-constant* is unique to C. Fortran 90 supports the use of a *KIND* specifier as part of the floating constant. Fortran also supports the use of the letter *D*, rather than *E*, in the exponent part to indicate that the constant has type **`double`** (rather than real, the single-precision default type). Java supports the optional suffixes *f* (type **`float`**, the default) and *d* (type **`double`**)

Coding Guidelines

Mapping to and from a hexadecimal floating constant, and its value as a floating-point literal, requires knowledge of the underlying representation. The purpose of supporting the hexadecimal floating constant notation is to allow developers to remove uncertainty over the accuracy of the mapping, of values expressed in decimal, performed by translators. Developers are unlikely to want to express floating constants in hexadecimal notation for any other reason and the guideline recommendation dealing with use of representation information is not applicable.

representation information using 569.1

Dev 569.1 Floating constant may be expressed using the hexadecimal floating-point notation.

The advantage of hexadecimal floating constants is that they guarantee an exact (when `FLT_RADIX` is a power of two) floating value in the program image, provided the constant has the same or less precision than the type.

integer constant not in visible source 825.3

For the same rationale as integer constants, there is good reason why most floating constants should not appear in the visible source.

Cg 842.1 No floating constant, other than `0.0` and `1.0`, shall appear in the visible source code other than as the sole preprocessing token in the body of a macro definition.

Usage

exponent 334 integer constant usage 825

Exponent usage information is given elsewhere. Also see elsewhere for a discussion of Benford's law and the first non-zero digit of constants (χ^2 = 1,680 is a very poor fit).

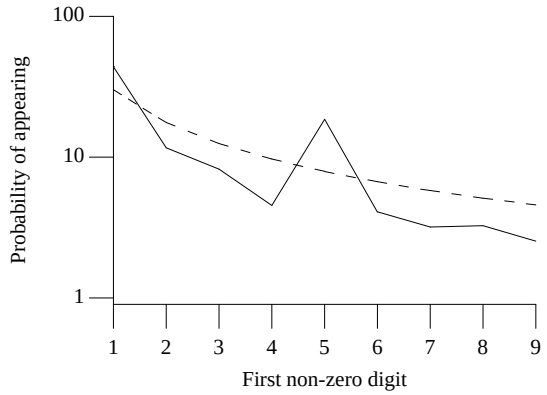

Figure 842.1: Probability of a *decimal-floating-constant* (i.e., not hexadecimal) starting with a particular digit. Based on the visible form of the `.c` files. Dotted line is the probability predicted by Benford's, i.e., $\log(1 + d^{-1})$, where d is the numeric value of the digit.

Table 842.1: Occurrence of various *floating-suffix*es (as a percentage of all such constants). Based on the visible form of the `.c` and `.h` files.

Suffix Character Sequence	`.c` files	`.h` files
none	98.3963	99.7554

L/l	0.2005	0.0550

Table 842.2: Common token pairs involving *floating-constant*s. Based on the visible form of the `.c` files.

Token Sequence	% Occurrence of First Token	% Occurrence of Second Token	Token Sequence	% Occurrence of First Token	% Occurrence of Second Token
, *floating-constant*	0.0	20.4	*floating-constant* /	5.8	1.8
= *floating-constant*	0.1	15.7	*= *floating-constant*	6.3	1.6
* *floating-constant*	0.2	12.5	*floating-constant* *	6.8	0.1
(*floating-constant*	0.0	8.8	*floating-constant* ;	26.5	0.1
+ *floating-constant*	0.4	7.7	*floating-constant*)	25.9	0.1
-v *floating-constant*	0.3	6.7	*floating-constant* ,	25.8	0.1
/ *floating-constant*	2.0	6.4			

Description

843 A floating constant has a *significand part* that may be followed by an *exponent part* and a suffix that specifies its type. significand part

Commentary

This defines the terms *significand part* and *exponent part*.

844 The components of the significand part may include a digit sequence representing the whole-number part, followed by a period (`.`), followed by a digit sequence representing the fraction part. whole-number part, fraction part

Commentary

A restatement of information given in the Syntax clause. The character denoting the period, which may appear when floating-point values are converted to strings, is locale dependent. However, the period character that appears in C source is not locale dependent.

A leading zero does not indicate an octal floating-point value.

C++

2.13.3p1 *The integer part, the optional decimal point and the optional fraction part form the significant part of the floating literal.*

The use of the term *significant* may be a typo. This term does not appear in the C++ Standard and it is only used in this context in one paragraph.

Other Languages

This form of notation is common to all languages that support floating constants, although in some languages the period (decimal point) in a floating constant is not optional.

Coding Guidelines

The term *whole-number* is sometimes used by developers. A more commonly used term is *integer part* (the term used by the C++ Standard). The commonly used term for the period character in a floating constant is *decimal point*.

floating constant digit layout

A common mathematical convention is to have a single nonzero digit preceding the period. This is a useful convention when reading source code since it enables a quick estimate of the magnitude of the value to be made. There are also circumstances where more than one digit before the period, or leading zeros before and after the period, can improve readability when the floating constant is one of many entries in a table. In this case the relative position of the first non zero digit may provide a useful guide to the relative value of a series of constants, which may be more important information than their magnitudes.

Your author knows of no research showing that any method of displaying floating constants minimizes the cognitive effort, or the error rate, in comprehending them. However, there does appear to be an advantage in having consistency of visual form between constants close to each other in the source. Comprehending the relationship between the various initializers appears to require less effort for `g_1` and `g_2` than it does for `g_3`.

```
double g_1[] = {
                 1.2,
                 0.12,
                 0.012,
                 0.0012,
                 0.00012,
                };
double g_2[] = {
                 1.2e-0,
                 1.2e-1,
                 1.2e-2,
                 1.2e-3,
                 1.2e-4,
                };
double g_3[] = {
                 1.2e-0,
                 0.12,
                 1.2e-2,
                 0.0012,
                 1.2e-4,
                };
```

floating constant assumed accuracy

Trailing zeros in the fractional part of a floating constant may not affect its value (unless a translator has poor character to binary conversion), but they do contain information. Trailing zeros can be interpreted as a statement of accuracy; for instance, the measurement 7.60 inches is more accurate than 7.6 inches.

Leading zeros are sometimes used for padding and have no alternative interpretation. Adding trailing zeros to a fractional part for padding purposes is misleading. They could be interpreted as giving a floating

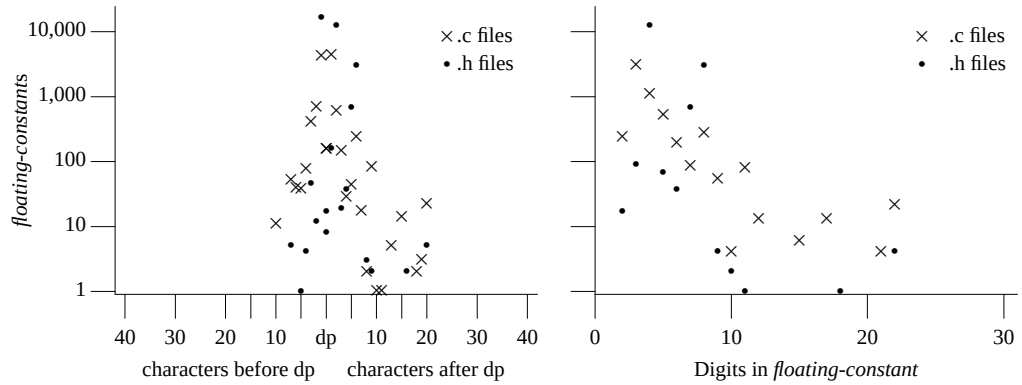

Figure 844.1: Number of *floating-constant*s, that do not contain an exponent part, containing a given number of digit sequences before and after the decimal point (dp), and the total number of digit in a *floating-constant*. Based on the visible form of the `.c` and `.h` files.

constant a degree of accuracy that it does not possess. While such usage does not affect the behavior of a program, it can affect how developers interpret the accuracy of the results.

Rev 844.1 Floating constants shall not contain trailing zeros in their fractional part unless these zeros accurately represent the known value of the quantity being represented.

---

845 The components of the exponent part are an **e**, **E**, **p**, or **P** followed by an exponent consisting of an optionally signed digit sequence.

Commentary

A restatement of information given in the Syntax clause.

C90

Support for *p* and *P* is new in C99.

C++

Like C90, the C++ Standard does not support the use of *p*, or *P*.

Other Languages

The use of the notation *e* or *E* is common to most languages that support the same form of floating constants. Fortran also supports the use of the letter *D*, rather than *E*, to indicate the exponent. In this case the constant has type **double** (there is no type **long double**).

Coding Guidelines

Amongst a string of digits, the letter `E` can easily be mistaken for the digit `8`. There is no such problem with the letter `e`, which also adds a distinguishing feature to the visual appearance of a floating constant (a change in the height of the characters denoting the constant). However, there is no evidence to suggest that this choice of exponent letter is sufficiently important to warrant a guideline recommendation. At the time of this writing there is little experience available for how developers view the exponent `p` and `P`. While the prefix indicates that a hexadecimal constant is being denoted, a lowercase `p` offers an easily distinguished feature that its uppercase equivalent does not.

Example

```
1  double glob[] = {
2                    67E9,
3                    9e76,
4                   };
```

Either the whole-number part or the fraction part has to be present; 846

Commentary

A restatement of information given in the Syntax clause.

Coding Guidelines

When only one of these parts is present, the period character might easily be overlooked, especially when floating constants occur adjacent to other punctuation tokens such as a comma. This problem can be overcome by ensuring that a digit (zero can always be used) appears on either side of the period. However, such usage is not, itself, free of problems. The period can be interpreted as a comma (if the source is being quickly scanned), causing the digits on either side of the period to be treated as two separate constants. The issue of white space between tokens is discussed elsewhere. In the case of digits after the decimal point, there is also the issue of assumed accuracy of the floating constant.

words 770
white space between
floating 844
constant
assumed accuracy

Example

```
1  extern int g(double, int, ...);
2
3  double glob[] = {
4                    12.3, .456, 789.,
5                    12.3,.456,789.,
6                    98.7, 0.654, 321.0,
7                    98.7,0.654,321.0,
8                   };
9
10 void f(void)
11 {
12 g(1.2, 45, 6., 0);
13 g(1.2, 45, 6,0);
14 g(7.8,90, 1.,2);
15 g(3.4,56, 7.0,8);
16 }
```

---

for decimal floating constants, either the period or the exponent part has to be present. 847

Commentary

A restatement of information given in the Syntax clause. Without one of these parts the constant would be interpreted as an integer constant.

Coding Guidelines

Is there a benefit, to readers, of including a period in the visible representation of a floating constant when an exponent part is present? Including a period further differentiates the appearance of a floating constant from that of other types of constants. Developers with a background in numerate subjects will have frequently encountered values that contain decimal points. The exponent notation used in C source code is rarely encountered outside of source code, powers of ten usually being written as just that (e.g., 10^2). Because of these relative practice levels, developers are much more likely to be able to automatically recognize a floating value with a constant that contains a period than one that only contains an exponent (which is likely to require

automatization 0

conscious attention). However, given existing usage (see Figure 844.1) a guideline recommendation does not appear worthwhile.

Developers reading source often only need an approximate estimate of the value of floating constants. The first few digits and the power of ten (sometimes referred to as the *order of magnitude* or simply the *magnitude*) contain sufficient value information. The magnitude can be calculated by knowing the number of nonzero digits before the decimal point and the value of the exponent. There are many ways in which these two quantities can be varied and yet always denote the same value. Is there a way of denoting a floating constant such that its visible appearance minimizes the cognitive effort needed to obtain an estimate of its value? The possible ways of varying the visible appearance of a floating constant including:

- Not using an exponent; the magnitude is obtained by counting the number of digits in the whole-number part.
- Having a fixed number of digits in the whole-number part, usually one; the magnitude is obtained by looking at the value of the exponent.
- Some combination of digits in the whole-number part and the exponent.

There are a number of factors that suggest developers' effort will be minimized when small numbers are written using only a few digits before the decimal point rather than using an exponent, including the following:

- Numbers occur frequently in everyday life and people are practiced at processing the range of values they commonly encounter. The prices of many items in shops in the UK and USA tend to have only a few digits after the decimal point, while in countries such as Japan and Italy they tend to have more digits (because of the relative value of their currency).
- *Subitizing* is the name given to the ability most people have of instantly knowing the number of items in a small set (containing up to five items, although some people can only manage three) without explicitly counting them. 1641 subitizing

Your author does not know of any algorithm that optimizes the format (i.e., how many digits should appear before a decimal point or selecting whether to use an exponent or not) in which floating-point constants appear, such that reader effort in extracting a value from them is minimized.

Example

Your author is not aware of any studies investigating the effect that the characteristics of human information processing (e.g., the Stroop effect) have on the probability of the value of a constant being misinterpreted. 1641 stroop effect

```
1  double d[] = {
2                 123.567,
3                 01.1,
4                 3.333e2,
5                 1.23456e8,
6                 1111.3,
7                 122.12e2,
8                };
```

Semantics

848 The significand part is interpreted as a (decimal or hexadecimal) rational number;

Commentary

One form is based on the human, base 10, representation of values, the other on the computer, base 2, representation.

C90

Support for hexadecimal significands is new in C99.

C++

The C++ Standard does not support hexadecimal significands, which are new in C99.

Other Languages

While support for the hexadecimal representation of floating constants may not be defined in other language standards, some implementations of these languages (e.g., Fortran) support it.

Example

What is the IEC 60559 single-precision representation of `12.345`? For the digits before the decimal point we have:

$$12_{10} = 1100_2 \tag{848.1}$$

For the digits after the decimal point we have:

```
   .345
   ×  2
0  .690
   ×  2
1  .380
   ×  2
0  .760
   ×  2
1  .520
   ×  2
1  .040
   ×  2
0  .080
   ×  2
0  .160
...
```

$$.345_{10} = .01000101100001010001111 1_2 \tag{848.2}$$

Writing the number in normalized form, we get:

$$1100.01011000010100011111 \times 2^0 = 1.10001011000010100011111 \times 2^3 \tag{848.3}$$

Representing the number in single-precision, the exponent bias is 127, giving an exponent of $127 + 3 = 130_{10} = 10000010_2$. The final bit pattern is (where | indicates the division of the 32-bit representation into sign bit, exponent, and significand):

$$0 \mid 10000010 \mid 10001011000010100011111 \tag{848.4}$$

What is the decimal representation of the hexadecimal floating-point constant, assuming an IEC 60559 representation of `0x0.12345p0`? For the significand we have:

$$.12345_{16} = .0001001000011010001012 = 1.0010001101000101 \times 2^{-4} \tag{848.5}$$

For the exponent we have:

$$127 - 4 = 123_{10} = 1111011_2 \tag{848.6}$$

which gives a bit pattern of:

$$0 \mid 1111011 \mid 00100011010001010000000 \tag{848.7}$$

Converting this to decimal, the exponent is $1111011_2 = 123 - 127 = -4_{10}$; and restoring the implicit 1 in the significand, we get the value:

$$1.0010001101000101_2 \times 2^{-4} \tag{848.8}$$
$$0.0001001000011010001012 \tag{848.9}$$
$$(1/16 + 1/128 + 1/2048 + 1/4096 + 1/16384 + 1/262144 + 1/1048576)_{10} \tag{848.10}$$
$$(74565/1048576)_{10} \tag{848.11}$$
$$7.111072540283203125\ldots_{10} \times 10^{-2} \tag{848.12}$$

Taking into account the accuracy of the representation, we get the value $7.111073_{10} \times 10^{-2}$.

---

849 the digit sequence in the exponent part is interpreted as a decimal integer.

Commentary

Even if the significand is in hexadecimal notation, the exponent is still interpreted as a decimal quantity.

C++

. . . , an optionally signed integer exponent, . . . 2.13.3p1

There is no requirement that this integer exponent be interpreted as a decimal integer. Although there is wording specifying that both the integer and fraction parts are in base 10, there is no such wording for the exponent part. It would be surprising if the C++ Standard were to interpret 1.2e011 as representing 1.2×10^9; therefore this issue is not specified as a difference.

---

850 For decimal floating constants, the exponent indicates the power of 10 by which the significand part is to be scaled.

Commentary

This specification is consistent with that for the significand.

---

851 For hexadecimal floating constants, the exponent indicates the power of 2 by which the significand part is to be scaled.

Commentary

Scaling the significand of a hexadecimal floating constant by a power of 2 means that no accuracy is lost when all the powers of 2 specified by the exponent are representable using the value of FLT_RADIX. (This is always true when FLT_RADIX has a value of 2, as specified by IEC 60559.) This scaling is performed during translation; it is not an execution-time issue.

C90

Support for hexadecimal floating constants is new in C99.

C++

The C++ Standard does not support hexadecimal floating constants.

---

floating constant representable value chosen

For decimal floating constants, and also for hexadecimal floating constants when **FLT_RADIX** is not a power of 2, the result is either the nearest representable value, or the larger or smaller representable value immediately adjacent to the nearest representable value, chosen in an implementation-defined manner. 852

Commentary

int to float 689 nearest representable value

This behavior is different from that specified for integer-to-float conversion. Having introduced hexadecimal floating constants, the Committee could not then restrict their use to implementations having a FLT_RADIX that was a power of 2. The advantage of exact representation does not always occur in implementations where FLT_RADIX is not a power of 2, but a translator is still required to support this form of floating constant.

hexadecimal constant 859 not represented exactly

When converting a value to a different base the best approximation can be obtained using a finite automaton if the two bases are both an integral power of a common integral root.[247] For hexadecimal floating constants this requires that the other base be a power of 2. Unless two bases have this property it is not possible to always find the best approximation, when converting a value between them, using a finite automaton (there are some numbers that require arbitrary precision arithmetic to obtain the best approximation). Thus, it is not possible to find the best n-bit binary approximation of a decimal real number using a finite automaton.[247] For this reason the C Standard does not require the best approximation and will accept the nearest representable values either side of the best approximation (see Figure 852.1).

Floating constants whose values have the same mathematical value, but are denoted by different character sequences (e.g., 1.57 and 15.7e-1), may be mapped to different representable values by a translator. (Depending on how its mapping algorithm works, the standard permits three different possibilities.) In fact the standard does not even require that implementations map the same sequence of characters to the same value internally (although an implementation that exhibited such behavior would probably be considered to have low quality). Neither is there any requirement, in this case, that if the constant value is exactly representable the exact representation be used.

DECIMAL_DIG conversion 379 recommended practice

C90

Support for hexadecimal floating constants is new in C99.

C++

2.13.3p1 *If the scaled value is in the range of representable values for its type, the result is the scaled value if representable, else the larger or smaller representable value nearest the scaled value, chosen in an implementation-defined manner.*

Figure 852.1: The nearest representable value to X is b, however, its value may also be rounded to a or c. In the case of Y, while d is the nearest representable value the result may be rounded to c or e.

Other Languages

This issue is not C specific. All languages have to face the problem that only a finite number of floating-point values can be represented and the mapping from a string to a binary representation may not be exact.

Common Implementations

A few implementations continue to use the *student* solution of multiply and add, a character at a time, moving left-to-right through the significand of the floating constant, followed by a loop that multiplies, or divides, the result by 10; the iteration count being given by the value of the exponent. Your author knows of no translator that maps identical floating constant tokens into different internal representations. Mapping different floating constant tokens, which have the same mathematical value, to different internal representations is not unknown.

Coding Guidelines

There are a number of factors that can introduce errors into the conversion of floating-point tokens (a sequence of characters) into the internal representation used for floating values (a pattern of bits) by the translator, including:

- Poor choice of conversion algorithm by the translator vendor, leading to larger-than-permitted, by the standard, error
- Poor choice of rounding direction when performing conversions
- The finite set of numbers that can be represented in any model of floating-point numbers

Translator errors in conversion of floating constants are most noticeable, by developers, when they have an exact representation in an integer type. In:

```
#include <stdio.h>

void f(void)
{
double d = 6.0;

if ((int)d != 6)
   printf("Oh dear\n");
/* ... */
}
```

The standard does not require that the character sequence `6.0` be converted to the floating value 6.0. The value 5.9999999 (continuing for a suitable number of 9s) is the smaller representable value immediately adjacent to the nearest representable value— a legitimate result— which, when cast to **`int`**, yields a value of 5. A translator that chooses to round-to-even, or not round toward zero, would not exhibit this problem.

These coding guidelines deal with developer-written code. Developers do not need to be told, in a guideline, to use high-quality implementation. If developers are in the position of having to use an implementation that does not correctly convert floating constant tokens, then all that can be suggested is that hexadecimal floating constants be used. The error introduced by the model used by an implementation to represent floating numbers has to be lived with. The issue of converting floating values to integer types is discussed elsewhere.

686.1 floating constant converted exactly

Example

```
#include <stdio.h>

int main(void)
{
if ((1.57 != 1.570) || (1.57 != 0.157E1) ||
    (0.0 != 0.000) || (0.0 != 0.0E10))
   printf("You can never enter the same stream twice\n");
}
```

For hexadecimal floating constants when **FLT_RADIX** is a power of 2, the result is correctly rounded. 853

Commentary

If FLT_RADIX is a power of 2, the hexadecimal value has a unique mapping to the representation of the significand (any additional digits, in excess of those required by the type of the floating constant, are used to form the correctly rounded result).

correctly rounded result 64

Common Implementations

All known implementations have a FLT_RADIX that is a power of 2.

An unsuffixed floating constant has type **double**. 854

Commentary

A floating constant has type **double**, independent of its value. This situation differs from the integer types where the value of the literal (as well as its form) is used to determine its type. There is no suffix to explicitly denote the type **double**.

Other Languages

Most languages do not have more than one floating-point type. A literal could only have a single type in these cases. A floating constant in Fortran has type **real** by default.

Common Implementations

Some translators[55] provide an option that allows this default behavior to be changed (perhaps to improve performance by using **float** rather than **double**).

Coding Guidelines

If an unsuffixed floating constant is immediately converted to another floating type, would it have been better to use a suffix? An immediate conversion of a floating constant to another floating type suggests that the developer is being sloppy and is omitting the appropriate suffix. In the case of a conversion to type **long double**, there is also the possibility of a loss of precision. The floating constant token is converted to **double** first, potentially losing any additional accuracy present in the original token, before being converted to **long double**; however, the issues are not that simple.

The precision to which a floating constant is represented internally by a translator need not be related to its type. It can be represented to less or greater precision depending on the value of the FLT_EVAL_METHOD macro. A suffix changes the type of a floating constant, but need not change the precision of its internal representation. On the other hand, a cast operation is required to remove any additional precision in a value, but does not have the information needed to provide additional precision.

FLT_EVAL_METHOD 354

Explicitly casting floating constants ensures the result is consistent (assuming the cast occurs during program execution, not at translation time, which can only happen if the FENV_ACCESS pragma is in the ON state) with casts applied to nonconstant operands having floating type.

The disadvantage of specifying a suffix on a floating constant, because of the context in which the constant is used, is that the applicable type may change. The issues involved with implicit conversion versus explicit conversion are discussed elsewhere. An explicit cast, using a typedef name rather than a suffix, is more flexible in this regard.

implicit conversion 654
integer constant with suffix, not immediately converted 835.2

The following guideline recommendations mirror those given for suffixed integer constants, except that it is specified as a review item, not a coding guideline. The process of resolving whether a suffix or cast is best in light of possible settings for the FLT_EVAL_METHOD needs human attention.

Rev 854.1 A floating constant containing a suffix shall not be immediately converted to another type.

Dev 854.1 The use of a macro defined in a system header may be immediately converted to another type.

Dev 854.1 The use of a macro defined in a developer-written system header may be immediately converted to another type, independent of how the macro is implemented.

Dev 854.1 The body of a macro may convert, to a floating type, one of the parameters of that macro definition.

Example

```
1  #include <stdio.h>
2
3  void f(void)
4  {
5  if ((1.0f / 3.0f) != ((float)1.0 / (float)3.0))
6     printf("No surprises here (float)\n");
7  if ((1.0 / 3.0) != ((double)1.0 / (double)3.0))
8     printf("No surprises here (double)\n");
9  if ((1.0L / 3.0L) != ((long double)1.0 / (long double)3.0))
10    printf("No surprises here (long double)\n");
11 }
```

---

855 If suffixed by the letter **f** or **F**, it has type **float**.

Commentary

Unlike its integer counterpart, **short**, there is a suffix for denoting a floating constant of type **float**. Hexadecimal floating constants require the *p* so that any trailing *f* is interpreted as the type **float** suffix rather than another hexadecimal digit.

Other Languages

Java supports the suffixes *f*, or *F*, to indicate type **float** (the default type for floating constants).

Coding Guidelines

What is the developers' intent when giving a floating constant a suffix denoting that it has type **float**? The type of a floating constant may not affect the evaluation type of an expression in which it is an operand (which is controlled by the value of the FLT_EVAL_METHOD macro). Even the value of the floating constant itself may be held to greater precision than the type **float**. [354] FLT_EVAL_ME

---

856 If suffixed by the letter **l** or **L**, it has type **long double**.

Commentary

If greater precision, or range of exponent than type **double**, is required in a floating constant, using the type **long double** suffix may offer a solution. However, possible interaction value of the FLT_EVAL_METHOD macro needs to be taken into account. [354] FLT_EVAL_ME

Coding Guidelines

Using the l suffix in a floating constant may lead to confusion with the digit 1.

Cg 856.1 If a *floating-suffix* is required only the forms *F* or *L* shall be used.

---

857 Floating constants are converted to internal format as if at translation-time.

floating constant internal format

Commentary

The key phrase here is *as if*. Translators wishing to maintain a degree of host independence can still translate to some intermediate form (which is converted to host-specific format as late as program startup). However, all the implications of the conversion must occur at translation-time, not during program execution or startup.

C90

No such requirement is explicitly specified in the C90 Standard.

In C99 floating constants may convert to more range and precision than is indicated by their type; that is, `0.1f` may be represented as if it had been written `0.1L`.

FLT_EVAL_METHOD 354

C++

Like C90, there is no such requirement in the C++ Standard.

Common Implementations

There are a few implementations that use an intermediate form to represent floating constants, independent of the final host on which a program image will execute. The intent is to create a degree of software portability at a lower level than the source code; for instance, implementations that interpret source code that has been translated into the instructions of some abstract machine.

---

floating constant conversion not raise exception

The conversion of a floating constant shall not raise an exceptional condition or a floating-point exception at execution time. 858

Commentary

This is a requirement on the implementation. A floating constant that is outside the representable range of floating-point values cannot cause an execution-time exception to be raised. Whether a translator issues a diagnostic if it encounters a floating constant that, had it occurred during program execution, would have raised an exception is a quality-of-implementation issue.

C90

No such requirement was explicitly specified in the C90 Standard.

C++

Like C90, there is no such requirement in the C++ Standard.

Recommended practice

---

hexadecimal constant not represented exactly

The implementation should produce a diagnostic message if a hexadecimal constant cannot be represented exactly in its evaluation format; 859

Commentary

floating constant representable value chosen 852

The issue of exact representation of floating constants is not unique to hexadecimal notation, but the intent of this notation could lead developers to expect that an exact representation will always be used. An inexact representation can occur if `FLT_RADIX` macro has a value that is not a power of 2, or the hexadecimal floating constant contains more digits than are representable in the significand used by the implementation for that floating type This is a quality-of-implementation issue, one of the many constructs that a quality implementation might be expected to diagnose. However, the floating-point contingent on the Committee is strong and hexadecimal constants are a new construct, so we have a recommended practice.

FLT_RADIX 366

C90

Recommended practices are new in C99, as are hexadecimal floating constants.

C++

The C++ Standard does not specify support for hexadecimal floating constants.

Coding Guidelines

A hexadecimal floating constant is a notation intended to be used to provide a mechanism for exactly representing floating-point values. A source file may contain a constant that is not exactly representable. However, support for hexadecimal floating constant notation is new in C99 and at the time of this writing insufficient experience on their use is available to know if any guideline recommendation is worthwhile.

Example

```
1   float f = 0x1.11111111111111111111111111111111111111111111111111111111111111p11;
```

---

860 the implementation should then proceed with the translation of the program.

Commentary

Thanks very much.

---

861 The translation-time conversion of floating constants should match the execution-time conversion of character strings by library functions, such as **strtod**, given matching inputs suitable for both conversions, the same result format, and default execution-time rounding.[64)]

Commentary

The C library contains many of the support functions needed to write a translator. Making these functions available in the C library is just as much about allowing implementation vendors to recycle their code as allowing behaviors to be duplicated. If the translator and its library both use identical functions for performing numeric conversions, there is likely to be consistent behavior between the two environments. The function `strtod` is an example of one such case. However, its behavior will only be the same if the various floating-point mode flags are also the same in both environments.

C90

This recommendation is new in C99.

C++

No such requirement is explicitly specified in the C++ Standard.

Other Languages

A common characteristic of many language translators is that they are written in the language they translate, even Cobol. If a translator is not written in its own language, the most common implementation language is C. Languages invariably specify functionality that performs conversions between character strings and floating-point values. However, it is their I/O mechanisms that perform this conversion and the generated character strings, or floating-point values, are not always otherwise available to an executing program.

Fortran has a large number of numeric functions in its library as does Java. Both of these languages have an established practice of writing their libraries in their respective languages. Although in the case of Fortran, there is also a history of using functions written in C. Java defines conversion functions in `java.lang.float` and `java.lang.double`.

Common Implementations

The majority of C translators are written in C and call the identical functions to those provided in their runtime library.

Coding Guidelines

Floating-point values can appear during program execution through two possible routes. They can be part of the character sequence that is translated to form the program image, or they can be read in as character sequences from a stream and converted using the functions defined in Clause 7.20.1.3. In a freestanding

environment the host processor floating-point support is likely to be different (it may be implemented via calls to internal implementation library functions) from that available during translation.

It is possible for the original source of the floating-point numbers to be the same; for instance, a file containing a comma separated list of values and this file being **#include**d at translation time and read during program execution.

Rev 861.1

A program shall not depend on the value of a floating constant appearing in the source code being equal to the value returned by a call to `strtod` with the same sequence of characters as its first argument.

Example

```
#include <stdlib.h>
#include <stdio.h>

#define flt_constant_eq_flt_string(x) (x == strtod(#x, NULL))

void f(void)
{
if (!flt_constant_eq_flt_string(1.2345))
   printf("This translator may not be implemented using its own library\n");
}
```

footnote 64

64) The specification for the library functions recommends more accurate conversion than required for floating constants (see 7.20.1.3). 862

Commentary

Clause 7.20.1.3 describes the `strtod`, `strtof`, and `strtold` functions.

C++

There observation is not made in the C++ Standard. The C++ Standard includes the C library by reference, so by implication this statement is also true in C++.

6.4.4.3 Enumeration constants

enumeration-constant: 863
identifier

Commentary

There is no phase of translation where an identifier that is an *enumeration-constant* is replaced by its constant value.

C++

The C++ syntax uses the terminator *enumerator*.

Other Languages

Other languages that contain enumeration constants also specify them as identifiers.

Coding Guidelines

enumeration constant naming conventions 792

The issue of naming conventions for enumeration constant identifiers is discussed elsewhere.

Semantics

enumeration constant type

An identifier declared as an enumeration constant has type **int**. 864

Commentary

There is no requirement that the enumerated type containing this enumeration constant also have type **int**, although any constant expression used to specify the value of an enumeration constant is required to be representable in an **int**.

1440 enumeration constant representable in int

C++

Following the closing brace of an enum-specifier, each enumerator has the type of its enumeration. Prior to the closing brace, the type of each enumerator is the type of its initializing value. If an initializer is specified for an enumerator, the initializing value has the same type as the expression. If no initializer is specified for the first enumerator, the type is an unspecified integral type. Otherwise the type is the same as the type of the initializing value of the preceding enumerator unless the incremented value is not representable in that type, in which case the type is an unspecified integral type sufficient to contain the incremented value.

7.2p4

This is quite a complex set of rules. The most interesting consequence of them is that each enumerator, in the same type definition, can have a different type (at least while the enumeration is being defined):
In C the type of the enumerator is always **int**. In C++ it can vary, on an enumerator by enumerator basis, for the same type definition. This behavior difference is only visible outside of the definition if an initializing value is calculated by applying the **sizeof** operator to a prior enumerator in the current definition.

```
#include <limits.h>

enum TAG { E1 = 2L,             // E1 has type long
           E2 = sizeof(E1),     // E2 has type size_t, value sizeof(long)
           E3 = 9,              // E3 has type int
           E4 = '4',            // E4 has type char
           E5 = INT_MAX,        // E5 has type int
           E6,                  // is E6 an unsigned int, or a long?
           E7 = sizeof(E4),     // E2 has type size_t, value sizeof(char)
         }                      // final type is decided when the } is encountered
           e_val;

int probably_a_C_translator(void)
{
return (E2 == E7);
}
```

Source developed using a C++ translator may contain enumeration with values that would cause a constraint violation if processed by a C translator.

```
#include <limits.h>

enum TAG { E1 = LONG_MAX }; /* Constraint violation if LONG_MAX != INT_MAX */
```

Other Languages

In most other languages that contain enumeration constants, the type of the enumeration constant is the enumerated type, a type that is usually different from the integer types.

Common Implementations

Some implementations support the use of the type **short** and **long**, in the enumeration declaration,[1040] to explicitly specify the type of the enumeration constant, while others[927] use pragmas, or command line options.[353]

Coding Guidelines

enumeration 517 set of named constants

The potential uses for enumeration constants are discussed elsewhere. On the whole these uses imply that an enumeration constant belongs to a unique type— the enumerated type it is defined within. Treating an enumeration constant as having some integer type only becomes necessary when use is made of its value—for instance, as an operand in an arithmetic or bitwise operation. The issues involved in mixing objects having enumerated type and the associated enumeration constants of that type as operands in an expressions are discussed elsewhere.

enumeration 517 set of named constants

Commentary

character 776 ' or " matches

The following is an undefined behavior potentially leading to a syntax violation:

```
1   char c = '\z';
```

footnote 879 65

because the characters that may follow a backslash are enumerated by the syntax. A backslash must be followed by one of the characters listed in the C sentence. This character sequence tokenizes as:

```
{char} {c} {=} {'}{\}{z}{'}{;}
```

character 886 constant single character value

A character-constant, that does not contain more than one character, is effectively preceded by an implicit conversion to the type **char**. If this type is signed and the constant sufficiently large, the resulting value is likely to be negative (the most common, undefined behavior, being to wrap).

Rationale

Proposals to add `'\e'` for ASCII ESC (`'\033'`) were not adopted because other popular character sets have no obvious equivalent.

Including *universal-character-name* as an *escape-sequence* removes the need to explicitly include it in other wording that refers to escape sequences (e.g., in conditional inclusion).

1881 #if escape sequences
2037 escape sequences future language directions

Lowercase letters as escape sequences are also reserved for future standardization, although permission is given to use other letters in extensions.

C90

Support for *universal-character-name* is new in C99.

C++

The C++ Standard classifies *universal-character-name* as an *escape-sequence*, not as a *c-char*. This makes no difference in practice to the handling of such *c-char*s.

Other Languages

In other languages the sequence of characters within a character constant usually forms part of the lexical grammar, not the language syntax. The constructs supported by *simple-escape-sequence* was once unique to C. A growing number of subsequent language (e.g., C++, C#, and Java; although Java does not support \?, \a, \v, or hexadecimal escape sequences). Perl also includes support for the escape sequences \e (escape) and \cC (Control-C).

Common Implementations

While lexing a character constant most translators simply look for a closing single-quote to match the one that began the *character-constant*. The internal, syntactic structure of the characters constant is not usually examined until a later phase of translation. As a consequence, many implementations do not diagnose the previous example as a violation of syntax.

Coding Guidelines

Character constants are usually used in code that processes data consisting of sequences of characters. This data may be, for instance, a line of text read from a file or command options typed as input to an executing program. Character constants are not usually the operands of arithmetic operators (see Table 866.3) or the index of an array (581 instances, or 1.4% of all character constants, versus 90,873 instances, or 5.3% of all integer constants).

825.3 integer constant not in visible source
842.1 floating constant not in visible source
822 constant syntax

Does the guideline recommendation dealing with giving symbolic names to constants unconditionally apply to character constants? The reasons given for why symbolic names should be used in preference to the constant itself include:

- *The value of the constant is likely to be changed during program maintenance.* Experience shows that the characters of interest to programs that process sequences of characters do not change frequently. Programs tend to process sets of characters (e.g., alphabetic characters), as shown by the high percentage of characters used in case labels (see Table 866.3).

- *A more meaningful semantic association is created.* Developers are experienced readers of sequences of characters (text) and they have existing strong semantic associations with the properties of many characters; for instance, it is generally known that the space character is used to separate words. That is, giving the name `word_delimiter` to the character constant `' '` is unlikely to increase the amount of semantic association.

- *The number of cognitive switches a reader has to perform is reduced.* Most of the characters constants used (see Figure 884.1) have printable glyphs. Are more or fewer cognitive switches needed to comprehend that, for instance, either `word_delimiter` or `' '` is a character used to delimit words? Use of the escape sequence `'\x20'` would require readers to make several changes of mental representation.

0 cognitive switch

The distribution of characters constants in the visible source (see Figure 884.1) has a different pattern from that of integer constants (see Figure 825.1). There are also more character constants whose lexical form might be said to provide sufficient symbolic information (e.g., the null character, new-line, space, the digit zero, etc.).

The number of cases where the appearance of a symbolic name, in the visible source, is more cost effective than a character constant would appear to be small. Given the cost of checking all occurrences of character constants for the few where replacement by a symbolic name would provide a benefit, a guideline recommendation is not considered worthwhile.

Table 866.1: Occurrence of various kinds of *character-constant* (as a percentage of all such constants). Based on the visible form of the `.c` files.

Kind of *character-constant*	% of all *character-constant*s
not an escape sequence	76.1
simple-escape-sequence	8.8
octal-escape-sequence	15.1
hexadecimal-escape-sequence	0.0
universal-character-name	0.0

Table 866.2: Occurrence of *escape-sequence*s within *character-constant*s and *string-literal*s (as a percentage of *escape-sequence*s for that kind of token). Based on the visible form of the `.c` files.

Escape Sequence	% of *character-constant* Escape Sequences	% of *string-literal* escape sequences	Escape sequence	% of *character-constant* Escape Sequences	% of *string-literal* Escape Sequences
\n	18.10	79.15	\b	0.66	0.04

Description

integer character constant

An integer character constant is a sequence of one or more multibyte characters enclosed in single-quotes, as in `'x'`.

Commentary

The syntax specification does not use the term *integer character constant*. It is used here, and throughout the standard, to distinguish character constants that are not wide character constants. While a character constant has type **int**, the common developer terminology is still *character constant* (the wide form being relatively rare; its use is explicitly called out).

C90

The example of ab as an integer character constant has been removed from the C99 description.

C++

A character literal is one or more characters enclosed in single quotes, as in `'x'`*, . . .* 2.13.2p1

A multibyte character is replaced by a *universal-character-name* in C++ translation phase 1. So, the C++ Standard does not need to refer to such entities here.

Coding Guidelines

The phrase *integer character constant* is rarely heard, although it is descriptive of the type and form of this integer constant. The common usage terminology is *character constant*, which does suggest that the constant has a character type. Coding guideline documents need to use the term *integer character constant* to remind developers that this form of constant has type **int**.

---

868 A wide character constant is the same, except prefixed by the letter **L**.

wide character constant
character constant wide

Commentary

The term *wide character constant* is used by developers to describe this kind of character constant. The prefix is an uppercase *L* only. There is no support for use of a lowercase letter.

Other Languages

Support for some form of wide characters is gradually becoming more generally available in programming languages. Fortran (since the 1991 standard) supports *char-literal-constant*s that contain a prefix denoting the character set used (e.g., `NIHONGO_'some kanji here'`). Later versions of Cobol supported similar functionality.

Common Implementations

While all implementations are required to support this form of character constant, they can vary significantly in the handling of the character sequences appearing within single-quotes. Many implementations simply support the same set of characters, in this context, as when no L prefix is given.

---

869 With a few exceptions detailed later, the elements of the sequence are any members of the source character set;

Commentary

The exceptions can occur through the use of escape sequences. The elements may also denote characters that are not in the source character set if an implementation supports any.

C++

[Note: in translation phase 1, a `universal-character-name` *is introduced whenever an actual extended character is encountered in the source text. Therefore, all extended characters are described in terms of* `universal-character-name`*s. However, the actual compiler implementation may use its own native character set, so long as the same results are obtained.]* 2.13.2p5

In C++ all elements in the sequence are characters in the source character set after translation phase 1. The creation of *character-literal* preprocessing tokens occurs in translation phase 3, rendering this statement not applicable to C++.

Common Implementations

Most implementations support characters other than members of the source character set. Any character that can be entered into the source code, using an editor, are usually supported within a character constant.

---

character constant mapped

they are mapped in an implementation-defined manner to members of the execution character set. 870

Commentary

translation phase 4 129
translation phase 5 133
translation phase 1 116
footnote 141 1874

This mapping can either occur in translation phase 4 (when the character constant occurs in an expression within a preprocessing directive) or 5 (all other occurrences). Those preprocessing tokens that are part of a preprocessing directive will have the values given them in translation phase 1. The two mapped values need not be the same.

C++

2.13.2p1 *An ordinary character literal that contains a single* `c-char` *has type* **`char`***, with value equal to the numerical value of the encoding of the* `c-char` *in the execution character set.*

2.2p3 *The values of the members of the execution character sets are implementation-defined, . . .*

2.13.2p2 *The value of a wide-character literal containing a single* `c-char` *has value equal to the numerical value of the encoding of the* `c-char` *in the execution wide-character set.*

Taken together, these statements have the same meaning as the C specification.

---

escape sequences
character constant
character constant escape sequences

The single-quote `'`, the double-quote `"`, the question-mark `?`, the backslash `\`, and arbitrary integer values are representable according to the following table of escape sequences: 871

```
single quote   '       \'
double quote   "       \"
question mark  ?       \?
backslash      \       \\
octal character        \octal digits
hexadecimal character  \xhexadecimal digits
```

Commentary

The standard defines a set of escape sequences that can occur both in character constants and string literals. It does not define a separate set for each kind of constant. A consequence of this single set is that there are multiple representations for some characters, for the two kinds of constants. Being able to prefix both the `'` and `"` characters with a backslash, without needing to know what delimiter they appear between, simplifies the automatic generation of C source code.

The single-quote `'` and the double-quote `"` characters have special meaning within character constants and string literals. The question-mark `?` character can have special meaning as part of a trigraph. To denote these characters in source code, some form of escape sequence is required, which in turn adds the escape sequence

character (the backslash \ character) to the list of special characters. Preceding any of these special characters with a backslash character is the convention used to indicate that the characters represent themselves, not their special meaning.

Octal and hexadecimal escape sequences provide a mechanism for developers to specify the numeric value of individual execution-time characters within an integer character constant. While the syntax does permit an arbitrary number of digits to occur in a hexadecimal escape sequence, the range of values of an integer character constant cannot be arbitrarily large.

882 escape sequence value within range

The conversion of these escape sequences occurs in translation phase 5.

133 translation phase 5

C++

The C++ wording, in Clause 2.13.2p3, does discuss arbitrary integer values and the associated Table 5 includes all of the defined escape sequences.

Other Languages

A number of languages designed since C have followed its example in offering support for escape sequences. Java does not support the escape sequence \?, or hexadecimal characters.

Common Implementations

Some implementations treat a backslash character followed by any character not in the preceding list as representing the following character only.

Coding Guidelines

Experience has shown that it is easy for readers to be confused by the character sequences \' and \\ when they occur among other integer character constants. However, a guideline recommendation telling developers to be careful serves no useful purpose.

What purpose does having a character constant containing an octal or hexadecimal escape sequence in the source serve? Since the type of an integer character constant is **int**, not **char**, an integer constant with the same value could appear in every context that an integer character constant could appear, with no loss of character set independence (because there was none in the first place).

One reason for using quotes, even around a hexadecimal or octal escape sequence, is to maintain the semantic associations, in a readers head, of dealing with a character value. Although integer character constants have type **int**, experience suggests that developers tend to think of them in terms of a character type. When comprehending code dealing with objects having character types, an initializer, for instance, containing other character constants, or values having semantic associations with character sets, a reader's current frame of mind is likely to be character based not integer based. The presence of a value between single-quotes is perhaps sufficient to maintain a frame of mind associated with character, not integer, values (i.e., there are no costs associated with a cognitive switch).

0 cognitive switch

Another reason for use of an escape sequence in a character constant is portability to C++, where the type of an integer character constant is **char**, not **int**. In this case use of an integer constant would not be equivalent (particularly if the constant was an argument to an overloaded function).

The character sequence \? is needed when sequences of the ? character occur together and a trigraph is not intended.

232 trigraph sequences replaced by

Example

```
#include <stdio.h>

#define TRUE  ('/'/'/')
#define FALSE ('-'-'-')

int main(void)
{
printf("%d%s\n", '\',',"'); // confusing ");
}
```

The double-quote " and question-mark ? are representable either by themselves or by the escape sequences \" and \?, respectively, but the single-quote ' and the backslash \ shall be represented, respectively, by the escape sequences \' and \\. 872

Commentary

The sequence \\ is only mapped once; that is, the sequence \\\\ represents the two characters \\, not the single character \.

Other Languages

To represent the character constant delimiter Pascal uses the convention of two delimiters immediately adjacent to each other (e.g., "'" represents the character single-quote).

escape sequence octal digits

The octal digits that follow the backslash in an octal escape sequence are taken to be part of the construction of a single character for an integer character constant or of a single wide character for a wide character constant. 873

Commentary

The value of the octal digits is taken as representing the value of a mapped single character in the execution character set. It is not possible to use an octal escape sequence to represent a character whose value is greater than what can be represented within three octal digits (e.g., 511). For the most common case of CHAR_BIT having a value of eight, this is not a significant limitation.

CHAR_BIT 307 macro

escape sequence octal value

The numerical value of the octal integer so formed specifies the value of the desired character or wide character. 874

Commentary

The maximum value that can be represented by three octal digits is 511. There are no prohibitions on using any of the octal values within the range of values that can be represented (unlike use of the \u form).

universal 815 character name syntax

Common Implementations

Most implementations use an 8-bit byte, well within the representable range of an octal escape sequence.

Coding Guidelines

character 871 constant escape sequences

As pointed out elsewhere, a character constant is likely to be more closely associated in a developer's mind with characters rather than integer values. One reason for representing characters in the execution character set using escape sequences is that a single character representation may not be available in the source character set. Is there any reason for a character constant to contain an octal escape sequence whose value represents a member of the execution character set that is representable in the source character set? There are two possible reasons:

1. For wide character constants, the mapping to the execution character might not be straight-forward. Use of escape sequences may be the natural notation to use to represent members. In this case it is possible that an escape sequence just happens to have the same value as a character in the source character set.
2. The available keyboards may not always support the required character (trigraphs are only available for characters in the basic source character set).

basic source 221 character set

Example

```
1  char CHAR_EOT = '\004';
2  char CHAR_DOL = '\044';
3  char CHAR_A   = '\101';
```

875 The hexadecimal digits that follow the backslash and the letter **x** in a hexadecimal escape sequence are taken to be part of the construction of a single character for an integer character constant or of a single wide character for a wide character constant.

escape sequence hexadecimal digits

Commentary

A hexadecimal escape sequence can denote a value that is outside the range of values representable in an implementation's **char** or `wchar_t` type. However, the specification states that an escape sequence represents a single character. This means that a large value cannot be taken to represent two or more characters (in an implementation that supports more than one character in an integer character constant) by using a hexadecimal value that represents the combined value of those two mapped characters.

Coding Guidelines

Occurrences of hexadecimal escape sequences are very rare in the visible source of the `.c` files. Given this rarity, developers are much more likely to be unfamiliar with the range of possible behaviors of hexadecimal escape sequences than the behaviors of octal escape sequences. Possible unexpected behaviors include:

866 escape sequence syntax
873 escape sequence octal digits

- The character 0 appears before the x or X in a hexadecimal constant, but not between the backslash and the *x* in an escape sequence.
- An arbitrary number of digits are permitted in a hexadecimal escape sequence, unlike octal escape sequences that contain a maximum of three digits. Padding the numeric part of hexadecimal escape sequences with leading zeros can provide a misleading impression. It is possible for a character not intended, by the developer, to be part of the hexadecimal escape sequence to be treated, by a translator, as being part of that sequence. (This requires implementation support for more than one character in a character constant.) This situation is more likely to occur in string literals.

877 escape sequence longest character sequence
885 character constant more than one character
895 string literal syntax

Cg 875.1 A hexadecimal escape sequence shall not be used in an integer character constant.

Example

```
1  char ch_1 = '\x00000000000000000000000041';
2  char ch_2 = '\0x42';
```

876 The numerical value of the hexadecimal integer so formed specifies the value of the desired character or wide character.

escape sequence hexadecimal value

Commentary

While there is no restriction on the number of digits in a hexadecimal escape sequence, there is a requirement that the value be in the range representable by the type **unsigned char** (which on some implementations is 32 bits) or the type `wchar_t`. There are no prohibitions on using any of the hexadecimal values within the range of values that can be represented (unlike use of the *\u* form).

882 escape sequence value within range
815 universal character name syntax

Common Implementations

The *desired character* in the execution environment, that is. As far as most translators are concerned, the numerical value is a bit pattern. In general they have no knowledge of which, if any, character this represents in the execution character set.

877 Each octal or hexadecimal escape sequence is the longest sequence of characters that can constitute the escape sequence.

escape sequence longest character sequence

Commentary

This specification resolves an ambiguity in the syntax. Although it is a little misleading in that it can be read to suggest that both octal and hexadecimal escape sequences may consist of an arbitrary long sequence of characters, the syntax permits a maximum of three digit characters in an octal escape sequence.

Coding Guidelines

Character constants usually consist of a single character, so much of the following discussion is not going to be applicable to them as often as it is to string literals.

For both forms of escape sequence there is the danger that any applicable digit characters immediately following them will be taken to be part of that sequence. The possible number of digits in an octal escape sequence is limited to three. If this number of digits is always used, there is never the possibility of a following character being included in the sequence.

Cg 877.1 An octal escape sequence shall always contain three digits.

Dev 877.1 The lexical form `'\0'` may be used to represent the null character.

CHAR_BIT 307 macro If `CHAR_BIT` has a value greater than 9, an octal escape sequence will not be able to denote all of the representable values in the type **`unsigned char`**.

Dev 875.1 A hexadecimal escape sequence may be used if an octal escape sequence cannot represent the required value.

Example

```
1  char a_char = '\02';
2  char null_char = '\0';
3  char b_char = '\0012';
```

In addition, characters not in the basic character set are representable by universal character names and certain nongraphic characters are representable by escape sequences consisting of the backslash \ followed by a lowercase letter: **\a**, **\b**, **\f**, **\n**, **\r**, **\t**, and **\v**.[65)] 878

Commentary

character display semantics A restatement of information given in the Syntax clause. The characters are nongraphical in the sense that they do not represent a glyph corresponding to a printable character. Their semantics are discussed elsewhere.

C90

Support for universal character names is new in C99.

C++

Apart from the rule of syntax given in Clause 2.13.2 and Table 5, there is no other discussion of these escape sequences in the C++ Standard. :-O

Other Languages

Support for universal character names is slowly being added to other ISO standardized languages. Java contains similar escape sequences.

Common Implementations

Some implementations define the escape sequence `\e` to denote *escape*; the Perkin-Elmer C compiler[1075] used escape sequences to represent characters not always available on keywords of the day.

digraphs 916

879 65) The semantics of these characters were discussed in 5.2.2.

footnote 65

Commentary

This discussion describes the effect of writing these characters to a display device.

character display semantics

880 If any other character follows a backslash, the result is not a token and a diagnostic is required.

Commentary

Such a sequence of characters does not form a valid preprocessing token (e.g., `'\D'` contains the preprocessing tokens {`'`}, {`\`}, {`D`}, and {`'`}, not the preprocessing token {`'\D'`}). When a preprocessing token contains a single-quote, the behavior is undefined.

776 character ' or " matches

776 character ' or " matches

It is possible that an occurrence of such a character sequence will cause a violation of syntax to occur, which will in turn require a diagnostic to be generated. However, implementations are not required to issue a diagnostic just because a footnote (which is not non-normative) says one is required.

C90

If any other escape sequence is encountered, the behavior is undefined.

C++

There is no equivalent sentence in the C++ Standard. However, this footnote is intended to explicitly spell out what the C syntax specifies. The C++ syntax specification is identical, but the implications have not been explicitly called out.

Common Implementations

Most C90 translators do not issue a diagnostic for this violation of syntax. They treat all characters between matching single-quotes as forming an acceptable character constant.

Coding Guidelines

There is existing practice that treats a backslash followed by another character as being just that character (except for the special cases described previously). The amount of source that contains this usage is unknown. Removing the unnecessary backslash is straight-forward for human-written code, but could be almost impossible for automatically generated code (access to the source of the generator is not always easy to obtain). Customer demand will ensure that translators continue to have an option to support existing practice.

881 See "future language directions" (6.11.4).

Constraints

882 The value of an octal or hexadecimal escape sequence shall be in the range of representable values for the type **`unsigned char`** for an integer character constant, or the unsigned type corresponding to **`wchar_t`** for a wide character constant.

escape sequence value within range

Commentary

A character can be represented in an object of type **`char`**, and all members of the basic source character set are required to be represented using positive values. This constraint can be thought of as corresponding to the general constraint given for constants being representable within their type. (Although integer character constants have type **`int`** they are generally treated as having a character type.)

477 char hold any member of execution character set

478 basic character set positive if stored in char object

823 constant representable in its type

C++

2.13.2p4

The value of a character literal is implementation-defined if it falls outside of the implementation-defined range defined for char (for ordinary literals) or **wchar_t** *(for wide literals).*

The wording in the C++ Standard applies to the entire character literal, not to just a single character within it (the C case). In practice this makes no difference because C++ does not provide the option available to C implementations of allowing more than one character in an integer character constant.

The range of values that can be represented in the type **char** may be a subset of those representable in the type **unsigned char**. In some cases defined behavior in C becomes implementation-defined behavior in C++.

```
1  char *p = "\0x80"; /* does not affect the conformance status of the program */
2                     // if CHAR_MAX is 127, behavior is implementation-defined
```

In C a value outside of the representable range causes a diagnostic to be issued. The C++ behavior is implementation-defined in this case. Source developed using a C++ translator may need to be modified before it is acceptable to a C translator.

Common Implementations

Some implementations perform a modulo operation on the value of the escape sequence to ensure it is within the representable range of the type **unsigned char**.

Example

```
1  unsigned char uc_1 = '\xffff';
2    signed char sc_1 = '\xff';
```

Semantics

character constant type

An integer character constant has type **int**. 883

Commentary

A character constant is essentially a way of representing the value of a character in the execution character set in a notation that is translator independent. C does not consider a character constant to be a special case of a string literal of length one (as some other languages do).

C++

2.13.2p1 *An ordinary character literal that contains a single* c-char *has type* **char***, . . .*

The only visible effect of this difference in type, from the C point of view, is the value returned by sizeof. In the C++ case the value is always 1, while in C the value is the same as sizeof(int), which could have the value 1 (for some DSP chips), but for most implementations is greater than 1.

2.13.2p1 *A multicharacter literal has type* **int** *and implementation-defined value.*

The behavior in this case is identical to C.

Other Languages

In most other languages a character constant has a character type.

Coding Guidelines

A common developer misconception is that integer character constants have type **char** rather than **int**. Apart from the C++ compatibility issue and character constants appearing as the immediate operand of the **sizeof** operator, it is unlikely that there will be any cascading consequences following from this misconception.

---

884 The value of an integer character constant containing a single character that maps to a single-byte execution character is the numerical value of the representation of the mapped character interpreted as an integer.

character constant value

Commentary

This mapping can occur in one of two contexts— translation phase 1, the results of which are used during preprocessing, and during translation phase 5. There is no requirement that the two mappings be the same.

116 translation phase 1
133 translation phase 5
1874 footnote 141

```
1   #include <stdio.h>
2
3   void f(void)
4   {
5   if ('a' == 97)
6      printf("'a' == 97 in translation phase 5\n");
7
8   #if 'a' == 97
9   printf("'a' == 97 in translation phase 1\n");
10  #endif
11  }
```

The mapping does not apply to any character constants that are denoted using octal or hexadecimal escape sequences (a fact confirmed by the response to DR #017, question 4 and 5).

Coding Guidelines

While translators treat character constants as numeric values internally, should developers be able to treat such constants as numeric values rather than symbolic quantities? The value of a character constant, which is not specified using an escape sequence, is representation information that depends on the implementation. (Although some of their properties are known, their range is specified and the digit characters have a contiguous encoding.) The guideline recommendation dealing with the use of representation information is applicable here.

882 escape sequence value within range
223 digit characters contiguous
569.1 representation information using

In some application domains a single representation is used for an implementations execution character set. Many character sets order the bit representations of their characters so that related characters have very similar bit patterns. For instance, corresponding upper- and lowercase letters are differentiated by a single bit in the Ascii character set, information that developers sometimes make use of to convert between upper- and lowercase (even though there are library functions available to perform the conversion). The following discussion looks at the issues involved in making use of character set representation details.

On seeing an arithmetic, bitwise, or relational operation involving a character constant, a reader needs to perform additional cognitive work that is not usually needed for other kinds of operations on this kind of operand, including:

- Performing a cognitive task switch. Character constants are usually thought of in symbolic rather than numeric terms. This is the rationale behind the lack of a guideline recommending that character constants be denoted, in the visible source by names, because of the strong semantic associations to readers of the source, created from experience in reading text.

0 cognitive switch
866 character constant syntax

- Recalling knowledge of the expected execution-time representation of character values. This is needed to deduce the intended consequences of the operation; for instance, using a bit-or operator to convert uppercase to lowercase.
- Deciding whether the result should continue to be treated as a symbolic quantity, or whether further operations are numeric in nature.

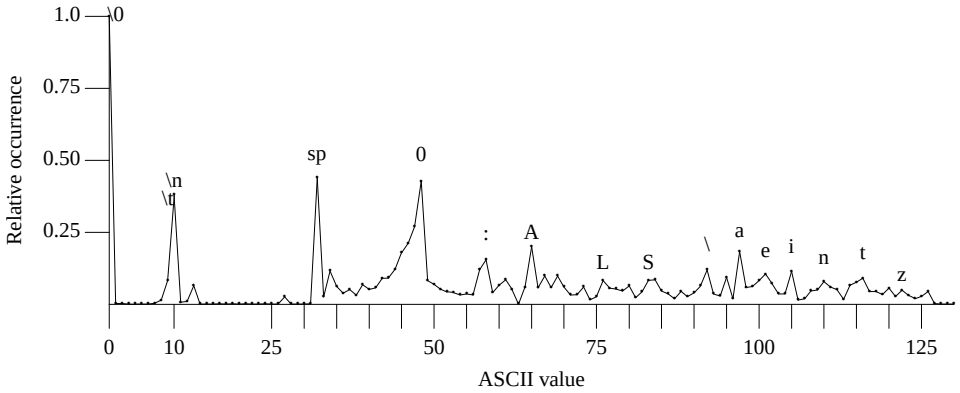

Figure 884.1: Relative frequency of occurrence of characters in an integer *character-constant* (as a fraction of the most common character, the null character). Based on the visible form of the `.c` files.

representation information using 569.1

An integer character constant appearing as the operand of a bitwise, arithmetic, or relational operator is making use of representation information and is covered by a guideline recommendation.

Example

```
#define mk_lower_letter(position) ('a' + (position))

void f(char p1, int p2)
{
if ('a' < 'b')
   ;
if ('a' < 97)
   ;

p1++;          /* Was p1 last assigned a decimal constant or an integer character constant? */
p1 = 'a' + 3;  /* Two different representation of an int being added. */
p1 = 'a' * 2;  /* What does multiplying 'a' by 2 mean? */
p1 = 'a' + p2; /* The value of p2 is probably not known at translation time. */
}
```

Table 884.1: Occurrence of a *character-constant* appearing as one of the operands of various kinds of binary operators (as a percentage of all such constants; includes escape sequences). Based on the visible form of the `.c` files. See Table 866.3 for more detailed information.

Operator	%
Arithmetic operators	4.5
Bit operators	0.5
Equality operators	31.3
Relational operators	4.1

character constant more than one character

The value of an integer character constant containing more than one character (e.g., **'ab'**), or containing a character or escape sequence that does not map to a single-byte execution character, is implementation-defined. 885

Commentary

Why does the C Standard allow for the possibility of more than one character in an integer character constant? There is some historical practice in this area. There is also a long-standing practice (particularly in Fortran)

of packing several characters into an object having a larger integer type.

C90

The value of an integer character constant containing more than one character, or containing a character or escape sequence not represented in the basic execution character set, is implementation-defined.

C++

The C++ Standard does not include any statement covering escape sequences that are not represented in the execution character set. The other C requirements are covered by words (2.13.2p1) having the same meaning.

889 wide character escape sequence implementation-defined

Other Languages

A character constant, in the lexical sense, that can contain more than one character is unique to C.

Common Implementations

Given that an integer character constant has type **int**, most implementations support as many characters as there are bytes in that type, within character constants. The ordering of the characters within the representation of the type **int** varies between implementations. Possibilities, when the type **int** occupies four bytes, include (where underscores indicate padding bytes):

```
  'ab' ⇒ __ab, ab__, ba__
'abcd' ⇒ abcd, badc, dcba
```

The implementation-defined behavior of most implementations, for an escape sequence denoting a value outside of the range supported by the type **char** (but within the supported range of the type **unsigned char**), is to treat the most significant bit of the value as a sign bit. For instance, if the type **char** occupies eight bits, the value of the escape sequence `'\xFF'` is -1— if it is treated as a signed type. If it is treated as an unsigned type, the same escape sequence would have value 255. The sequence of casts `(int)(char)(unsigned char)0xFF` is one way of thinking about the conversion process.

Coding Guidelines

The representation, in storage during program execution, of an integer character constant containing more than one character depends on implementation-defined behavior; it also defeats the rationale of using a character constant (i.e., its character'ness). The guideline recommendation dealing with the use of representation information is applicable.

569.1 representation information using

Table 885.1: Number of *character-constant*s containing a given number of characters. Based on the visible form of the `.c` files.

Number of Characters	Occurrences	Number of Characters	Occurrences
0	27	4	21
1	50,590	5	4
2	0	6	4
3	8	7	0

886 If an integer character constant contains a single character or escape sequence, its value is the one that results when an object with type **char** whose value is that of the single character or escape sequence is converted to type **int**.

character constant single character value

Commentary

char 477 hold any member of execution character set
basic character set 478 positive if stored in char object
escape sequence 882 value within range
char 516 range, value, implementation and behavior
escape sequence 882 value within range

A member of the basic execution character set can be represented in an object of type **char**, and all such members are represented using positive values. Under this model an escape sequence can be thought of as representing a sequence of bits. The value of this bit representation must be representable in the type **unsigned char**, but the actual value used is the bit representation treated as having a type **char**. The type **char** supports the same range of values as either the signed or unsigned character types, and the value of an escape sequence must be representable in the type **unsigned char**. If the type **char** is treated as being signed, any escape sequences whose value is greater than SCHAR_MAX results in implementation-defined behavior.

C++

The requirement contained in this sentence is not applicable to C++ because this language gives character literals the type **char**. There is no implied conversion to **int** in C++.

Other Languages

In most other languages character constants have type **char** and these issues do not apply.

Coding Guidelines

It is possible that a character constant may denote a value that is not representable in some implementations **char** type. An implementation's inability to support the desired behavior for these values is an issue that may need to be taken into account when selecting which vendors' translator to use. A guideline recommending against creating such a character constant serves no practical purpose (it is assumed that such a value was denoted using a character constant for a purpose).

---

wide character constant type of

A wide character constant has type **wchar_t**, an integer type defined in the **<stddef.h>** header. 887

Commentary

It is the responsibility of the implementation to ensure that the definition of wchar_t contained in the **<stddef.h>** header is compatible with the internal type used by the translator to assign a type to wide character constants. A developer-defined typedef whose name is wchar_t does not have any affect on the type of a wide character constant, as per the behavior for **sizeof** and size_t.

sizeof 1127 result type

C++

2.13.2p2 *A wide-character literal has type **wchar_t**.[23)]*

In C++ **wchar_t** is one of the basic types (it is also a keyword). There is no need to define it in the **<stddef.h>** header.

3.9.1p5 *Type **wchar_t** shall have the same size, signedness, and alignment requirements (3.9) as one of the other integral types, called its underlying type.*

Although C++ includes the C library by reference, the **<stddef.h>** header, in a C++ implementation, cannot contain a definition of the type **wchar_t**, because **wchar_t** is a keyword in C++. It is thus possible to use the type **wchar_t** in C++ without including the **<stddef.h>** header.

Other Languages

In Java all character constants are capable of representing the full Unicode character set; there is no distinction between ordinary characters and wide characters.

Common Implementations

The type wchar_t usually has a character type on implementations that only support the basic execution character set.

Coding Guidelines

A program that contains wide characters is also likely to use the type `wchar_t` and the coding guideline issues are discussed under that type.

---

888 The value of a wide character constant containing a single multibyte character that maps to a member of the extended execution character set is the wide character corresponding to that multibyte character, as defined by the **`mbtowc`** function, with an implementation-defined current locale.

multibyte character mapped by mbtowc

Commentary

This requirement applies to members of the extended character set, not to members of the basic source character set.

216 extended character set

From the practical point of view, translators need at least some of the members of the basic source character set to always map to the same values. For instance, the format specifiers used in the `scanf` family of functions treat white space as a special directive. Multibyte characters in the format string are converted to widechars in parsing the format, but there is no `iswspace` library function to test for these characters. The only method is to check whether a character value is within the range of the basic execution character set and use the `isspace` library function. The translator behaves as-if the program fragment:

```
1  save_locale();
2  setlocale("LC_ALL", current_locale);
3  value = mbtowc(wide_character_constant);
4  restore_locale();
```

were executed in translation phase 7, where `curr_locale` is the implementation-defined current locale. The call to the `mbtowc` function cannot use the C locale by default because that locale does not define any extended characters. A related issue is discussed elsewhere.

215 extended characters
2024 L'x' == 'x'

C++

The value of a wide-character literal containing a single `c-char` *has value equal to the numerical value of the encoding of the* `c-char` *in the execution wide-character set.* 2.13.2p2

The C++ Standard includes the `mbtowc` function by including the C90 library by reference. However, it does not contain any requirement on the values of wide character literals corresponding to the definitions given for the `mbtowc` function (and its associated locale).

There is no requirement for C++ implementations to use a wide character mapping corresponding to that used by the `mbtowc` library function. However, it is likely that implementations of the two languages, in a given environment, will share the same library.

Coding Guidelines

Accepting the implementation-defined behavior inherent in using wide string literals is part of the decision process that needs to be gone through when using any extended character set. One of the behaviors that developers need to check is whether the implementation-defined locale used by the translator is the same as the locale used by the program during execution.

---

889 The value of a wide character constant containing more than one multibyte character, or containing a multibyte character or escape sequence not represented in the extended execution character set, is implementation-defined.

wide character escape sequence implementation-defined

Commentary

Support for wide character constants containing more than one multibyte character is consistent with such support for integer character constants. This specification requires the multibyte character to be a member of the extended execution character set. The equivalent wording for integer character constants requires that the value map to single-byte execution character.

885 character constant more than one character

C++

The C++ Standard (2.13.2p2) does not include any statement covering escape sequences that are not represented in the execution character set.

Example

```
#include <wchar.h>

wchar_t w_1 = L'\xff',
        w_2 = L'ab';
```

EXAMPLE 1 The construction **'\0'** is commonly used to represent the null character. 890

Commentary

null character 219 There are many ways of representing the null character. The construction '\0' is the shortest *character-constant*. This character sequence is also used within string literals to denote the null character.

EXAMPLE 2 Consider implementations that use two's-complement representation for integers and eight bits for objects that have type **char**. In an implementation in which type **char** has the same range of values as **signed char**, the integer character constant **'\xFF'** has the value **-1**; if type **char** has the same range of values as **unsigned char**, the character constant **'\xFF'** has the value **+255**. 891

Commentary

This difference of behavior, involving hexadecimal escape sequences, is often a novice developer's first encounter with the changeable representation of the type **char**.

EXAMPLE 3 Even if eight bits are used for objects that have type **char**, the construction **'\x123'** specifies an integer character constant containing only one character, since a hexadecimal escape sequence is terminated only by a non-hexadecimal character. To specify an integer character constant containing the two characters whose values are **'\x12'** and **'3'**, the construction **'\0223'** may be used, since an octal escape sequence is terminated after three octal digits. (The value of this two-character integer character constant is implementation-defined.) 892

Commentary

An example of what is specified in the syntax.

EXAMPLE 4 Even if 12 or more bits are used for objects that have type **wchar_t**, the construction **L'\1234'** specifies the implementation-defined value that results from the combination of the values **0123** and **'4'**. 893

wide character escape sequence implementation-defined 889

Commentary

What is meant by "combination of the values" is not defined by the standard. The construction L'\1234' might be treated as equivalent to the wide character constant L'S4' (*S* having the Ascii value 0123), or some alternative implementation-defined behavior may occur.

Forward references: common definitions **<stddef.h>** (7.17), the **mbtowc** function (7.20.7.2). 894

6.4.5 String literals

string literal syntax

895

string-literal:
" *s-char-sequence*$_{opt}$ "
L" *s-char-sequence*$_{opt}$ "

```
s-char-sequence:
            s-char

            s-char-sequence s-char
s-char:
            any member of the source character set except
                        the double-quote ", backslash \\, or new-line character
            escape-sequence
```

Commentary

Escape sequences are part of the syntax of string literals. This means that the consequences called out in footnote 64 also apply to string literals.

862 footnote 64

C++

In C++ a *universal-character-name* is not considered to be an escape sequence. It therefore appears on the right side of the *s-char* rule.

Other Languages

Some languages use the single-quote, ', character to delimit string literals. Character sequences were originally denoted in Fortran using the notation of a character count followed by the letter *H* (after Herman Hollerith, the inventor of the 80-column punch card), followed by the character sequence (e.g., `11HHello world`).

Common Implementations

When building a *string-literal* preprocessing token from a sequence of characters, most implementations simply search for the terminating *double-quote*. This means that escape sequences that are not part of the syntax, such as `\z`, are included as part of the string literal. Any multibyte characters contained within string literals and character constants are likely to be translated without diagnostic being issued. The execution-time behavior is dependent on the support provided by an implementation's library functions.

Most implementations issue a diagnostic if a *new-line* character is encountered before the terminating *double-quote* is seen. Syntax error recovery after this point can be very poor. Some implementations continue to look for a closing *double-quote*, while others terminate the string literal at that point. However, by then it is likely that characters intended to form other tokens have been subsumed into the string literal.

Coding Guidelines

Other coding guideline subsections discuss recommendations that symbolic names be associated with constant values. Do the same cost/benefit considerations also apply to string literals? The following list discusses the possibility of the benefits obtained by using symbolic names for other kinds of constants also providing benefits when applied to string literals:

825.3 integer constant not in visible source
842.1 floating constant not in visible source
866 character constant syntax
822 constant syntax

- *The string literal value may be changed during program maintenance.* In practice string literals are usually unique within the program that contains them. While it is unlikely that the same changes

will have to be made to identical string literals, relationships between other constants may exist. For instance:

```
#define MAX_NAME 12
#define NAME_FMT "%12s"   /* The digits must be the same as MAX_NAME. */
```

String literals are different from other constants in that it is sometimes necessary to make a change that relates to all of them. The common feature of string literals is usually the language in which their contents is written. (It may be decided to change messages to use the past tense rather than the present tense, add/remove full stops, or as an intermediate stage in localization.)

- *A symbolic name provides a more meaningful semantic association.* For some string literals it is possible to deduce a semantic association by reading the contained character sequence.
- *Reducing the cost of cognitive switches.* It is not possible to estimate whether reading the contents of the string literal, rather than reading a symbolic name to deduce a semantic association, incurs a greater or lesser cognitive switch cost.

While there may not be a worthwhile benefit in having a guideline recommending that names be used to denote all string literals in visible source code, there may be source configuration-management reasons why it may be worthwhile to place related string literals in a single file and reference them using a symbolic name. This consideration falls outside the scope of these coding guidelines.

Usage

Usage of escape sequences in string literal and string lengths is given elsewhere (see Table 866.2 and Figure 293.1).

Description

---

character string literal

A *character string literal* is a sequence of zero or more multibyte characters enclosed in double-quotes, as in **"xyz"**. 896

Commentary

This is a restatement of information given in the Syntax clause which also defines the term *character string literal*.

The ordering of the sequence of characters in a source file forming a string literal token is honored in their ordering in storage. (There is no such guarantee for character constants containing more than one character.) The standard requires that implementations support a minimum number of characters in a string literal. limit 293 string literal

A string literal has uses other than for organizing characters to be sent to an output stream. The characters can also represent data that is used by algorithms within a program— for instance, the four letters ATCG representing the DNA bases in a program that recognizes sequences in genes.

Other Languages

Virtually every language has some form of string literal. Some languages enclose the characters in single-quotes.

Coding Guidelines

Any conversion by the translator of multibyte characters in string literals and character constants occurs in the locale of the translator. This locale need not be the same as the one that applies during program execution (which can be changed during program execution via calls to the `setlocale` library function). Ensuring consistency between translation- and execution-time locales is a software engineering issue that is outside the scope of these coding guidelines.

---

wide string literal

A *wide string literal* is the same, except prefixed by the letter **L**. 897

Commentary

This defines the term *wide string literal*. The prefix changes the type of the string literal. Like character string literals, the ordering of wide string characters in storage is the same as that given in the source code. The standard says nothing about the ordering of bytes within an object that has type `wchar_t`.

---

898 The same considerations apply to each element of the sequence in a character string literal or a wide string literal as if it were in an integer character constant or a wide character constant, except that the single-quote `'` is representable either by itself or by the escape sequence `\'`, but the double-quote `"` shall be represented by the escape sequence `\"`.

escape sequences string literal

Commentary

These issues are discussed in the subsection on character constants.

871 escape sequences character constant

Other Languages

The idea of doubling up on the string delimiter to represent a single one of these characters is used in some languages, while others use some form of escape sequence. Pascal represents a `'` character within a string literal using the notation ''. The null string is represented by '', and '''' represents a string containing one single-quote, not two null strings. Pascal also uses the `'` character to delimit both character constants and string literals.

Coding Guidelines

The same possibilities for confusing sequences of escape sequences applies to string literals as integer character constants.

871 escape sequences character constant

Semantics

---

899 In translation phase 6, the multibyte character sequences specified by any sequence of adjacent character and wide string literal tokens are concatenated into a single multibyte character sequence.

Commentary

Being able to concatenate character and wide string literals is needed in a number of situations, including:

135 translation phase 6

- Macros in the header **<stdint.h>** define character string literals for use in formatted I/O; these may need to be appended to wide string literals that are also part of the format specifier.
- The preprocessor macros `__DATE__`, and `__TIME__`, may need to be appended to wide string literals.

C90

The C90 Standard does not allow character and wide string literals to be mixed in a concatenation:

> *In translation phase 6, the multibyte character sequences specified by any sequence of adjacent character string literal tokens, or adjacent wide string literal tokens, are concatenated into a single multibyte character sequence.*

The C90 Standard contains the additional sentence:

> *If a character string literal token is adjacent to a wide string literal token, the behavior is undefined.*

C90 does not support the concatenation of a character string literal with a wide string literal.

C++

2.13.4p3

In translation phase 6 (2.1), adjacent narrow string literals are concatenated and adjacent wide string literals are concatenated. If a narrow string literal token is adjacent to a wide string literal token, the behavior is undefined.

The C++ specification has the same meaning as that in the C90 Standard. If string literals and wide string literals are adjacent, the behavior is undefined. This is not to say that a translator will not concatenate them, only that such behavior is not guaranteed.

Other Languages

In some languages white space acts as a concatenation operator, while in some other languages the token `+` is used to indicate concatenation. Whichever method is used to indicate the operation, it usually takes place during program execution, although some implementations may carry out optimizations that perform it during translation.

Example

```
1  char *p1 = "A very long string ..."
2             "that needs to be split across a line";
3
4  char *p2 = "\0xff" "f"; /* Concatenation happens after processing of escape sequences. */
```

Usage

In the visible form of the `.c` files 4.9% (`.h` 15.6%) of all string literals are concatenated (i.e., immediately adjacent to another string literal) and 1.4% (`.h` 10.7%) occupied more than one source line (i.e., line splicing occurred).

line splicing 118

If any of the tokens are wide string literal tokens, the resulting multibyte character sequence is treated as a wide string literal; 900

Commentary

This requirement can be viewed as a promotion of the string to its widest version. There is no requirement that when a character string literal and wide string literal are concatenated, the elements in the character string literal be converted as if by a call to the `btowc` function. Also, there is no requirement that `ch == wctob(btowc(ch))` when `ch` is a member of the basic character set. The meaningfulness of the resulting wide string literal will depend on the mapping used for the basic character set (i.e., does `L'x' == 'x'` hold).

L'x' == 'x' 2024

Example

```
1  #include <stddef.h>
2
3  wchar_t *wp = L"My ascii friend said: " "Hello " L"Tamai San";
```

---

otherwise, it is treated as a character string literal. 901

Commentary

There is no reason to treat it otherwise.

Example

```
1  char *long_string = "Strings that span more than one"
2                      "line are best split up to make"
3                      "them more readable.";
```

902 In translation phase 7, a byte or code of value zero is appended to each multibyte character sequence that results from a string literal or literals.[66)]

string literal zero appended

Commentary

This zero value byte specifies how string literals are delimited in C. An alternative specification would have been to specify that a length byte, or word, should be placed before the first character of the string literal. This byte becomes part of the value of the string literal. It is always added, even if the multibyte character sequence already contains a byte with value zero anywhere within itself. However, there is a special case involving initializers where this byte is not added.

1700 EXAMPLE array initialization

Other Languages

Few languages specify the representation of string literals. Many implementations of Pascal originally used a byte at the front of the string to hold the number of characters in the literal. Using of a length byte limits the maximum length of a string literal. A number of Pascal implementations subsequently migrated to the null byte termination representation (which also provided compatibility with C).

Coding Guidelines

Experience has shown that developers regularly fail to take this zero value appearing at the end of a string literal into account. For instance, when allocating storage for a copy of a string literal, forgetting to add one to the value returned by the `strlen` function.

Example

```
1  char sa[4] = "abc";              /* sa[3] initialized with the value zero. */
2  char *two_strings = "abc" "def"; /* Zero value appended to the concatenated string literal. */
3  char *two_zeros = "1\000";       /* A zero byte is still appended. */
```

903 The multibyte character sequence is then used to initialize an array of static storage duration and length just sufficient to contain the sequence.

string literal static storage duration

Commentary

151 static storage duration initialized before startup

This initialization occurs during program startup. The array of static storage duration is the sequence of storage locations used to hold the individual multibyte characters. Note that this storage area is not **const** qualified. Modifying a string literal is not prohibited, but it may have unexpected effects. Unlike the specification for compound literals, this array is not referred to as an unnamed object (although it is effectively one).

909 string literal modify undefined

1058 compound literal unnamed object

Other Languages

Most languages treat string literals as if they had static storage duration, but do not always explicitly call out this fact. Few languages discuss the underlying representation details of how string literals are allocated storage.

Common Implementations

Some freestanding implementations place string literals in read-only memory, often in the same storage area as the executable code. The reasons for this are economic as well as technical, read-only storage being cheaper than read/write storage. This usage also occurs on some hosted implementations, but is becoming rarer as vendors don't always want to give users read access to storage containing executable code (usually for security reasons).

A few hosted implementations mark the storage used for string literals as read-only. Such usage requires hardware support and only a few hosts provide such fine-grain memory management of program data.

string literal type

For character string literals, the array elements have type **char**, and are initialized with the individual bytes of the multibyte character sequence; 904

Commentary

A character string literal is thus indistinguishable in storage from an array of **char** that has had each element assigned the appropriate character value, the last array element being assigned the value zero.

C++

2.13.4p1 *An ordinary string literal has type "array of n* `const char` *" and static storage duration (3.7), where n is the size of the string. . . .*

```
1  char *g_p = "abc"; /* const applies to the array, not the pointed-to type. */
2
3  void f(void)
4  {
5  "xyz"[1] = 'Y'; /* relies on undefined behavior, need not be diagnosed */
6  "xyz"[1] = 'Y'; // ill-formed, object not modifiable lvalue
7  }
```

Example

If the identifier `anonymous` denotes the arrays of static storage duration allocated by the implementation to hold string literals, then the following initializers are equivalent:

```
1  static char anonymous_a[] = "a\xFF";
2  static char anonymous_b[] = {(char)'a', (char)0xFF, 0};
```

wide string literal type of

for wide string literals, the array elements have type **wchar_t**, and are initialized with the sequence of wide characters corresponding to the multibyte character sequence, as defined by the **mbstowcs** function with an implementation-defined current locale. 905

Commentary

The `mbstowcs` function maps from the representation used in the wide string to the wide character representation used for the type `wchar_t`. This function maps a sequence of such multibyte characters, while the `mbtowc` function specified for wide character constants operates on a single multibyte character. A developer-defined typedef whose name is `wchar_t` does not have any affect on the type of a wide character constant, as per the behavior for wide character constants.

multibyte character mapped by mbtowc 888

wide character constant type of 887

C90

The specification that `mbstowcs` be used as an implementation-defined current locale is new in C99.

C++

2.13.4p1 *An ordinary string literal has type "array of n* `const char` *" and static storage duration (3.7), where n is the size of the string. . . .*

The C++ Standard does not specify that `mbstowcs` be used to define how multibyte characters in a wide string literal be mapped:

2.13.4p5

The size of a wide string literal is the total number of escape sequences, universal-character-names, and other characters, plus one for the terminating `L'\0'`.

The extent to which the C library function `mbstowcs` will agree with the definition given in the C++ Standard will depend on its implementation-defined behavior in the current locale.

Coding Guidelines

The issue of ensuring consistency of locales is discussed elsewhere.

888 multibyte character mapped by mbtowc

---

906 66) A character string literal need not be a string (see 7.1.1), because a null character may be embedded in it by a **\0** escape sequence.

footnote 66

Commentary

This footnote is highlighting an important distinction— a string is terminated by the first null character in a sequence of characters, while a character string literal is simply a sequence of characters enclosed between double-quote characters. A translator will still append a zero to a string literal, even if it already contains one.

902 string literal zero appended

C++

This observation is not made in the C++ document.

Other Languages

Many languages do not specify how strings are to be represented, but their implementations do need to select some method. Any implementation that chooses to indicate the end of a string by using a value that could be contained within a string literal will encounter this issue.

Coding Guidelines

The usual method of finding the end of a string literal is to search for the terminating null character. If a string literal contains more than one such byte, some other method of knowing the number of bytes may be needed. Such usage is certainly unusual and runs counter to common developer expectations (always a potential source of faults). However, there is little evidence to show that faults are introduced into programs because of the presence of multiple null characters in string literals.

Example

```
1  char *seven_nulls = "\0\0\0\0\0\0\0"; /* 7th added by translator. */
2  char *packed_alphabet = "a\0abilities\0ability\0able\0about";
```

---

907 The value of a string literal containing a multibyte character or escape sequence not represented in the execution character set is implementation-defined.

Commentary

A string literal is the sum of its parts. This specification of behavior mimics that given for character constants.

885 character constant more than one character
889 wide character escape sequence implementation-defined

C90

This specification of behavior is new in C99.

C++

Like C90, there is no such explicit specification in the C+ Standard.

Common Implementations

Most implementations map octal and hexadecimal escape sequences to their numeric value and copy this into the program image.

Usage

In the visible form of the .c files 2.1% (.h 2.9%) of characters in string literals are not in the basic execution character set (the value of escape sequences were compared using the values of the Ascii character set).

---

string literal distinct array

It is unspecified whether these arrays are distinct provided their elements have the appropriate values. 908

Commentary

string literal 1068 distinct object

A translator may assign string literals that contain the same values to the same storage locations. This has the advantage of reducing the total amount of storage required for static data. It is also possible to overlay string literals with characters at the end of other string literals. However, there is a possible interaction here with the **restrict** qualifier. Passing a string literal as an argument to a function whose parameter is a pointer to a restrict-qualified type could be undefined behavior, if the storage used to hold the string literal was shared by more than one reference to that literal.

restrict 1491 intended use

footnote 1073 82

string literal 1068 distinct object

There is a similar statement for string literals associated with compound literals.

C++

Clause 2.13.4p4 specifies that the behavior is implementation-defined.

Other Languages

Most languages do not permit the contents of string literals to be modified, so whether they share the same storage locations is not an issue.

Coding Guidelines

The developer does not usually have any control over how string literals are allocated in storage; but the developer can choose not to modify them.

string literal 909 modify undefined

Example

In the following code do p1 and p2 both initially point to the same static array? Does p3 == (p1 + 6)?

```
1  char *p1 = "Hello World";
2  char *p2 = "Hello World";
3  char *p3 = "World";
```

Table 908.1: Number of *string-literal*s (the empty *string-literal*, i.e., "", was not counted). Based on the visible form of the .c and .h files. Although many of the program source trees contain more than one program, they were treated as a single entity. A consequence of this is that the number of unique matches represents a lower bound; having a smaller number of string literals is likely to reduce the probability of matches occurring.

	gcc	idsoftware	linux	netscape	openafs	openMotif	postgresql	Total
Number of strings	38,063	21,811	177,224	30,358	30,574	11,285	16,387	325,702
Bytes in strings	656,366	324,667	4,050,258	512,766	737,015	288,018	298,888	6,867,978
Number of unique strings	18,602	9,148	114,170	17,192	18,483	7,401	7,930	187,549
Bytes in unique strings	434,028	170,170	3,189,466	378,917	562,555	240,811	219,690	5,159,385

---

string literal modify undefined

If the program attempts to modify such an array, the behavior is undefined. 909

Commentary

If a string literal occupies storage that has been used to represent more than one string literal, then a modification of one string literal could affect the values of other string literals. If the string literal has been placed in read-only memory, any attempted modification will have no effect.

Other Languages

Most languages treat string literals as read-only data, although some (e.g., Fortran) do not specify that their values cannot be changed.

Common Implementations

Most hosted implementations allow the modification to take place without complaint. The decision on shared storage will have been made by the translator, and the host O/S or the implementation's runtime system is unlikely to have any say in the matter.

Coding Guidelines

The following deviation assumes the modification will have the desired effect.

0 deviations
coding guidelines

Cg 909.1

A program shall not modify a string literal during its execution.

Dev 909.1

If string literals occupy a substantial amount of the storage available to a program and worthwhile savings are obtained by allowing them to be modified, they may be modified.

Example

```
1  char *p1 = "Hello World";
2  char *p2 = "Hello World";
3  char *p3 = "World";
4
5  void f(void)
6  {
7  "Hello World"[3] = 'a';
8
9  *p1 = 'B'; /* Does the character pointed to by p2 now equal 'B'? */
10 *p3 = 'w'; /* Does p2 now point at the string Hello World? */
11 }
```

---

910 EXAMPLE This pair of adjacent character string literals

```
"\x12" "3"
```

produces a single character string literal containing the two characters whose values are **'\x12'** and **'3'**, because escape sequences are converted into single members of the execution character set just prior to adjacent string literal concatenation.

Coding Guidelines

This example shows the advantage of using an octal escape sequence in this context. A leading zero could have been given to ensure that the character '3' would not have been interpreted as belonging to that octal escape sequence.

---

911 **Forward references:** common definitions **<stddef.h>** (7.17), the **mbstowcs** function (7.20.8.1).

6.4.6 Punctuators

---

punctuator
syntax

912

punctuator: one of

```
[ ] ( ) { } . ->
++ -- & * + - ~ !
/ % << >> < > <= >= == != ^ | && ||
? : ; ...
= *= /= %= += -= <<= >>= &= ^= |=
, # ##
<: :> <% %> %: %:%:
```

Commentary

In most cases it is only necessary for a lexer to lookahead one character when dividing up the input stream into preprocessing tokens (the need to potentially tokenize the punctuators **%:%:** and **...** requires two characters of lookahead, for when the last character is not one needed to build them).

The only graphic characters from the Ascii character set not included in this list are *$*, *@*, and \ (which is used to indicate an escape sequence).

C90

Support for **<: :> <% %> %: %:%:** was added in Amendment 1 to the C90 Standard. In the C90 Standard there were separate nonterminals for punctuators and operators. The C99 Standard no longer contains a syntactic category for operators. The two nonterminals are merged in C99, except for **sizeof**, which was listed as an operator in C90.

C++

The C++ nonterminal *preprocessing-op-or-punc* (2.12p1) also includes:

```
::   .*   ->*   new   delete
and   and_eq   bitand   bitor   compl
not   not_eq   or   or_eq   xor   xor_eq
```

The identifiers listed above are defined as macros in the header **<iso646.h>** in C. This header must be included before these identifiers are treated as having their C++ meaning.

Other Languages

C contains a much larger set of punctuators than most other programming languages. Some languages use the *$* character as an operator/punctuator (e.g., Snobol 4). One of the original design aims of Cobol was to make programs written in it read like English prose. To this end keywords were used to represent operators that were normally indicated by punctuators in other languages:

```
01 data-value PIC 9(3) OCCURS 10 TIMES.
MOVE x to b.
ADD x to y GIVING z.
WRITE report-out AFTER ADVANCING PAGE.
```

Some languages (e.g., Ada and Fortran) include the ** operator (usually as a binary operator denoting exponentiation). Fortran uses abbreviated names for some operators (e.g., **.EQ.** for **==** and **.LT.** for **<**).

Common Implementations

Some implementations include the *@* character in the list of punctuators.

Coding Guidelines

Some punctuators are visually very similar to other punctuators (e.g., **!=** and **|=**). Other punctuators are very easily overlooked— for instance, the comma character. One of the reasons for these visual similarities is the font used to display source. The importance of presenting characters in an easy-to-read form has been recognized in other disciplines; for instance, chemistry and mathematics have specific fonts that have been designed for them. While a great deal of effort has been invested in creating fonts that make it easier to read text documents, such as books, or grab people's attention (e.g., advertising) very little effort has gone into designing a font to make source code easier to read.

Baecker and Marcus[77] make a number of interesting suggestions. For instance, unary operators can be made more noticeable by having them in superscript (e.g., $i = j * {}^{-}k$ versus $i = j *^{-} k$ or $x = y + {}^{+}- z$ versus $x = y^{++} - z$). While some fonts do deal with character pairs, the pairs that occur in source tend to be separated by other characters; for instance, matching bracketing characters, such as **[ ]**, **( )**, and **{ }**, can be nested within each other. Having the outer brackets displayed in a larger point size (e.g., $\big(\big((\ldots)\big)\big)$) makes the job of matching them up much easier to do visually.

It would be impractical for these coding guidelines to recommend the use of particular fonts when any that have been tuned to the display of C source are not commonly available, or where such usage requires particular tool support.

Table 912.1: Commonly used terms for punctuators and operators.

Punctuator/ Operator	Term	Punctuator/ Operator	Term
`[ ]`	left square bracket or opening square bracket or bracket	`^`	circumflex or xor or exclusive *or*
`( )`	left round bracket or opening round bracket or bracket or parenthesis	`|`	vertical bar or bitwise *or* or *or*
`{ }`	left curly bracket or opening curly bracket or bracket or brace	`&&`	and and or logical and
`.`	dot or period or full stop or dot selection	`||`	logical *or* or *or*
`->`	indirect or indirect selection	`?`	question mark
`*`	times or star or dereference or asterisk	`:`	colon
`+`	plus	`;`	semicolon
`-`	minus or subtract	`...`	dot dot dot or ellipsis
`~`	tilde or bitwise not	`=`	equal or assign
`!`	exclamation or shriek	`*=`	times equal
`++`	plus plus	`/=`	divide equal
`--`	minus minus	`%=`	percent equal or remainder equal
`&`	and or address of or ampersand or bitwise-and	`+=`	plus equal
`/`	slash or divide or solidus	`-=`	minus equal
`%`	remainder or percent	`<<=`	left-shift equal
`<<`	left-shift	`>>=`	right-shift equal
`>>`	right-shift	`&=`	and equal
`<`	less than	`^=`	xor equal or exclusive or equal
`>`	greater than	`|=`	or equal
`<=`	less than or equal	`,`	comma
`>=`	greater than or equal	`#`	hash or sharp or pound
`==`	equal	`##`	hash hash or sharp sharp or pound pound
`!=`	not equal	`<: :>` `<% %> %:` `%:%:`	no commonly used terms

Table 912.2: Occurrence of *`punctuator`* tokens (as a percentage of all tokens; multiply by 1.88 to express occurrence as a percentage of all punctuator tokens). Based on the visible form of the `.c` and `.h` files.

Punctuator	% of Tokens	Punctuator	% of Tokens	Punctuator	% of Tokens	Punctuator	% of Tokens
`,`	8.82	`==`	0.53	`||`	0.16	`-=`	0.03
`)`	8.09	`:`	0.46	`+=`	0.11	`++v`	0.02
`(`	8.09	`-v`	0.40	`>`	0.11	`%`	0.02
`;`	7.80	`*p`	0.40	`<<`	0.09	`--v`	0.01
`=`	3.08	`+`	0.38	`?:`	0.08	`...`	0.01
`->`	3.00	`*v`	0.34	`?`	0.08	`>>=`	0.01
`}`	1.87	`&`	0.32	`|=`	0.08	`^`	0.01
`{`	1.87	`!`	0.31	`>=`	0.07	`+v`	0.00
`.`	1.26	`v++`	0.27	`/`	0.06	`%=`	0.00
`*`	1.10	`&&`	0.26	`>>`	0.06	`##`	0.00
`#`	1.00	`!=`	0.26	`~`	0.05	`*=`	0.00
`]`	0.96	`<`	0.22	`v--`	0.04	`/=`	0.00
`[`	0.96	`-`	0.19	`&=`	0.04	`<<=`	0.00
`&v`	0.58	`|`	0.17	`<=`	0.04	`^=`	0.00

Semantics

A punctuator is a symbol that has independent syntactic and semantic significance. 913

Commentary

preprocessing token syntax 770
preprocessing token converted to token 137
postfix expression syntax 985

The syntactic form of a punctuator that is a *preprocessing-token* also has the syntactic form of a punctuator that can be converted (in translation phase 6) to a *token*. Some punctuators have syntactic significance only (e.g., **;**), while others can occur in several contexts— for instance, the pair **( )** can be used to bracket expressions or to denote the function call operator.

C90

A punctuator is a symbol that has independent syntactic and semantic significance but does not specify an operation to be performed that yields a value.

The merging of this distinction between operators and punctuators, in C99, makes no practical difference.

C++

This observation is not made in the C++ Standard.

operator

Depending on context, it may specify an operation to be performed (which in turn may yield a value or a function designator, produce a side effect, or some combination thereof) in which case it is known as an *operator* (other forms of operator also exist in some contexts). 914

Commentary

This defines the term *operator*. The meaning of some punctuators is dependent on the context in which they occur. For instance, the **:** token can occur after a case label in a bit-field declaration, or as the second operator in a ternary expression using the **?** operator. (The **:** character can also appear as one of the characters in a digraph.)

C90

In the C90 Standard operators were defined as a separate syntactic category, some of which shared the same spelling as some punctuators.

An operator specifies an operation to be performed (an evaluation) that yields a value, or yields a designator, or produces a side effect, or a combination thereof.

An *operand* is an entity on which an operator acts. 915

Commentary

This defines the term *operand*, which is common to most languages.

C++

The nearest C++ comes to defining *operand* is:

5p1 *An expression is a sequence of operators and operands that specifies a computation.*

916 In all aspects of the language, the six tokens[67] digraphs

```
<:  :>  <%  %>  %:  %:%:
```

behave, respectively, the same as the six tokens

```
[   ]   {   }   #   ##
```

except for their spelling.[68]

Commentary

The intent of introducing digraphs was to produce more readable alternatives to trigraphs. The character sequences chosen are shorter and matching pairs do contain some symmetry.

C90

These alternative spellings for some tokens were introduced in Amendment 1 to the C90 Standard. As such there is no change in behavior between C90 and C99.

Other Languages

Digraphs are unique to C (and C++).

Common Implementations

Even though digraphs were first introduced in 1993, vendors have been slow to add support for them in translators.

The Perkin-Elmer C compiler[1075] treated the following character sequences:

```
(|  |)  (<  >)  \!!  \!  \(  \)  \^
```

as being equivalent, respectively, to the tokens (the last four character pairs were also treated as escape sequences): 866 escape sequence syntax

```
[   ]   {   }   ||   |   {   }   ~
```

Coding Guidelines

Digraphs have several advantages over trigraphs. They are more readable and they are not substituted for inside string literals and character constants. Their only disadvantage is the continuing lack of support in a large number of translators. The characters used to denote digraphs were chosen for the very low probability of their occurring in existing programs outside of string literals. It is possible for a program to exhibit behavior that depends on whether digraphs are supported or not. But such usage is likely to be rare and not worth a guideline recommendation.

Example

```
1  #include <stdio.h>
2
3  #define prog_code(x) prog_string(%: x)
```

```
#define prog_string(y) "prog: " #y

void c_feather(void)
{
printf("%s\n", prog_code(10));
}
```

Without support for digraphs the output is:

```
prog: %: 10
```

With support for digraphs the output is:

```
prog: "10"
```

Usage

The visible form of the `.c` files contained zero digraphs.

Forward references: expressions (6.5), declarations (6.7), preprocessing directives (6.10), statements (6.8). 917

6.4.7 Header names

header name syntax

918

```
header-name:
                < h-char-sequence >
                " q-char-sequence "
h-char-sequence:
                h-char
                h-char-sequence h-char
h-char:
                any member of the source character set except
                                the new-line character and >
q-char-sequence:
                q-char
                q-char-sequence q-char
q-char:
                any member of the source character set except
                                the new-line character and "
```

Commentary

Headers enclosed between the < and > delimiters are commonly called a *system header* or *implementation header*. Such headers are generally special in that they are usually supplied by the implementation, host OS, or third-party API vendor. The " delimited form is commonly called a *header*.

Other Languages

While many languages do not specify any kind of header name tokens, their implementations usually add support for some such functionality as an extension. Use of double-quotes is commonly seen.

Usage

source file inclusion 1896

Header name usage information is given elsewhere.

Semantics

919

The sequences in both forms of header names are mapped in an implementation-defined manner to headers or external source file names as specified in 6.10.2.

Commentary

The *header-name* preprocessing token can only occur as part of a **#include** preprocessing directive. The issues involved in the implementation-defined mapping are discussed elsewhere.

924 header name recognized within #include
1896 source file inclusion

---

920 If the characters ', \, ", //, or /* occur in the sequence between the < and > delimiters, the behavior is undefined.

characters between < and >delimiters

Commentary

The character sequences // and /* denote the start a comment. The character \ denotes the start of an escape sequence. The characters ' and " delimit character constants and string literals, respectively.

Preprocessing tokens and comments are handled in translation phase 3. The standard specifies no ordering dependencies on these operations. A lexical analyzer which has no knowledge of the context in which sequences of characters occur, would return a sequence of preprocessing tokens that subsequent processing (e.g., in translation phase 4) would need to join together to form a *header-name* preprocessing token. The characters listed above could all cause behavior such that a translator would not be able to join the necessary preprocessing tokens together in translation phase 4.

124 translation phase 3
129 translation phase 4

C90

The character sequence // was not specified as causing undefined behavior in C90 (which did not treat this sequence as the start of a comment).

Other Languages

Because support for some form of **#include** directive is usually provided as an extension by language implementations, the issue of certain sequences of characters having special meaning within a header name is part of an implementation's behavior, not the language specification.

Common Implementations

Most translators maintain sufficient context information that they are aware that a sequence of characters occurs on the same line as a **#include** preprocessing directive. In this case translators have sufficient information to know that a *header-name* preprocessing token is intended and can act accordingly.

Coding Guidelines

The mapping issues involved with these characters are discussed elsewhere.

116 translation phase 1
1897 #include h-char-sequence

---

921 Similarly, if the characters ', \, //, or /* occur in the sequence between the " delimiters, the behavior is undefined.[69)]

Commentary

The issues involved are the same as those discussed in the previous sentence.

920 characters between < and >delimiters

C90

The character sequence // was not specified as causing undefined behavior in C90 (which did not treat this sequence as the start of a comment).

Coding Guidelines

One difference between the " delimiter and the < and > delimiters is that in the former case developers are likely to have some control over the characters that occur in the *q-char-sequence*.

920 characters between < and >delimiters

---

922 67) These tokens are sometimes called "digraphs".

footnote 67 digraphs

Commentary

There is no other term in common usage; in fact many developers are not aware of the existence of digraphs.

---

923 68) Thus [and <: behave differently when "stringized" (see 6.10.3.2), but can otherwise be freely interchanged.

footnote 68

Commentary

operator 1958 All six digraphs and their respective equivalent tokens behave differently when stringized. Token glueing is not an issue because there is only one situation where it might be possible to glue two digraphs together to form another meaningful token, and the Committee has already specified that this case does not create a valid token. The term *stringize* is not defined by the standard. However, its common usage is as the name of the # operator.

EXAMPLE 1966
#

operator 1950

Coding Guidelines

Stringizing is a relatively rare operation and use of digraphs is even rarer. A guideline recommendation covering this case does not appear to be worthwhile.

Example

```
#define MK_STR(x) #x

char *p1 = MK_STR([);    /* Assigns the string "[" */
char *p2 = MK_STR(\??(); /* Assigns the string "[" */
char *p3 = MK_STR(<#);   /* Assigns the string "<#" */
```

header name recognized within #include

~~A header name preprocessing token is~~ Header name preprocessing tokens are recognized only within a **#include** preprocessing ~~directive.~~ directives or in implementation-defined locations within **#pragma** directives[DR324)]. 924

Commentary

header name 783 exception to rule

The consequences of this requirement are discussed elsewhere.

The wording was changed by the response to DR #324.

C90

This statement summarizes the response to DR #017q39 against the C90 Standard.

C++

The C++ Standard contains the same wording as the C90 Standard.

Common Implementations

All known translators implemented this requirement, even though it was not what C90 originally, technically specified. Most implementations simply take all characters on the line to the right of a **#include** and do their own special processing on it. In other contexts characters are processed through the usual preprocessing token creation machinery.

EXAMPLE tokenization

EXAMPLE The following sequence of characters: 925

```
0x3<1/a.h>1e2
#include <1/a.h>
#define const.member@$
```

forms the following sequence of preprocessing tokens (with each individual preprocessing token delimited by a *{* on the left and a *}* on the right).

```
{0x3}{<}{1}{/}{a}{.}{h}{>}{1e2}
{#}{include} {<1/a.h>}
{#}{define} {const}{.}{member}{@}{$}
```

Commentary

The tokenization formed for the character sequence `member@$` may be different when using implementations that support additional characters within an identifier preprocessing token.

926 **Forward references:** source file inclusion (6.10.2).

6.4.8 Preprocessing numbers

pp-number syntax

927

pp-number:
digit
. *digit*
pp-number digit
pp-number identifier-nondigit
pp-number **e** *sign*
pp-number **E** *sign*
pp-number **p** *sign*
pp-number **P** *sign*
pp-number **.**

Commentary

This syntax supports the creation of preprocessing tokens that have no meaning as integer or floating-point tokens. The rationale for this relaxed syntax was to simplify the lexing of characters into preprocessing tokens rather than to support the stringizing of rather unusual sequences of characters. This flexibility also allows constructs such as:

```
1  #define glue(a, b) a ## b
2
3  float f = glue(1e+, 20);
```

to work as expected. The *identifier-nondigit* is needed to support hexadecimal constants.

There have been a number of requests to WG14 to tighten up the syntax of *pp-number*. The stated aim being to reduce the number of cases where a sequence of characters are treated as a *pp-number*, but cannot be converted to the token constant. The Committee's response to these requests is given in DR #003.

C90

The C90 Standard used the syntax nonterminal *nondigit* rather than *identifier-nondigit*.

Rationale

C99 replaces *nondigit* with *identifier-nondigit* in the grammar to allow the token pasting operator, ##, to work as expected. Given the code

```
#define  mkident(s)  s ## 1m
/* ... */
int mkident(int) = 0;
```

if an identifier is passed to the `mkident` macro, then 1m is parsed as a single pp-number, a valid single identifier is produced by the ## operator, and nothing harmful happens. But consider a similar construction that might appear using Greek script:

```
#define  μμμμk(p)  p ## 1μ
/* ... */
int μk(int) = 0;
```

For this code to work, 1μ must be parsed as only one pp-token. Restricting pp-numbers to only the basic letters would break this.

Support for additional digits via UCNs is new in C99. Also support for *p* and *P* in a *pp-number* is new in C99.

C++

Support for *p* and *P* in a *pp-number* is new in C99 and is not specified in the C++ Standard.

Other Languages

Most languages restrict the sequence of characters that can occur in an integer or floating-point token to those that are meaningful numbers. But then most languages do not include a preprocessor. The *p* and *P* form of exponents is unique to C.

Example

The character sequences:

```
1   22 .7  3.1E-41 1.2.3  4E+5SOME_OBJ6e+7
```

form the *pp-numbers*:

```
    {22} {.7}  {3.1E-41} {1.2.3}  {4E+5SOME_OBJ6e+7}
```

not:

```
    {22} {.7}  {3.1E-41} {1.2} {.3}  {4E+5} {SOME_OBJ} {6e+7}
```

Description

A preprocessing number begins with a digit optionally preceded by a period (**.**) and may be followed by valid identifier characters and the character sequences **e+**, **e-**, **E+**, **E-**, **p+**, **p-**, **P+**, or **P-**. 928

Commentary

This is a restatement of information given in the Syntax clause.

C90

Support for the *P* form of exponent is new in C99.

C++

The C++ Standard does not make this observation and like C90 does not support the *P* form of the exponent.

Preprocessing number tokens lexically include all floating and integer constant tokens. 929

Commentary

This describes in words what is specified in the syntax.

C++

This observation is not made in the C++ Standard.

Common Implementations

They also lexically include the binary constants supported by some implementations (e.g., 0b01010101).

Semantics

A preprocessing number does not have type or a value; 930

Commentary

A preprocessing number is nothing more than a sequence of characters.

Other Languages

Languages that do not include a preprocessor usually give a value and a type to such tokens as soon as they are created, that is immediately after lexing.

---

931 it acquires both after a successful conversion (as part of translation phase 7) to a floating constant token or an integer constant token.

Commentary

A preprocessing number may acquire a type and a value prior to translation phase 7 if it occurs within a **#if** preprocessor directive.

136 translation phase 7
1880 #if operand type uintmax_*

Coding Guidelines

A *pp-number* that occurs within a **#if** preprocessor directive is likely to have a different type than the one it would be given as part of translation phase 7. The implications of this difference are discussed elsewhere.

1880 #if operand type uintmax_*

---

932 69) Thus, sequences of characters that resemble escape sequences cause undefined behavior.

footnote 69

Commentary

Escape sequences start with the character \, one of the characters whose appearance in a *header-name* causes undefined behavior. Developers may make an association between a sequence of characters starting with \ and escape sequences (which are not converted until translation phase 5, but at which time any *header-name* preprocessing token will have ceased to exist), which technically does not exist at the same time that the *header-name* preprocessing directive exists.

866 escape sequence syntax
133 translation phase 5

Common Implementations

On some translator host environments, in particular the MS-DOS file system, the \ character is the directory separator. Because of the large volume of existing source code using the MS-DOS directory naming conventions, many implementations also support it as a directory separator (treating it as equivalent to the separator actually used— e.g., / under Linux).

Example

```
1  #include "dir\phile.h"
```

---

933 DR324) For an example of a header name preprocessing token used in a **#pragma** directive, see Subclause 6.10.9.

footnote DR324

Commentary

This footnote was added by the response to DR #324.

2030 _Pragma operator

6.4.9 Comments

Commentary

Comments do not affect the behavior of a program. They are intended to be of use to developers or tools that read the source code containing them. A number of tools use comments to help them do their job. These usually work by specifying sequences of characters at the start of the comment, which act as flags that can be detected when the tool reads the source. Uses include the following:

- *Version control.* Some revision control tools, such as `rcs`, search for identification keywords while checking out source. Matches against such keywords (e.g., `$Revision$` or `$Date$`) cause the keyword to be replaced with the appropriate values.[135] A source file may contain such identification keywords in comments, or sometimes in string literals (e.g., `static const char rcsid[] = "$Header$";`). The advantage of string literals is that they appear in the translated object code.

- *Documentation extraction.* Special flag characters indicate how the remaining source text is to be treated (e.g., man page, TEX source, etc.[523]).

Other Languages

In some implementations of Basic, mostly interpreter-based and seen in early hobbiest computers, the program source code was held in storage and interpreted directly. Comments needed to be skipped during program execution. In such environments the presence of comments could adversely affect a programs performance.

Common Implementations

There have been a few implementations that allowed translator directives to be placed within comments. The majority of modern translators use the **#pragma** preprocessing directive for this purpose.

#pragma 1994 directive

Coding Guidelines

Many coding guideline documents[912, 1305] specify what they consider to be good commenting practices. Although the use of comments is generally considered to be a *good thing* to do, there have been no studies quantifying their costs or benefits. These coding guidelines do not get involved in making recommendations on how to comment. There are a number of reasons for this:

- Writing effective comments is a skill (these coding guidelines do not aim to teach skills).
- Automatic enforcement of any guideline recommendation dealing with comments is likely to be difficult. If some form of commenting were shown to have a worthwhile cost/benefit ratio, the corresponding recommendation would need to be handled through code reviews. (The state of the art in static analysis of comments is many years away from having the natural language semantics capability needed for automatic enforcement.)

The grammar of comment layout

Technically comments can appear between any two preprocessing tokens in the source. In practice comments invariably appear in only a small number of locations in the source, relative to other preprocessing tokens. Experience shows that most developers visually organize comments; there might be said to be a comment layout grammar. Whether the use of a comment grammar simply represents the original author's desire for a pleasing layout, is simply a by-product of following simple rules while writing code, or is a cost-effective mechanism for reducing the effort needed by subsequent readers to comprehend the source is not known.

The presence of comments can also affect the layout of the constructs to which they refer. Components of this comment grammar include:

- Comments *attached* to the source statement they refer to (e.g., visually located immediately above the source line it refers to, or to the right of it on the same line).
- Vertical alignment of comment boundaries. Visual neatness as an aid in associating one comment spread over multiple lines.
- *header* comments (e.g., at the start of a source file, or function definition) provide information about the sequence of lines/statements that follow it).

```
1  if (valu == 0) /* Comment to the right of the if it refers to. */
2     {
3     blah blah ; /* Comment about one statement. */
4
5  if (valu == 0) /* Comment about the if.               */
6     {           /* Continuing commentary about the if. */
7     blah blah ; /* and even more continuation of general commentary. */
```

```
8
9   /* Comment refers to statement below it. */
10  x=3;
11
12  /* Previous blank line helps delimit this comment from about C statement. */
13  y=3;
14
15  /*
16   * We could write a long comment that describes the conditions
17   * under which x and y take on certain values.  Developers are
18   * likely to associate the x & y mentioned in this comment with the
19   * identifier names in the if statement below.
20   */
21  if ((x == 3) && /* This comment implicitly refers to x. */
22      (y == 4))   /* Expression layout has been integrated into comment structure. */
```

Overview

Writing comments is a cost that has no short-term benefit for the developer who incurs that cost. They are purely an investment for a possible future benefit, probably to a different developer than the one who wrote them. Comments can reduce, and sometimes increase, the cost of comprehending source code.

Comments can reduce the effort needed to comprehend source code by providing information in a form that requires less effort to comprehend than source code. Comments can also increase the probability that subsequent modifications are correct by providing background information (i.e., on intended affects) that is not explicitly contained in the adjacent source code.

Comments can increase the effort needed to comprehend source code by providing incorrect, or misleading, information. The presence of comments can also increase the effort needed to visually scan source code. The visual organization of comments often has a structure that is separate from the grammar of the surrounding statements and declarations.[1397]

Comments are used for a variety of purposes, including:

- *To contain management information.* This can include the change history of a file, or function, and the person responsible. It might also be cross-references to other source files and documents, the comments effectively providing a means of embedding links within a source file.
- *To present information in a diagramatic fashion* (the hope being that this alternative form of presentation will be easier for the reader to interpret than source code).
- *To present information in natural language prose.* For readers new to the source code, the use of natural language may provide a more direct route to a reader's model of the world than the code itself.
- *To create place markers in the source.* For instance, placing a comment on the closing brace of a compound block to indicate the kind of statement that occurs at the start of the block (if, while, switch, etc.). Another example is the specification of source yet to be written at that point.

Documentation in comments

The quantity of documentation associated with programs can vary enormously. The case of no documentation, outside of the source code, is not uncommon, while for some large projects a large percentage of the total effort went into creating documentation.[166] Having this kind of information within the same file as the source code has several advantages:

- If the source code is available, the documentation is available (developers will be familiar with programs whose documentation has been lost, or requires significant effort to obtain).
- The colocation of documentation and source code might be thought to ensure that both are updated together (experience suggests that this is not always the case).

cost/accuracy trade-off

- People perform a cost/accuracy calculation when deciding where to obtain information from. Having documentation available in the source file reduces information access cost (compared to having to obtain it from another file), potentially leading to increased accuracy of the information used.

comment disadvantages

It also has disadvantages:

- Information within comments, which duplicates what appears in other documents, runs the risk of not being updated when the original document is changed, or vice versa. Duplicating information creates the problem of keeping both up-to-date, and if they are differences between them, knowing which is correct.
- Opinions formed early, based on limited data, interfere with information presented later using more accurate data.

belief maintenance

The environment in which developers work can also have an impact. An environment that provides support services for ensuring that documentation is maintained and readily available may have less of a need to duplicate large amounts of information in comments. In an environment where support services are poor and developers are responsible for providing and maintaining their own documentation, there are plenty of reasons why this task may not get done. When support services are poor, having documentation within source code may be the only way of ensuring that this information is available to subsequent maintainers.

literate programming

Literate programming

An extreme form of colocating source code and documentation is espoused by the so-called *literate programming*[752] approach to documentation. Here the source code and its associated documentation are kept in a single file. Various tools are used to separate out the program source and its documentation. The development method proposed by Knuth has gained some influential supporters and needs to be discussed. The choice of the term *literate programming* expresses an admirable intent. However, by concentrating on the end result— a beautifully laid out, typeset program and associated documentation— Knuth has completely ignored the context where most of a developer's interaction with source code occurs (i.e., reading the original source). The original *literate programming* source from which both the source code and program documentation are extracted is much more difficult to read than either of the two documents it contains.

The target market for Knuth's form of literate programming is widespread publication of source and documentation, where it is expected to be read by many people, usually for educational or training purposes. Comprehension of the contents of the original material (in its single file) only need be performed by a small number of people, and is not required to be simple or easy to do. Much of the published praise of Knuth's literate programming has concentrated on the quality of the final output documents. There is no published research comparing the costs of maintaining two separate documents versus a single document from which both the code and documentation is extracted. Your author can see no obvious advantages to using Knuth's literal programming approach to software development in a commercial environment. In this environment there are a small readership of the code and documentation, and most of the time is spent working with this material directly.

Reducing source code comprehension costs

The effectiveness of a comment has to be measured by the extent to which it reduces the cost of developer comprehension of the surrounding source code. Writing effective comments is a different kind of skill than writing code. Developers receive feedback when they write code, at the very least the translator issues diagnostics if they violate a constraint or syntax rule. The only way developers receive feedback on the effectiveness of their comments is when other people read them. In the short-term, the only time when this is likely to occur is during code review. The following are some of the cost/benefit analysis issues that apply to the use of comments:

- *Practice and feedback are needed to learn to write effective comments.* Is the cost of learning to comment, including the cost of poor commenting that will have been written in source during that

period, significantly less than the benefits likely to be obtained later? The issue of who pays this cost also needs to be considered in light of the probability of trained developers changing jobs.

- *Comments may need to be updated when the source they refer to is modified.* Does the person making the source code change know enough to be able to make an associated, meaningful change to the comment? What is the cost associated with updating all of the related comments? As source code nears the end of its useful life, it may be more cost effective to delete comments when the source they refer to is modified rather than updating them. (The update cost is not likely to be recouped; deleting comments removes the potential liability caused by them being incorrect.)
- *The liabilities of incorrect, or out-of-date, comments.* If the contents of comments disagrees with the behavior of the source code developers become confused and need to spend extra time deducing which is correct. This deduction process may reach an incorrect conclusion, possibly leading to faults being introduced.
- *How much benefit do comments provide?* There has been no study, using experienced developers, that has attempted to measure the benefit of comments.

A study by Roediger, Jacoby, and McDermott[1176] looked at the false memories created by misleading information. They found that memories of past events are influenced by previous recollections of those events. Also information retrieved during the most recent account of an event may have a larger effect on the current recollection than the original event itself.

Self commenting code

There is a school of thought that claims it is possible to write self-documenting programs, rendering comment redundant. It is just a matter of choosing the right names for identifiers. The function

```
1  unsigned int square_root(unsigned int valu)
2  {
3  unsigned int root = 0;
4
5  valu = (valu + 1) >> 1;
6  while (root < valu)
7     valu -= root++;
8
9  return root;
10 }
```

contains no comments, but its name makes it obvious to readers what it does. Is that sufficient? Are we going to trust that this algorithm really does return the square root of its argument? A comment giving a brief outline of the mathematics behind the algorithm might increase confidence in its behavior. IEC 60559 requires that implementation support a square root operation. A comment could explain that for certain ranges of argument this function is faster than making use of hardware-supported square root (which requires conversions to/from floating point, plus the actual square root operation).

A study of maintenance programmers by IBM[429] found that understanding the original authors intent was the most difficult problem they had.

Comment layout

Experience shows that developers do not like writing comments. Making it more difficult than it is already perceived to be could result in less time being spent in creating comments. Some developers invest a lot of time in formatting their comments. Whether or not this cost leads to any measurable benefit is debatable. However, some of the layouts used can require additional workload (compared to alternative layouts) should they need to be modified. For instance, in the comment

```
1  /*********************************************************
2   * Allocate a local variable of the given size.          *
3   * The offset depends on which way the system stack grows.*
```

```
4    * (Although the offsets are always positive)            *
5    *                                                       *
6    *  If the stack is ascending, we need to                *
7    *     i. Align on the correct boundary                  *
8    *    ii. The offset of the variable is the current offset*
9    *   iii. Increment the offset to allow for this variable *
10   *                                                       *
11   *  If the stack is descending, we                       *
12   *     i. Increment the current offset for this variable  *
13   *    ii. Align on the correct boundary                  *
14   *   iii. The offset of the variable is the current offset*
15   *                                                       *
16   * If the stack is descending, the offsets from the frame *
17   * pointer (fp) are negative within the interpreter but   *
18   * stored as positive offsets in mcc.  Thus aligning      *
19   * upwards on mcc's offsets actually aligns downwards in  *
20   * memory (which is what we require).                     *
21   *********************************************************/
```

the bounding of the text by star characters may be visually appealing (leaving aside the issue of whether any comment is important enough to warrant this degree of visual impact). But maintaining this layout, when the comment is updated, requires additional developer effort. Reducing the expected cost of writing a comment may increase the likelihood that no updates will be made to the contents of existing comments.

```
1    /*********************************************************
2       Lines can be added to this comment without the need to worry
3       about overrunning the length of the box that contains them,
4       or having to use tab/space as padding to add a terminating *
5
6       Existing wording can be edited without having to spend time
7       repositioning all those * characters.
8
9       The contained text is still visibly delimited.
10   *********************************************************/
```

Comment layout is a complex process[1397] and even the simplest of worthwhile recommendations are likely to be very difficult to enforce automatically (interested readers can find suggestions in other coding guideline documents[912, 1305]). The following recommendation is intended to help ensure that existing comments are kept up-to-date.

Rev 933.1 Comments shall not be laid out in a fashion that requires significant additional effort for developers wanting to modify their contents.

Visual affects

The presence of comments in source can create visual patterns that distract developers' attention away from patterns that may present in the declarations and statements. In the following example, the aligned comments down the right have the effect of creating two vertical visual groupings. The prominence of the horizontal empty space, separating declarations from statements, is reduced (see Figure 770.2).

```
1    #define BASE_COST 23             /* Production tooling costs.          */
2
3    extern int widgets_in_product;
4
5    int sum_widget_costs(void)       /* Return how much this will cost.    */
6    {
7    int num_widgets;                 /* A local count of widgets.          */
8    int total_cost;                  /* Running total of the costs.        */
9                                     /* this is the value returned.        */
```

```
10  widgets_in_product--;            /* Subtract one to make it zero-based. */
11
12  total_cost=BASE_COST;            /* A startup cost cannot be avoided.   */
13  if (widgets_in_product != 0)     /* make sure we have something to do.  */
14     { /* ... */ }
15  }
```

By drawing attention to itself, this form of blocked commenting has taken attention away from the declarations and statements. Comments have the lowest attention priority and their presentation needs to reflect this fact. Straker[1305] discusses visual effect issues in more detail.

Example

```
1  extern int *ptr;
2
3  void f(void)
4  {
5  int loc = 4 /*ptr; /* Blah blah. */;
6  }
```

Usage

While over 30% of the characters in this book's benchmark programs (see Table 770.3) are contained within comments, they only represent around 2% of the tokens. A study by Fluri et al[432] of the releases of three large Java programs over a 6 year period (on average) found three different patterns in the ratio of number of comment lines to number of non-comment lines for each program.

A study of comments in C++ source by Etzkorn[399] found that 57% contained English sentences (that could be automatically parsed by the tool used).

Table 933.1: Common formats of nonsentence style comments. Adapted from Etzkorn, Bowen, and Davis.[399]

Style of Comment	Example
Item name— Definition	MaxLength— Maximum CFG Depth.
Definition	Maximum CFG Depth.
Unattached prepositional phrase	To support scrolling text.
Value definitions	0 = not selected, 1 = is selected.
Mathematical formulas	Can be Boolean expressions...

Table 933.2: Breakdown of comments containing parsable sentences. Adapted from Etzkorn, Bowen, and Davis.[399]

Percentage	Style of Sentence	Example
51	Operational description	This routine reads the data. Then it opens the file.
44	Definition	General Matrix— rectangular matrix class.
2	Description of definition	This defines a NIL value for a list.
3	Instructions to reader	See the header at the top of the file.

Comments are usually written in the present tense, with either indicative mood or imperative mood.

Table 933.3: Common formats of sentence-style comments. Adapted from Etzkorn, Bowen, and Davis.[399]

Part of Speech	Percentage	Example
Present Tense	75	
Indicative mood, active voice		This routine reads the data.
Indicative mood, active voice, missing subject		Reads the data.
Imperative mood, active voice		Read the data.
Indicative mood, passive voice		This is done by reading the data.
Indicative mood, passive voice, missing subject		Is done by reading the data.
Past Tense	4	
Indicative mood, either active or passive voice, occasional missing subject		This routine opened the file. or Opened the file.
Future Tense	4	
Indicative mood, either active or passive voice, occasional missing subject		This routine will open the file. or Will open the file.
Other	15	

comment /*

Except within a character constant, a string literal, or a comment, the characters /* introduce a comment. 934

Commentary

The exception cases are implied by the phases of translation.

C++

The C++ Standard does not explicitly specify the exceptions implied by the phases of translation.

Other Languages

All programming languages support some form of commenting. The character sequences used to introduce the start of a comment vary enormously; for instance, Basic uses the character sequence **rem**, while Scheme and many assembly languages use **;**. Java supports what is called a documentation comment: such a comment is introduced by the character sequence /**; the additional * character distinguishing it from a nondocumentation comment.

Coding Guidelines

This form of comment introduction enables the creation of multiline comments. This has the advantage of simplifying the job of writing a long comment and the disadvantage of comments sometimes terminating in unexpected locations in the source.

commenting out

Developers sometimes use the /* style of commenting to *comment out* sections of source to prevent it being translated and executed. This might be necessary, for instance, because the source code is not yet working properly, or because it has been decided that its functionality is not needed at the moment. Use of comments for this purpose is sometimes said to run the risk of having a nested comment change the intended effect. In practice, the change of behavior usually occurs during translation, not program execution; for instance, attempting to comment out the following sequence of statements

```
1  some_value = 3;
2  if (test_bit == 1)
3    total++; /* Special case. */
4  do_something();
```

will cause a syntax violation at the closing comment sequence placed after the call to `do_something`. The opening comment sequence placed before the assignment to `some_value` being terminated by the */ characters appearing in the comment within the source being commented out.

Although it might be thought that a syntax violation would be sufficient warning for the developer to look more closely at the source, experience suggests that developers can become confused to the extent of deleting the terminating comment characters without deleting the introductory comment characters (the syntax violation goes away). Using the /* form of comments to temporarily stop declarations or statements influencing the behavior of a program is a known root cause of faults.

Some implementations provide an option to support the nesting of comments. The standard explicitly states that comments do not nest. If it is necessary to prevent source code from being translated, either the **#if** preprocessing directive (because such directives nest), or the // form of commenting needs to be used. 939 footnote 70 936 comment //

Cg 934.1 The /* kind of comment shall not be used to comment out source code.

This guideline recommendation does not prevent the use of source code within comments where it is plainly intended to be part of the exposition of the comment— for instance:

```
/*
 * A discussion on some application issue and the following is an
 * example of one possible way of solving it:
 *
 * some_value = 3;
 * if (test_bit == 1)
 *   total++;
 * do_something();
 *
 * But we chose not to do it this way ...
 */
```

One way of distinguishing commented out code from code that is part of a comment is to examine the context and commenting style. A simple opening comment character sequence, followed by declarations or statements, followed by the closing comment character sequence is obviously commented out code. In the above case the presence of comment text that discusses the code might be viewed as sufficient to distinguish the usage (of course it could have been a comment that happened to precede the statements that was subsequently merged with the following comment). The use of star characters at the start of every line further reduces the probability that this is commented out code.

A practical way of measuring the probability of source code within a comment being commented out code is the ease with which it can be converted to executable machine code. Only having to remove a single line, at the start and end of the comment, gives a high probability of the source being commented out. In the preceding case it is necessary to delete the first four lines and last three lines of the comment, followed by deleting the star character at the start of every line. It is very unlikely to be commented out source.

When using the /* form of commenting, care has to be taken to ensure that the contents of the comment are easily distinguishable from what is outside the comment. The following example shows how poor layout might lead to confusion:

```
extern void farm(int *);

void f(void)
{
int loc;

/* We are now going to perform some calculation that involves
a complicated formula.  The details can be found in
barns (1999), which is the best reference */
farm(&loc);
}
```

There are a number of techniques developers can use to make comments and their contents appear as a distinct visual unit. Starting each line of comment with a character that rarely occurs at the beginning of a

noncomment line creates continuity. Making it easy for readers to match the opening and closing comment character sequences helps to create visual symmetry.

```
extern void farm(int *);

void f(void)
{
int loc;

/*
 * We are now going to perform some calculation that involves
 * a complicated formula.  The details can be found in
 * barns (1999), which is the best reference
 */
farm(&loc);
}
```

sentence-picture relationships

Comments sometimes contain a diagram. A theoretical discussion of the advantages of a diagram over a purely sentence-based description is given by Larkin and Simon.[811] Experimental verification that pictures can enhance text memory is provided by a study by Waddill and McDaniel.[659] Readers of the source often compare diagrams against sequences of statements in the source code. The intent of this comparison is to verify that the two representations are consistent with each other. The following discussion is based on studies by Clark and Chase,[243] and Carpenter and Just.[202]

In a study by Clark and Chase[243] subjects were shown a display consisting of a sentence and a picture. They had to quickly press a button indicating whether the sentence was true or false. The sentences were "star is above plus", "star is below plus", "star isn't above plus", and "star isn't below plus", and the same four sentences with the words *star* and *plus* swapped. The pictures had the form $\overset{*}{+}$, or $\overset{+}{*}$. These sentences and pictures can be combined into four different kinds of questions. The sentence could be true/false, they could also be affirmative (state that a relationship is true) or negative (state that a relationship is not true) (see Table 934.1).

Table 934.1: Four types of questions.

Statement Relative to Fact	Example
true-affirmative (TA)	star is above plus: $\overset{*}{+}$
false-affirmative (FA)	plus is above star: $\overset{+}{*}$
false-negative (FN)	star isn't above plus: $\overset{*}{+}$
true-negative (TN)	plus isn't above star: $\overset{*}{+}$

Clark and Chase created a model using four parameters (whether above/below was used, the sentence being true/false, the sentence being stated in a negative form was the sum of two parameters) to account for the differing delays in subjects' responses to the information displayed. The predicted response time for answering a question could be obtained by adding the delays required by the parameters.

Carpenter and Just built a model (known as *The Constituent Comparison Model*; each proposition within the mental representation is referred to as a constituent) that combined these four parameters into one. This model makes two assumptions:

1. The information content of sentences and pictures is assumed to be mentally represented in propositional form. A proposition can be affirmative or negative; for instance, "The star is above the plus" is represented as *(AFFIRMATIVE (ABOVE, STAR, PLUS))*, and "The star isn't above the plus" as *(NEGATIVE (ABOVE, STAR, PLUS))*. Propositions can be embedded within one another *e.g., {FORTUNATE [NEG (RED, DOTS)]}). Pictures are assumed to always be represented affirmatively; that is, the mental representation specifies what the picture is, not what it is not.

propositional form 1707

2. The comparison process, between the two propositional forms, uses a single mental operation—retrieve and compare. Corresponding constituents from the sentence and picture representations are retrieved and compared, pair by pair. A subject's delay in responding is determined by the number of these operations.

The algorithm for determining the number of retrieve and compare operations is:

A boolean flag is used to hold the result state of the comparison process; its initial value is assumed to be true. Every time a mismatch is encountered the flag changes state (it can flip-flop between them). The time required for the change-of-state operation is assumed to be small, compared to the retrieve-and-compare operation.

When the comparison of a constituent proposition mismatches, the following operations occur:

1. the flag changes state,
2. the mismatching constituent is tagged to indicate that when the restarted comparison process encounters it again, it should be treated as a match,
3. the comparison process goes back to the innermost constituents and starts comparing from where it first started.

The time taken to determine whether a sentence matches a picture is proportional to the number of comparison operations. Two consequences of the Just and Carpenter model are that the greater the number of mismatches, the greater the number of comparison operations needed, and those mismatches that occur later will require more comparison operations than those that occur earlier. These predictions are borne out by the response timing from a variety of studies.[243]

This model assumes that pictures are represented propositionally. Is this always the case? A study by MacLeod, Hunt, and Mathews[883] found that 23% of subjects maintained a visual representation of the picture and converted the sentences they read into a mental image of the picture described. Because these subjects used pictorial representations, the linguistic structure of the sentence (e.g., the use of a negative) could not affect their performance.

Example

```
1  /* A simple comment on a single line, so why was this style used? */
2
3  #define OBSCURE_TEN (2/*/*/*/*/*/5)
4
5  /*
6   * A comment with a simple, straight-forward, easy-to-understand
7   * format.  Hmmm, if *'s appear at the start of a line then why not // ?
8   */
```

Table 934.2: Occurrence of kinds of comments (as a percentage of all comments; last row as a percentage of all new-line characters). Based on the visible form of the `.c` and `.h` files.

Kind of Comment	`.c` files	`.h` files
/* comment */	91.0	90.1
// comment	9.0	9.9
/* on one line */	70.3	79.1
new-lines in /* comments	12.3	17.5

935 The contents of such a comment are examined only to identify multibyte characters and to find the characters `*/` that terminate it.[70)]

comment contents only examined to

Commentary

translation phase 3 124
trigraph sequences phase 1 117
line splicing 118

Comments are processed in translation phase 3. Trigraphs and line splicing will already have been handled.

C++

The C++ Standard gives no explicit meaning to any sequences of characters within a comment. It does call out the fact that comments do not nest and that the character sequence // is treated like any other character sequence within such a comment.

2.7p1 *The characters /* start a comment, which terminates with the characters */.*

Other Languages

Some languages support the use of translator directives within comments. This directive might control, for instance, the generation of listing files, the alignment of storage, and the use of extensions. Java supports the use of HTML tags inside its documentation comments. A few languages (e.g., Common Lisp) support nested comments and the contents of this form of comment need to be examined to identify the start/end of each nested comment.

Common Implementations

The contents of comments are sometimes examined by tools that analyze source code like a translator. The SVR5 `lint` tool[1393] includes the following:

```
extern int select;

void f(void)
{
if (select == 3)
   {
   return;
   /* NOTREACHED */  // Indicate that we know the statement is not reached
   select--;
   }
switch (select)
   {
   case 3: select++;
   /* FALLTHRU */  // Indicate that we know the case falls through
   case 4: select++;
           break;
   }
}
```

Coding Guidelines

Skipping all characters until the sequence */ is found is a rather open-ended operation. Experience suggests that the /* */ style of comment is not ideally suited for single-line comments; for instance, developers sometimes omit the closing */ characters. Also the characters */ occupy two positions on a line, which sometimes causes lines to wrap on display devices. The // form of comments does not have these problems.

Example

```
/\
* line splicing occurs before the comment is recognized
*\
/

/* ??) is a trigraph.  More importantly so is *??/
/
```

936 Except within a character constant, a string literal, or a comment, the characters // introduce a comment that includes all multibyte characters up to, but not including, the next new-line character.

comment //

Commentary

Many comments occupy a single line. The only form of comment supported by C90 required an explicit end-of-comment delimiter. Experience showed that omission of this closing delimiter is a cause of program faults. Also source code editors often wrap long lines and the two characters needed to close a comment can generate the need to abbreviate a comment or to have to accept a wrapped line in the displayed source. This newly introduced form of commenting does not suffer from these problems.

The C preprocessor is often used as a general preprocessor for other languages. The introduction of // as a comment start sequence in C99 is likely to cause problems for some developers; for instance, Fortran format statements can contain sequences of these two characters.

C90

Support for this style of comment is new in C99.

There are a few cases where a program's behavior will be altered by support for this style of commenting:

```
1  x = a //* */ b
2        + c;
3
4  #define f(x) #x
5
6  f(a//) + g(
7  );
```

Occurrences of these constructs are likely to be rare.

C++

The C++ Standard does not explicitly specify the exceptions implied by the phases of translation.

Other Languages

This style of comment is supported in BCPL, C++, Java, and many languages created in the last 10 years. Ada and Basic support the same commenting concept, they terminate at the end of line; the character sequences being used are `--` and **REM**, respectively. Fortran has always supported this concept of commenting; source lines that contain the letter C in the fifth column are treated as comments.

Common Implementations

Many implementations supported this style of commenting in their C90 translators.

937 The contents of such a comment are examined only to identify multibyte characters and to find the terminating new-line character.

Commentary

As previously pointed out, this statement is a simplification.

935 comment contents only examined to

C++

The C++ Standard includes some restrictions on the characters that can occur after the characters //, which are not in C90.

> *The characters // start a comment, which terminates with the next new-line character. If there is a form-feed or a vertical-tab character in such a comment, only white-space characters shall appear between it and the new-line that terminates the comment; no diagnostic is required.*

2.7p1

A C source file using the // style of comments may use form-feed or vertical-tab characters within that comment. Such a source file may not be acceptable to a C++ implementation. Occurrences of these characters within a comment are likely to be unusual.

Coding Guidelines

The // comment form is expected to occupy a single physical source line. It often comes as a surprise to readers of the source if such a comment includes the line that follows it.

Cg 937.1 The physical line containing the // from of comment shall not end in a line splice character.

EXAMPLE 938

```
"a//b"                  // four-character string literal
#include "//e"          // undefined behavior
// */                   // comment, not syntax error
f = g/**//h;            // equivalent to f = g / h;
//\
i();                    // part of a two-line comment
/\
/ j();                  // part of a two-line comment
#define glue(x,y) x##y
glue(/,/) k();          // syntax error, not comment
/*//*/ l();             // equivalent to l();
m = n//**/o
  + p;                  // equivalent to m = n + p;
```

Commentary

This example lists some of the more visually confusing character sequences that can occur in source code.

footnote 70) Thus, /* ... */ comments do not nest. 939

Commentary

translation phase 3 124 A comment is a single lexical entity, replaced by one space character in translation phase 3. Support for nested comments would require that they have an internal structure.

Other Languages

While few language specifications support the nesting of comments, some of their implementations do.

Common Implementations

Some pre-C Standard translators supported the nesting of comments and some translators[578] continue to provide an option to support this functionality (although support for such an option is not as common as for many other pre-C Standard behaviors).

Coding Guidelines

The /* comment form is sometimes used for *commenting out* source code. Such usage is error prone because comments might already occur within the source that is intended to be removed from subsequent translator processing (meaning that some of this source is not *commented out*). This issue is discussed elsewhere. Enabling a translator's support for nested comments is doing more than enabling an extension, it can also change the behavior of strictly conforming programs.

commenting out 934 extensions 95.1 cost/benefit

Example

```
1  #include <stdio.h>
2
3  int main(void)
4  {
5  if (/*/*/0*/**/1)
6     printf("On this implementation comments nest\n");
```

```
7   else
8     printf("On this implementation comments do not nest\n");
9   }
```

6.5 Expressions

940 An *expression* is a sequence of operators and operands that specifies computation of a value, or that designates an object or a function, or that generates side effects, or that performs a combination thereof. expressions

Commentary

This defines the term *expression*. The operators available for use in C expressions reflect the kinds of operations commonly supported by processor instruction sets. Processors often contain instructions for performing operations that have no equivalent in C. For instance, the Intel SSE extensions[627] to the Intel x86 instruction set support the SHUFPS instruction (see Figure 940.1). There is no equivalent operator in C.

Expressions in C differ from expressions encountered in most algebra books in that in C the representable range is finite and contains an additional representable quantity, NaN (a few advanced books[897] cover the issues of infinity and NaN). Some of the expression transformations that deliver the same result in mathematics can deliver different results in C. 339 NaN

Although the evaluation of an expression is often thought about by developers as if it was a single sequence of operations, the only sequencing requirements are those imposed by sequence points. 187 sequence points

Most expressions need to be evaluated during program execution. The generation of machine code to evaluate expressions is a very simple problem. The complexities seen in industrial-strength translators are caused by the desire to generate machine code that minimizes some attribute (usually either execution time, size of generated code, or electrical power consumed). It is known that the selection of an optimal sequence of instructions, for an expression, is an NP-complete problem[8] (even for a processor having a single register[172]). Algorithms (whose running time is linear in the size of the input) that minimize the number of executed instructions, or accesses to storage, are known for those expressions that do not contain common subexpressions (for processors without indirection,[1214] stack-based processors of finite depth,[173] and general register-based processors[7]). expression optimal evaluation 1712 common subexpression

Unless stated otherwise, the result type of an operator is either that of the promoted operand or the common type derived from the usual arithmetic conversions. 706 usual arithmetic conversions

C++

The C++ Standard (5p1) does not explicitly specify the possibility that an expression can designate an object or a function.

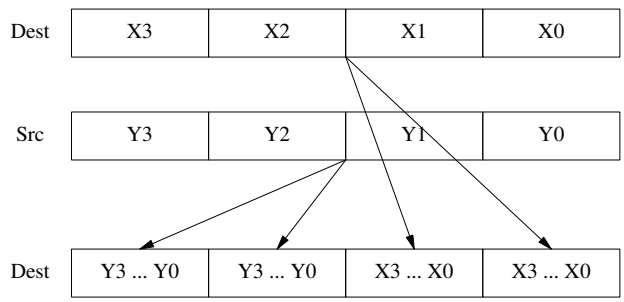

Figure 940.1: The SHUFPS (shuffle packed single-precision floating-point values) instruction, supported by the Intel Pentium processor,[627] places any two of the four packed floating-point values from the destination operand into the two low-order doublewords of the destination operand, and places any two of the four packed floating-point values from the source operand into the two high-order doublewords of the destination operand. By using the same register for the source and destination operands, the SHUFPS instruction can shuffle four single-precision floating-point values into any order.

Other Languages

This definition could be said to apply to most programming languages, which often contain a common core of similar operators operating on the same operand types. Languages vary in their support for additional operators and operand types that the core operators may operate on. A few languages (e.g., Algol 68, `gcc` supports compound statements in an expression) support the use of statements within an expression, or to be more exact, statements can return a value. Functional languages are side effect free. Evaluation of an expression returns a value and has no other effect.

Common Implementations

Evaluation of expressions is what causes translators to generate a large proportion of the machine code output to a program image. Optimization technology has improved over the years. The first optimizers operated at the level of a single expression, or statement. As researchers discovered new algorithms, and faster processors with more main memory became available, the emphasis moved to basic blocks. Here, the generation of machine code for expressions takes the context in which they occur into account. Optimizing register allocation, detecting and making use of common subexpressions, and on modern processors performing instruction scheduling to try to avoid pipeline stalls.[218] The continuing demand for more optimization has led to further research and commercialization of optimizers working at the so-called *super basic block* level, the level of a complete function definition, and most recently at the complete program level.

basic block 1710
register 1369 storage-class
common 1712 subexpression
basic block 1710
function 1821 definition syntax
translation unit 1810 syntax

Performance is often an issue in programs that operate on floating-point data. A number of transformations are sometimes used to produce expressions that deliver their results more quickly. These transformations can result in changes of behavior, including a greater range on the error bounds. Possible transformations are discussed under the respective operators. The Diab Data compiler[353] supports the `-Xieee754-pedantic` option to control whether these (i.e., convert divide to multiple) optimizations are attempted.

expression processor evaluation

Expression evaluation often requires that intermediate results be temporarily stored. The almost universal technique used is for processors to contain temporary storage locations— registers. (Stack architectures[762] may be simpler and cheaper to implement, but do not usually offer the cost/performance advantages of a register-based architecture, although they are occasionally seen in modern processors.[621, 1129]) The use of registers is discussed in more detail elsewhere.

register 1369 storage-class

The fact that operators are defined to operate on one or two values, returning a single value as a result, is not a hindrance to extending them to operate in parallel on vectors of operands as some extensions have done. In the quest for performance a number of processors are starting to offer vector operations. Operations to manipulate elements of a vector exist in these processors, but have yet to become sufficiently widely used to be explicitly discussed by the C Standard.

processor SIMD

There is no requirement in C that the operators in an expression be executed one at a time, although this is how the majority of processors have traditionally worked. The quest for performance has led processor vendors to try to perform more than one operation at the same time. Some vendors have chosen not to require translator support, the selection of the operations to execute in parallel being chosen dynamically by the processor (i.e., the latest members of the Intel x86 processor family[628]). Other vendors have introduced processors that operate on more than one data value at the same time, using the same instruction (known as *SIMD*, Single Instruction Multiple Data— pronounced sim-d). For such processors operations on arrays in a loop need not occur an element at a time; they can be performed 8, 16, 32, or however many parallel data operations are supported, elements at a time. Such processors require that translators recognize those situations where it is possible to perform the same operation on more than one value at the same time. SIMD processors used to be the preserve of up-market users, who could afford a Cray or one of the myriad of companies set up to sell bespoke systems. They are starting to become available as single-chip coprocessors for special embedded applications.[1448]

A description of how arithmetic operations are performed on integer and floating-point operands at the hardware level is given in Hennessy.[560]

Coding Guidelines

During almost all of human history, natural language has been used purely in a spoken form. The need to generate and comprehend sequences of words in realtime, using a less-than-perfect processor (the human brain), restricted the complexity of reliable communication. Realtime communication also provides an opportunity for feedback between speaker and listener, allowing content to be tailored for individual consumption.

It is often said that C source code is difficult to read. This is a special case of a more general observation. Most material created by people who are untrained in communicating ideas in written form is difficult to read. The written form of communication is not constrained by the need to be created in realtime, does not offer the opportunity for immediate feedback, and may have a readership that is not known to the author. An additional contribution to the *unreadability* of source code is that it is often written by people who consider themselves to be communicating with a computer rather than communicating with another person. Writers of C statements have the time needed to write complex constructs and the specifications they are given to work from are often complex. Duplicating this complexity often requires less effort than creating a simplified representation (i.e., copying can require less effort than creating).

A study by Miller and Isard[937] investigated subjects' ability to memorize sentences that varied in their degree of embedding. The following sentences are written with increasing amounts of embedding (the parse tree of two of them is shown in Figure 940.2).

1. She liked the man that visited the jeweler that made the ring that won the prize that was given at the fair.
2. The man that she liked visited the jeweler that made the ring that won the prize that was given at the fair.
3. The jeweler that the man that she liked visited made the ring that won the prize that was given at the fair.
4. The ring that the jeweler that the man that she liked visited made won the prize that was given at the fair.
5. The prize that the ring that the jeweler that the man that she liked visited made won was given at the fair.

The results showed that subjects' ability to correctly recall wording decreased as the amount of embedding increased, although their performance did improve with practice.

Other studies of reader's performance with processing natural languages have found the following:

- People have significant comprehension difficulties when the degree of embedding in a sentence exceeds two.[126]
- Readers' ability to comprehend syntactically complex sentences is correlated with their working memory capacity, as measured by the reading span test.[732] 1707 reading span
- Readers parse sentences left-to-right.[1083] An example of this characteristic is provided by so called *garden path* sentences, in which one or more words encountered at the end of a sentence changes the parse of words read earlier:

```
The horse raced past the barn fell.
The patient persuaded the doctor that he was having trouble with to leave.
While Ron was sewing the sock fell on the floor.
Joe put the candy in the jar into my mouth.
The old train their dogs.
```

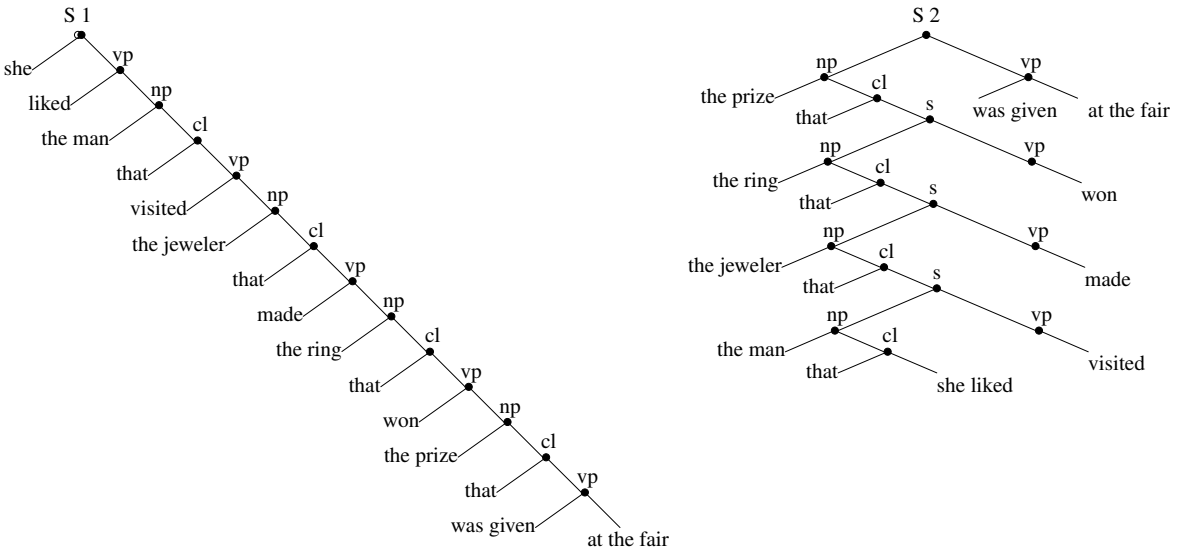

Figure 940.2: Parse tree of a sentence with no embedding (S 1) and a sentence with four degrees of embedding (S 2). Adapted from Miller and Isard.[937]

> In computer languages, the extent to which an identifier, operand, or subexpression encountered later in a full expression might change the tentative meaning assigned to what appears before it is not known.

How to readers represent expressions in memory? Two particular representations of interest here are the spoken and visible forms. Developers sometimes hold the sound of the spoken form of an expression in short-term memory; they also fix their eyes on the expression. The expression becomes the focus of attention. (This visible form of an expression, the number of characters it occupies on a line and possibly other lines, represents another form of information storage.)

Complicated expressions might be visually broken up into chunks that can be comprehended on an individually basis. The comprehension of these individual chunks then being combined to comprehend the complete expression (particularly for expressions having a boolean role). These chunks may be based on the visible form of the expression, the logic of the application domain, or likely reader cognitive limits. This issue is discussed in more detail elsewhere.

boolean role 476

memory 0
chunking

The possible impact of the duration of the spoken form of an identifier appearing in an expression on reader memory resources is discussed elsewhere.

identifier 792
primary
spelling issues
dead code 190
words 770
white space
between

Expressions that do not generate side effects are discussed elsewhere. The issue of spacing between tokens is discussed elsewhere. Many developers have a mental model of the relative performance of operators and sometimes use algebraic identities to rewrite an expression into a form that uses what they believe to be the faster operators. In some cases some identities learned in school do not always apply to C operators (e.g., if the operands have a floating-point type).

The majority of expressions contain a small number of operators and operands (see Figure 1731.1, Figure 1739.8, Figure 1763.1, and Figure 1763.2). The following discussion applies, in general, to the less common, longer (large number of characters in its visible representation), more complex expressions.

Readers of the source sometimes have problems comprehending complex expressions. The root cause of these problems may be incorrect knowledge of C or human cognitive limitations. The approach taken in these coding guideline subsections is to recommend, where possible, a usage that attempts to nullify the effects of incorrect developer knowledge. This relies on making use of information on common developer mistakes and misconceptions. Obviously a minimum amount of developer competence is required, but every effort is made to minimize this requirement. Documenting common developer misconceptions and then

recommending appropriate training to improve developers' knowledge in these areas is not considered to be a more productive approach. For instance, a guideline recommending that developers memorise the 13 different binary operator precedence levels does not protect against the reader who has not committed them to memory, while a guideline recommending the use of parenthesis does protect against subsequent readers who have incorrect knowledge of operator precedence levels.

943 operator precedence
943.1 expression shall be parenthesized

An expression might only be written once, but it is likely to be read many times. The developer who wrote the expression receives feedback on its behavior through program output, during testing, which is affected by its evaluation. There is an opportunity to revise the expression based on this feedback (assumptions may still be held about the expression— order of evaluation— because the translator used happens to meet them). There is very little feedback to developers when they read an expression in the source; incorrect assumptions are likely to be carried forward, undetected, in their attempts to comprehend a function or program.

The complexity of an expression required to calculate a particular value is dictated by the application, not the developer. However, the author of the source does have some control over how the individual operations are broken down and how the written form is presented visually.

Many of these issues are discussed under the respective operators in the following C sentences. The discussion here considers those issues that relate to an expression as a whole. While there are a number of different techniques that can be used to aid the comprehension of a long or semantically complex expression, your author does not have sufficient information to make any reliable cost-effective recommendations about which to apply in most cases. Possible techniques for reducing the cost of developer comprehension of an expression include:

- A comment that briefly explains the expression, removing the need for a reader to deduce this information by analyzing the expression.
- A complex expression might be split into smaller chunks, potentially reducing the maximum cognitive load needed to comprehend it (this might be achieved by splitting an assignment statement into several assignment statements, or information hiding using a macro or function).
- The operators and operands could be laid out in a way that visually highlights the structure of the semantics of what the expression calculates.

The last two suggestions will only apply if there are semantically meaningful subexpressions into which the full expression can be split.

Visual layout

expression visual layout

An expression containing many operands may need to be split over more than one line (the term *long* expression is often used, referring to the number of characters in its visible form). Are there any benefits in splitting an expression at any particular point, or in visually organizing the lines in any particular manner? There are a number of different circumstances under which an expression may need to be split over several lines, including:

- The line containing the expression may be indented by a large amount. In this case even short, simple expressions may need to be split over more than one line. The issue that needs to be addressed in this case is the large indentation; this is discussed elsewhere.
- The operands of the expression refer to identifiers that have many characters in their spelling. The issue that needs to be addressed in this case is the spelling of the identifiers; this is discussed elsewhere.
- The expression contains a large number of operators. The rest of this subsection discusses this issue.

1707 statement visual layout
792 visual skimming

Expressions do not usually exist in visual isolation and are not always read in isolation. Readers may only look at parts of an expression during the process of scanning the source, or they may carefully read an expression. (The issue of how developers read source is discussed elsewhere.) Some of the issues involved in the two common forms of code reading include the following:

770 reading kinds of

- During a careful reading of an expression reducing the cost of comprehending it, rather than differentiating it from the surrounding code, is the priority. Whether a reader has the semantic knowledge needed to comprehend how the components of an expression are mapped to the application domain is considered to be outside the scope of these coding guideline subsections. Organizing the components of an expression into a form that optimizes the cognitive resources that are likely to be available to a reader is within the scope of these coding guideline subsections. Experience suggests that the cognitive resource most likely to be exceeded during expression comprehension is working memory capacity. Organizing an expression so that the memory resources needed at any point during the comprehension of an expression do not exceed some maximum value (i.e., the capacity of a typical developer) may reduce comprehension costs (e.g., by not requiring the reader to concentrate on saving temporary information about the expression in longer-term memory). Studies have found that human memory performance is improved if information is split into meaningful *chunks*. Issues, such as how to split an expression into *chunks* and what constitutes a recognizable structure, are skills that developers learn and that are not yet amenable to automatic solution. The only measurable suggestion is based on the phonological loop component of working memory, which can hold approximately two seconds worth of sound. If the spoken form of a chunk takes longer than two seconds to say (by the person trying to comprehend it), it will not be able to fit completely within this form of memory. This provides an upper bound on one component of chunk size (the actual bound may be lower).

memory 0 chunking

phonolog-0 ical loop

- When scanning the code, being able to quickly look at its components, rather than comprehending it in detail, is the priority; that is, differentiating it from the surrounding code, or at least ensuring that different lines are not misinterpreted as being separate expressions. The edges of the code (the first non-white-space characters at the start and end of lines) are often used as reference points when scanning the source. For instance, readers quickly scanning down the left edge of source code might assume that the first identifier on a line is either modified in some way or is a function call.

Table 940.1: Occurrence of a token as the last token on a physical line (as a percentage of all occurrences of that token and as a percentage of all lines). Based on the visible form of the `.c` files.

Token	% Occurrence of Token	% Last Token on Line	Token	% Occurrence of Token	% Last Token on Line
`;`	92.2	36.0	`#else`	89.1	0.2
* ... *\	97.9	8.4	`int`	5.3	0.2
`)`	20.6	8.3	`||`	23.7	0.2
`{`	86.7	8.1	`|`	12.3	0.1
`}`	78.9	7.4	`+`	3.8	0.1
,	13.9	6.1	`?:`	7.3	0.0
`:`	74.3	1.7	`?`	7.1	0.0
header-name	97.7	1.5	`do`	21.3	0.0
\\	100.0	0.9	`#error`	25.1	0.0
`#endif`	81.9	0.8	`:b`	7.2	0.0
`else`	42.2	0.7	`double`	3.1	0.0
string-literal	8.0	0.4	`^`	3.1	0.0
`void`	18.2	0.4	`union`	6.2	0.0
`&&`	17.8	0.2			

One way of differentiating multiline expressions is for the start, and end, of the lines to differ from other lines containing expressions. One possible way of differentiating the two ends of a line is to use tokens that don't commonly appear in those locations. For instance, lines often end in a semicolon, not an arithmetic operator (see Table 940.1), and at the start of a line additional indentation for the second and subsequent lines containing the same expression will set it off from the surrounding code. Some developers prefer to split expressions just before binary operators. However, the appearance of an operator as the last non-white-space character is more likely to be noticed than the nonappearance

of a semicolon (the human visual system is better at detecting the presence rather than the absence of a stimulus). Of course, the same argument can be given for an identifier or operator at the start of a line. These coding guidelines give great weight to existing practice. In this case this points to splitting expressions before/after binary operators; however, there is insufficient evidence of a worthwhile benefit for any guideline recommendation.

770 distinguishing features

Optimization

Many developers have a view of expressions that treats them as standalone entities. This viewpoint is often extended to translator behavior, which is then thought to optimize and generate machine code on an expression-by-expression basis. This developer though process leads on to the idea that performing as many operations as much as possible within a single expression evaluation results in translators generating more efficient machine code. This thought process is not cost effective because the difference in efficiency of expressions written in this way is rarely sufficient to warrant the cost, to the current author and subsequent readers, of having to comprehend them.

Whether a complex expression results in more, or less, efficient machine code will depend on the optimization technology used by the translator. Although modern optimization technology works on units significantly larger than an expression, there are still translators in use that operate at the level of individual expressions.

0 translator optimizations

Example

```
1  extern int g(void);
2  extern int a,
3             b;
4
5  void f(void)
6  {
7  a + b;           /* A computation. */
8  a;               /* An object. */
9  g();             /* A function. */
10 a = b;           /* Generates side effect. */
11 a = b , a + g(); /* A combination of all of the above. */
12 }
```

Usage

A study by Bodík, Gupta, and Soffa[131] found that 13.9% of the expressions in SPEC95 were partially redundant, that is, their evaluation is not necessary under some conditions.

190 partial redundancy elimination

See Table 1713.1 for information on occurrences of full expressions, and Table 770.2 for visual spacing between binary operators and their operands.

1712 full expression

Table 940.2: Occurrence of a token as the first token on a physical line (as a percentage of all occurrences of that token and as a percentage of all lines). */* new-line */* denotes a comment containing one or more new-line characters, while */* ... */* denotes that form of comment on a single line. value profiling

Recent research[189,467,859] has found that for a few expressions, a large percentage of their evaluations return the same value during program execution. Depending on the expression context and the probability of the same value occurring, various optimizations become worthwhile[986] (0.04% of possible expressions evaluating to the same value a sufficient percentage of the time in a context that creates a worthwhile optimization opportunity). Some impressive performance improvements (more than 10%) have been obtained for relatively small numbers of optimizations. Citron[238] studied how processors might detect previously executed instruction sequences and reuse the saved results (assuming the input values were the same).

Table 940.3: Breakdown of invariance by instruction types. These categories include integer loads (*ILd*), floating-point loads (*FLd*), load address calculations (*LdA*), stores (*St*), integer multiplication (*IMul*), floating-point multiplication (*FMul*), floating-point division (*FDiv*), all other integer arithmetic (*IArth*), all other floating-point arithmetic (*FArith*), compare (*Cmp*), shift (*Shft*), conditional moves (*CMov*), and all other floating-point operations (*FOps*). The first number shown is the percent invariance of the topmost value for a class type, while the number in parenthesis is the dynamic execution frequency of that type. Results are not shown for instruction types that do not write a register (e.g., branches). Adapted from Calder, Feller, and Eustace.[189]

Studies of operand values during program execution (investigating ways of minimizing processor power consumption) have found that a significant percentage of these values use fewer representation bits than are available to them (i.e., they are small positive quantities). Brooks and Martonosi[163] found that 50% of operand values in SPECint95 required less than 16 bits.

Table 940.4: Number of objects defined (in a variety of small multimedia and scientific programs) to have types represented using a given number of bits (i.e., mostly 32-bit **int**) and number of objects having a maximum bit-width usage (i.e., number of bits required to represent any of the values stored in the object; rounded up to the nearest byte boundary). Adapted from Stephenson,[1290] whose analysis was performed by static analysis of the source.

Bits	Objects Defined	Objects Requiring Specified Bits
1	0	203
8	7	134
16	27	108
32	686	275

941 Between the previous and next sequence point an object shall have its stored value modified at most once by the evaluation of an expression. DR287)

object modified once between sequence points

Commentary

A violation of this requirement results in undefined behavior. If an object is modified more than once between sequence points, the standard does not specify which modification is the last one. The situation can be even more complicated when the same object is read and modified between the same two sequence points. This requirement does not specify exactly what is meant by *object*. For instance, the following full expression may be considered to modify the object `arr` more than once between the same sequences points.

942 object read and modified between sequence points

```
1  int arr[10];
2
3  void f(void)
4  {
5  arr[1]=arr[2]++;
6  }
```

C++

Between the previous and next sequence point a scalar object shall have its stored value modified at most once by the evaluation of an expression. 5p4

The C++ Standard avoids any ambiguity in the interpretation of *object* by specifying scalar type.

Other Languages

In most languages assignment is not usually considered to be an operator, and assignment is usually the only operator that can modify the value of an object; other operators that modify objects are not often available. In such languages function calls is often the only mechanism for causing more than one modification between two sequence points (assuming that such a concept is defined, which it is not in most languages).

Common Implementations

Most implementations attempt to generate the best machine code they can for a given expression, independently of how many times the same object is modified. Since the surrounding context often has a strong influence on the code generated for an expression, it is possible that the evaluation order for the same expression will depend on the context in which it occurs.

Coding Guidelines

As the example below shows, a guideline recommendation against modifying the same object more than once between two adjacent sequence points is not sufficient to guarantee consistent behavior. A guideline recommendation that is sufficient to guarantee such behavior is discussed elsewhere.

expression 944.1
same result for all evaluation orders

Example

In following the first expression modifies `glob` more than once between sequence points:

```
1  extern int glob,
2             valu;
3
4  void f(void)
5  {
6  glob = valu + glob++;                    /* Undefined behavior. */
7  glob = (glob++, glob) + (glob++, glob); /* Undefined and unspecified behavior. */
8  }
```

Possible values for `glob`, immediately after the sequence point at the semicolon punctuator, include

- `valu + glob`
- `glob + 1`
- `((valu + glob) && 0xff00) | ((glob + 1) && 0x00ff)`

The third possibility assumes a 16-bit representation for **`int`**— a processor whose store operation updates storage a byte at a time and interleaves different store operations. In the second expression the evaluation of the left operand of the comma operator may be overlapped. For instance, a processor that has two arithmetic logic units may split the evaluation of an expression across both units to improve performance. In this case `glob` is modified more than once between sequence points. Also, the order of evaluation is unspecified.

expression 944
order of evaluation

In the following:

```
1  struct T {
2            int mem_1;
3            char mem_2;
4           } *p_t;
5
6  extern void f(int, struct T);
7
8  void g(void)
9  {
10 int loc = (*p_t).mem_1++ + (*p_t).mem_2++;
11         f((*p_t).mem_1++,   *p_t)        ; /* Modify part of an object. */
12 }
```

there is an object, `*p_t`, containing various subobjects. It would be surprising if a modification of a subobject (e.g., `(*p_t).mem_1`) was considered to be the same as a modification of the entire object. If it was, then the two modifications in the initialization of expression for `loc` would result in undefined behavior. In the call to `f` the first argument modifies a subobject of the object `*p_t`, while the second argument accesses all of the object `*p_t` (and undefined behavior is to be expected, although not explicitly specified by the standard).

Furthermore, the prior value shall be read only to determine the value to be stored.[71)] 942

object read and modified between sequence points

Commentary

In expressions, such as `i++` and `i = i*2`, the value of the object `i` has to be read before its value can be operated on and a potentially modified value written back. The semantics of the respective operators ensure that this ordering between operations occurs.

In expressions, such as `j = i + i--`, the object `i` is read twice and modified once. The left operand of the binary plus operator performs a read of `i` that is not necessary to determine the value to be stored into it. The behavior is therefore undefined. There are also cases where the object being modified occurs on the left side of an assignment operator; for instance, `a[i++] = i` contains two reads from `i` to determine a value and a modification of `i`.

Coding Guidelines

The generalized case of this undefined behavior is covered by a guideline recommendation dealing with evaluation order.

944.1 expression same result for all evaluation orders

---

943 The grouping of operators and operands is indicated by the syntax.[72)]

expression grouping operator precedence
943 operator precedence
955 operator associativity

Commentary

The two factors that control the grouping are precedence and associativity.

Other Languages

Most programming languages are defined in terms of some form of formal, or semiformal, BNF syntax notation. While a few languages allow operators to be overloaded, they usually keep their original precedence. In APL all operators have the same precedence and expressions are interpreted right-to-left (e.g., `1*2+3` is equivalent to `1*(2+3)`). The designers of Ada recognized[619] that developers do not have the same amount of experience handling the precedence of the logical operators as they do the arithmetic operators. An expression containing a sequence of the same logical binary operator need not be parenthesized, but a sequence of different logical binary operators must be parenthesized (parentheses are not required for unary **`not`**).

Common Implementations

Most implementations perform the syntax analysis using a table-driven parser. The tables for the parser are generated using some automatic tool (e.g., `yacc`, `bison`) that takes a LALR(1) grammar as input. The grammar, as specified in the standard, and summarized in Annex A, is not in LALR(1) form as specified. It is possible to transform it into this form, an operation that is often performed manually.

Coding Guidelines

Developers over learn various skills during the time they spend in formal education. These skills include the following:

- The order in which words are spoken is generally intended to reduce the comprehension effort needed by the listener. The written form of languages usually differs from the spoken form. In the case of English, it has been shown[1083] that readers parse its written form left-to-right, the order in which the words are written. It has not been confirmed that readers of languages written right-to-left parse them in a right-to-left order.
- Many science and engineering courses require students to manipulate expressions containing operators that also occur in source code. Students learn, for instance, that in an expression containing a multiplication and addition operator, the multiplication is performed first. Substantial experience is gained over many years in reading and writing such expressions. Knowledge of the ordering relationships between assignment, subtraction, and division also needs to be used on a very frequent basis. Through constant practice, knowledge of the precedence relationships between these operators becomes second nature; developers often claim that they are natural (they are not, it is just constant practice that makes them appear so).

Your author knows of no research studying how developers read expressions. The assumption made in these coding guidelines subsections is that developers' extensive experience reading prose is a significant factor affecting how they read source code. Given the significant differences in the syntactic structure of natural

770 reading practice

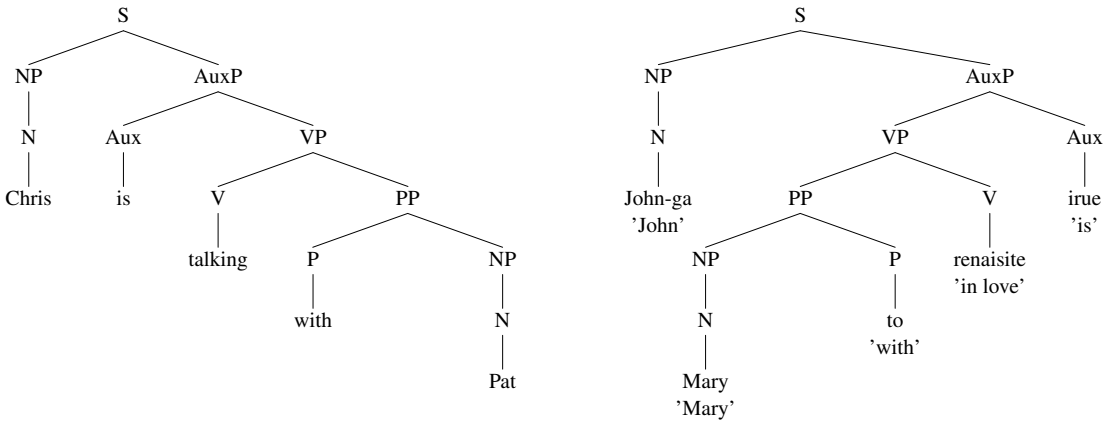

Figure 943.1: English ("Chris is talking with Pat") and Japanese ("John-ga Mary to renaisite irue") language phrase structure for sentences of similar complexity and structure. While the Japanese structure may seem back-to-front to English speakers, it appears perfectly natural to native speakers of Japanese. Adapted from Baker.[86]

languages (see Figure 943.1) the possibility of an optimal visual expression organization, which is universal to all software developers, seems remote.

While developers are likely to have had significant previous experience in reading and writing the commonly occurring C operators, few of developers attain the same level of practice with the other operators. Consequently, developer knowledge of the precedence levels of other operators is often faulty (which does not prevent them from being willing to jump to conclusions). A study by Jones[685] found that subjects (developers with an average of 14 years professional experience) failed to correctly parenthesize 33% of expressions containing two binary operators.

operator 770
relative spacing
operand 792
name context

Factors that have been found to effect developer operator precedence decisions include the relative spacing between operators and the names of the operands.

One solution to faulty developer knowledge of operator precedence levels is to require the parenthesizing of all subexpressions (rendering any precedence knowledge the developer may have, right or wrong, irrelevant). Such a requirement often brings howls of protest from developers. Completely unsubstantiated claims are made about the difficulties caused by the use of parentheses. (The typing cost is insignificant; the claimed unnaturalness is caused by developers who are not used to reading parenthesized expressions, and so on for other developer complaints.) Developers might correctly point out that the additional parentheses are redundant (they are in the sense that the precedence is defined by C syntax and the translator does not require them); however, they are not redundant for readers who do not know the correct precedence levels.

An alternative to requiring parentheses for any expression containing more than two operators is to provide a list of special where it is believed that developers are very unlikely to make mistakes (these cases have the advantage of being common). Listing special cases could either be viewed as the thin end of the edge that eventually drives out use of parentheses, or as an approach that gradually overcomes developer resistance to the use of parentheses.

When combined with binary operators, the correct order of evaluation of unary operators is simple to deduce and developers are unlikely to make mistakes in this case. However, the ordering relationship, when a unary operator is applied to the result of another unary operator, is easily confused when unary operators appear to both the left and right of the same operand. This is a case where the use of parentheses removes the possibility of reader mistakes.

In C both function calls and array indexing are classified as operators. There is likely to be considerable developer resistance to parenthesizing these operators because they are not usually thought of in these terms (they are not operators in many other languages); they are also unary operators and the pair of characters used is often considered as forming bracketed subexpressions.

In the following guideline recommendation the expression within

- the square brackets used as an array subscript operator are treated as equivalent to a pair of matching parentheses, not as an operator; and
- the arguments in a function invocation are each treated as full expressions and are not considered to be part of the rest of the expression that contains the function invocation for the purposes of the deviations listed.

An issue related to precedence, but not encountered so often, is associativity, which deals with the evaluation order of operands when the operators have the same precedence. If the operands in an expression have different types, the evaluation order specifies the pairings of operand types that need to go through the usually arithmetic conversions.

955 operator associativity

706 usual arithmetic conversions

Cg 943.1 Each subexpression of a full expression containing more than one operator shall be parenthesized.

Dev 943.1 A full expression that only contains zero or more additive operators and a single assignment operator need not be parenthesized.

Dev 943.1 A full expression that only contains zero or more multiplication, division, addition, and subtraction operators and a single assignment operator need not be parenthesized.

Dev 943.1 A full expression that only contains zero or more additive operators and a single relational or equality operator need not be parenthesized.

Dev 943.1 A full expression that only contains zero or more multiplicative and additive operators and a single relational or equality operator need not be parenthesized.

Developers appear to be willing to accept the use of parentheses in so-called complex expressions. (An expression containing a large number of operators, or many different operators, is often considered complex; exactly how many operators is needed varies depending on who is asked.) Your author's unsubstantiated claim is that more time is spent discussing under what circumstances parentheses should be used than would be spent fully parenthesizing every expression developers ever write. Management needs to stand firm and minimize discussion on this issue.

Example

```
1  *p++;            /* Equivalent to *(p++); */
2
3  (char)!+-~***+p; /* Operators applied using an inside out order. */
4
5  ;m<-++pq++->m;   /* The token -> is not usually thought of as a unary operator. */
6
7  a = b = c;       /* Equivalent to  a = (b  = c); */
8  x + y + z;       /* Equivalent to (x +  y) + z ; */
```

944 Except as specified later (for the function-call `()`, `&&`, `||`, `?:`, and comma operators), the order of evaluation of subexpressions and the order in which side effects take place are both unspecified.

expression order of evaluation

Commentary

The exceptional cases are all operators that involve a sequence point during their evaluation.

This specification, from the legalistic point of view, renders all expressions containing more than one operand as containing unspecified behavior. However, the definition of strictly conforming specifies that the output must not be dependent on any unspecified behavior. In the vast majority of cases all orders of evaluation of an expression deliver the same result.

91 strictly conforming program output shall not

Other Languages

Most languages do not define an order of evaluation for expressions. Snobol 4 defines a left-to-right order of evaluation for expressions. The Ada Standard specifies " . . . in some order that is not defined", with the intent[619] that there is some order and that this excludes parallel evaluation. Java specifies a left-to-right evaluation order. The left operand of a binary operator is fully evaluated before the right operand is evaluated.

Common Implementations

Many implementations build an expression tree while performing syntax analysis. At some point this expression tree is walked (often in preorder, sometimes in post-order) to generate a lower-level representation (sometimes a high-level machine code form, or even machine code for the executing host). An optimizer will invariably reorganize this tree (if not at the C level, then potentially though code motion of the intermediate or machine code form).

Even the case where a translator performs no optimizations and the expression tree has a one-to-one mapping from the source, it is not possible to reliably predict the order of evaluation. (There is more than one way to walk an expression tree matching higher-level constructs and map them to machine code.) As a general rule, increasing the number of optimizations performed increases the unpredictability of the order of expression evaluation.

Coding Guidelines

The order of evaluation might not affect the output from a program, but it can affect its timeliness. In:

```
1  printf("Hello ");
2  x = time_consuming_calculation() + print("World\n");
```

the order in which the two function calls on the right-hand side of the assignment are invoked will affect how much delay occurs between the output of the character sequences **Hello** and **World**.

In the expression `i = func(1) + func(2)`, the value assigned to `i` may, or may not, depend on the order in which the two invocations of `func` occur. Also the order of invocation may result in other objects having differing values. The sequence point that occurs prior to each function being invoked does not prevent these different behaviors from occurring. Sequence points are too narrow a perspective; it is necessary to consider the expression evaluation as a whole.

function call sequence point 1025

Cg 944.1

The state of the C abstract machine, after the evaluation of a full expression, shall not depend on the order of evaluation of subexpressions or the order in which side effects take place.

Example

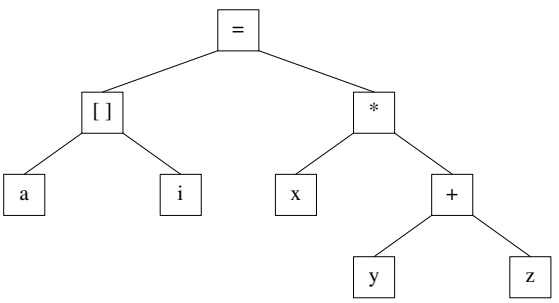

Figure 944.1: A simplified form of the kind of tree structure that is likely to be built by a translator for the expression `a[i]=x*(y+z)`.

```
1   #include <stdio.h>
2
3   extern volatile int glob;
4
5   void f(void)
6   {
7   int loc = glob + glob * glob;
8
9   /*
10   * In the following the only constraints on the order in
11   * which characters appear are that:
12   *    ) x must be output before y and
13   *    ) a must be output before b
14   */
15  loc = printf("x"),printf("y") + printf("a"),printf("b");
16  }
```

945 Some operators (the unary operator ~, and the binary operators <<, >>, &, ^, and |, collectively described as *bitwise operators*) are required to have operands that have integer type. bitwise operators

Commentary

This defines the term *bitwise operators*.

C++

The C++ Standard does not define the term bitwise operators, although it does use the term bitwise in the description of the **&**, **^** and **|** operators.

Other Languages

PL/1 has a bit data type and supports bitwise operations on values having such types.

Coding Guidelines

Bitwise operations provide a means for manipulating an object's underlying representation. They also provide a mechanism for using a new data type, the *bit-set*. There is a guideline recommendation against making use of an object's underlying representation. The following discussion looks at possible deviations to this recommendation. 569.1 representation information using

Performance issues

The result of some sequences of bitwise operations are the same as some arithmetic operations. For instance, left-shifting and multiplication by powers of two. There is a general belief among developers that processors execute these bitwise instructions faster than the arithmetic instructions. The extent to which this belief is true varies between processors (it tends to be greater in markets where processor cost has been traded-off against performance). The extent to which a translator automatically performs these mappings will depend on whether it has sufficient information about operand values and the quality of the optimizations it performs. If performance is an issue, and the translator does not perform the desired optimizations, the benefit of using bitwise operations may outweigh any other factors that increase costs, including:

- Subsequent reader comprehension effort— switching between thinking about bitwise and arithmetic operations will require at least a cognitive task switch. 0 cognitive switch
- The risk that a change of representation in the types used will result in the bitwise mapping used failing to apply. This may cause faults to occur.
- Treating the same object as having different representations, in different parts of the visible source requires readers to use two different mental models of the object. Two models may require more cognitive effort to recall and manipulate than one, and interference may also occur in the reader's memory, potentially leading to mistakes being made.

Dev 569.1 A program may use bitwise operators to perform arithmetic operations provided a worthwhile cost/benefit has been shown to exist.

Bit-set

Some applications, or algorithms, call for the creation of a particular kind of set data type (in mathematics a set can hold many values, but only one of each value). The term commonly used to describe this particular kind of set is *bit-set*, which is essentially an array of boolean values. The technique used to implement this bit-set type is to interpret every bit of an integer type as representing a member of the set. (When the bit is set, the member is considered to be in the set; when it is not set, the member is not present.) The number of members that can be represented using this technique is limited by the number of bits available in an integer type. This technique essentially provides both storage and performance optimization. An alternative representation technique is a structure type containing a member for each member of the bit-set, and appropriate functions for testing and setting these members.

boolean role 476

While the boolean role is defined in terms of operations that may be performed on a value having certain properties, it is possible to define a bit-set role in terms of the operations that may be performed on a value having certain properties.

bit-set role

An object having an integer type, or value having an integer type has a bit-set role if it appears as the operand of a bitwise operator or the object is assigned a value having a bit-set role.

bitwise operator result bit-set role numeric role

For the purpose of these guideline recommendations the result of a bitwise operator has a bit-set role.

An object having an integer type, or value having an integer type has a numeric role if it appears as the operand of an arithmetic operator or the object is assigned a value having a numeric role. Objects having a floating type always have a numeric role.

arithmetic operator result numeric role

For the purpose of these guideline recommendations the result of an arithmetic operator is defined to have a numeric role.

integer promotions 675
usual arithmetic conversions 706

The sign bit, if any, in the value representation shall not be used in representing a bit-set. (This restriction is needed because, if an operand has a signed type, the integer promotions or the usual arithmetic conversions can result in an increase in the number of bits used in the value representation.)

Dev 569.1 An object having a bit-set role that appears as the operand of a bitwise operator is not considered to be making use of representation information.

Example

Bitwise operations allow several conditions to be checked at the same time.

```
#define R_OK (0x01)
#define W_OK (0x02)
#define X_OK (0x04)

_Bool f(unsigned int permission)
{
return (permission & (R_OK | W_OK)) == 0;
}
```

---

bitwise operations signed types

These operators yield values that depend on the internal representations of integers, and have implementation-defined and undefined aspects for signed types. 946

Commentary

The choice of behavior was largely influenced by what the commonly available processors did at the time the standard was originally written. In some cases there is a small set of predictable behaviors; for instance, left-shift can exhibit undefined behavior, while under the same conditions right-shift is implementation-defined.

left-shift 1193
undefined
right-shift 1196
negative value

Efficiency of execution has been given priority over specifying the exact behavior (which may be inefficient to implement on some processors).

Warren[1443] provides an extensive discussion of calculations that can be performed and information obtained via bitwise operations on values represented in two's complement notation.

C++

These operators exhibit the same range of behaviors in C++. This is called out within the individual descriptions of each operator in the C++ Standard.

Other Languages

The issues involved are not specific to C. They are caused by the underlying processor representations of integers and how instructions that perform bitwise operations on these types are defined to operate. As such, other languages that support bitwise operations also tend to exhibit the same kinds of behaviors.

Coding Guidelines

The issues involved in using operators that rely on undefined and implementation-defined behavior are discussed under the respective operators.

---

947 If an *exceptional condition* occurs during the evaluation of an expression (that is, if the result is not mathematically defined or not in the range of representable values for its type), the behavior is undefined. exception condition

Commentary

This defines the term *exceptional condition*. Note that the wording does not specify that an exception is raised, but that the condition is exceptional (i.e., unusual). These exceptional conditions can only occur for operations involving values that have signed integer types or real types.

There are only a few cases where results are not mathematically defined (e.g., divide by zero). The more common case is the mathematical result not being within the range of values supported by its type (a form of overflow). For operations on real types, whether values such as infinity or NaN are representable will depend on the representation used. In the case of IEC 60559 there is always a value that is capable of representing the result of any of its defined operations.

C90

The term *exception* was defined in the C90 Standard, not *exceptional condition*.

C++

If during the evaluation of an expression, the result is not mathematically defined or not in the range of representable values for its type, the behavior is undefined, unless such an expression is a constant expression (5.19), in which case the program is ill-formed. 5p5

The C++ language contains explicit exception-handling constructs (Clause 15, **try**/**throw** blocks). However, these are not related to the mechanisms being described in the C Standard. The term exceptional condition is not defined in the C sense.

Other Languages

Few languages define the behavior when the result of an expression evaluation is not representable in its type. However, Ada does define the behavior— it requires an exception to be raised for these cases.

Common Implementations

In most cases translators generate the appropriate host processor instruction to perform an operation. Whatever behavior these instructions exhibit, for results that are not representable in the operand type, is the implementation's undefined behavior. For instance, many processors trap if the denominator in a division operation is zero. It is rare for an implementation to attempt to detect that the result of an expression

evaluation overflows the range of values representable in its type. Part of the reason is efficiency and part because of developer expectations (an implementation is not expected to do it).

On many processors the instructions performing the arithmetic operations are defined to set a specified bit if the result overflows. However, the unit of representation is usually a register (some processors have instructions that operate on a subdivision of a register— a halfword or byte). For C types that exactly map to a processor register, detecting an overflow is usually a matter of generating an additional instruction after every arithmetic operation (branch on overflow flag set). Complications can arise for mixed signed/unsigned expressions if the processor also sets the overflow flag for operations involving unsigned types. (The Intel x86, IBM 370 set the carry flag in this case; SPARC has two add instructions, one that sets the carry flag and one that does not.) A few processors have versions of arithmetic instructions that are either defined to trap on overflow (often limited to add and subtract, e.g., MIPS) or provide a mechanism for toggling trap on overflow (IBM 370, HP–was DEC– VAX).

Example

In the following the multiplication by `LONG_MAX` will deliver a result that is not representable in a **`long`**.

```
1  extern int i;
2  extern long j;
3
4  void f(void)
5  {
6  i = 30000;
7  j = i * LONG_MAX;
8  }
```

---

effective type

The *effective type* of an object for an access to its stored value is the declared type of the object, if any.[73)] 948

Commentary

This defines the term *effective type*, which was introduced into C99 to deal with objects having allocated storage duration. In particular, to provide a documented basis for optimizers to attempt to work out which objects might be aliased, with a view to generating higher-quality machine code. Knowing that a referenced object is not aliased at a particular point in the program can result in significant performance improvements (e.g., it might be possible to deduce that its value can be held in a register throughout the execution of a critical loop rather than loaded from storage on every iteration).

Computing alias information can be very resource (processor time and storage needed) intensive. To reduce this overhead, translator vendors try to make simplifying assumptions. One assumption commonly made is that pointers to `type_A` are disjoint from pointers to `type_B`. The concept of effective type provides a mechanism for knowing the possible types that an object can be referenced through. If the same object is accessed using effective types that do not meet the requirements specified in the standard the behavior is undefined; one possible behavior is to do what an optimizing translator happens to do based on the assumption that accesses through different effective types do not occur.

object 960 value accessed if type

Storing a value into an object that has a declared type, through an lvalue having a different type, does not change that object's effective type.

C90

The term *effective type* is new in C99.

C++

The term *effective type* is not defined in C++. A type needs to be specified when the C++ new operator is used. However, the C++ Standard includes the C library, so it is possible to allocate storage via a call to the `malloc` library function, which does not associate a type with the allocated storage.

Common Implementations

The RTC tool[866] performs type checking on accesses to objects during program execution. The type information associated with every storage location written to specifies the number of bytes in the type and one of unallocated, uninitialized, integer, real, or pointer. The type of a write to a storage location is checked against the declared type of that location, if any, and the type of a read from a location is checked against the type of the value last written to it.

Coding Guidelines

While an understanding of effective type might be needed to appreciate the details of how library functions such as `memcpy` and `memcmp` operate, developers rarely need to get involved in this level of detail.

---

949 If a value is stored into an object having no declared type through an lvalue having a type that is not a character type, then the type of the lvalue becomes the effective type of the object for that access and for subsequent accesses that do not modify the stored value.

Commentary

Only objects with allocated storage duration have no declared type. The type is assigned to such an object through a value being stored into it in name only; there is no requirement for this information to be represented during program execution (although implementations designed to aid program debugging sometimes do so). The type of an object with allocated storage duration is potentially changed every time a value is stored into it. A parallel can be drawn between such an object and another one having a union type.

Storing a value through an lvalue occurs when the left operand of an assignment operator is a dereferenced pointer value. The effective type is derived from the dereferenced pointer type in this case.

The character types are special in that they are the types often used to access the individual bytes in an object (e.g., to copy an object). This usage is sufficiently common that the Committee could not mandate that an object modified via an lvalue having a character type will only be accessed via a character type (it would also create complications for the specification of some of the library functions— e.g., `memcpy`.) An object having allocated storage duration can only have a character type as its effective type if it is accessed using such a type.

959 effective type
lvalue used for access

Other Languages

Many languages that support dynamic storage allocation require that a type be associated with that allocated storage. Some languages (e.g., awk) allocate storage implicitly without the need for any explicit operation by the developer.

Coding Guidelines

Objects with no declared type must have allocated storage duration and can only be referred to via pointers (this C sentence refers to the effective type of the objects, not the type of the pointers that refer to them). Objects having automatic and static storage duration have a fixed effective type— the one appearing in their declaration. The type of an object having allocated storage duration can change every time a new assignment is made to it.

Allocating storage for an object and treating it as having `type_a` in one part of a program and later on treating it as having `type_b` creates a temporal dependency (the two kinds of usage have to be disjoint) and a spatial dependency (the allocated storage needs to be large enough to be able to represent both types). Keeping track of these dependencies is a cost (developer cognitive resources needed to learn, keep track of, and take them into account) that is often significantly greater than the benefit (smaller, slightly faster-executing program image through not deallocating and reallocating storage). Explicitly deallocating storage when it is not needed and allocating it when it is needed is a minor overhead that creates none of these dependencies between different parts of a program.

Having the same allocated object referred to by pointers of different types creates a union type in all but name:

```
1  #include <stdlib.h>
2
3  float *p_f;
4  int *p_i;
5
6  void f(void)
7  {
8  void *p_v = malloc(sizeof(float)); /* Assume float & int are same size. */
9
10 /* Treat as union. */
11 p_f = p_v;
12 p_i = p_v;
13
14 p_v = malloc(sizeof(float)+sizeof(int));
15
16 /* Treat as struct. */
17 p_f = p_v;
18 p_i = (int *)((char *)p_v + sizeof(float));
19 }
```

Cg 949.1

Once an object having no declared type is given an effective type, it shall not be given another effective type that is incompatible with the one it already has.

Dev 949.1

Any object having no declared type may be accessed through an lvalue having a character type.

---

footnote 71

71) This paragraph renders undefined statement expressions such as 950

```
i = ++i + 1;
a[i++] = i;
```

while allowing

```
i = i + 1;
a[i] = i;
```

Commentary

The phrase *statement expressions* is used to make a distinction between the full expression contained within the statement and the syntactic construct *expression-statement*. Expressions can exhibit undefined behavior, but statements cannot (or at least are not defined by the standard to do so).

Other Languages

Even languages that don't contain the ++ operator can exhibit undefined behavior for one of these cases. If a ++ operator is not available, a function may be written by the developer to mimic it (e.g., `a[post_inc(i)] := i`). Many languages do not define the order in which the evaluation of the operands in an assignment takes place, while a few do.

---

footnote 72

72) The syntax specifies the precedence of operators in the evaluation of an expression, which is the same as the order of the major subclauses of this subclause, highest precedence first. 951

Commentary

Every operator is assigned a *precedence* relative to the other operators. When an operand syntactically appears between two operators, it binds to the operator with highest precedence. In C there are thirteen levels of precedence for the binary operators and three levels of precedence for the unary operators.

Requirements on the operands of operators, and their effects, appear in the constraints and semantics subclauses. These occur after the corresponding syntax subclause.

Other Languages

Many other language specification documents use a similar, precedence-based, section ordering. Ada has six levels of precedence, while operators in APL and Smalltalk all have the same precedence (operator/operand binding is decided by associativity).

Example

In the expression `a+b*c` multiply has a higher precedence and the operand `b` is operated on by it rather than the addition operator.

---

952 Thus, for example, the expressions allowed as the operands of the binary `+` operator (6.5.6) are those expressions defined in 6.5.1 through 6.5.6.

Commentary

The subsections occur in the standard in precedence order, highest to lowest. For instance, in `a + b*c` the result of the multiplicative operator (discussed in clause 6.5.5) is an operand of the additive operator (discussed in clause 6.5.6). Also the ordering of subclauses within a clause follows the ordering of the nonterminals listed in that syntax clause.

---

953 The exceptions are cast expressions (6.5.4) as operands of unary operators (6.5.3), and an operand contained between any of the following pairs of operators: grouping parentheses `()` (6.5.1), subscripting brackets `[]` (6.5.2.1), function-call parentheses `()` (6.5.2.2), and the conditional operator `?:` (6.5.15).

Commentary

A *`cast-expression`* is a separate subclause because there is a context where this unary operator is not permitted to occur syntactically as the last operator operating on the left operand of an assignment operator (although some implementations support this usage as an extension). In this context a *`unary-expression`* is required.

1133 cast-expression syntax
1288 assignment-expression syntax
1080 unary-expression syntax

The parentheses `()`, subscripting brackets `[]`, and function-call parentheses `()` all provide a method of enclosing an expression within a bracketing construct that cuts it off from the syntactic effects of any surrounding operators. The conditional operator takes three operands, each of which are different syntactic expressions.

1264 conditional-expression syntax

Other Languages

Many languages do not consider array subscripting and function-call parentheses as operators.

---

954 Within each major subclause, the operators have the same precedence.

Commentary

However, the operators may have different associativity.

955 operator associativity

C++

This observation is true in the C++ Standard, but is not pointed out within that document.

Other Languages

Many language specification documents are similarly ordered.

---

955 Left- or right-associativity is indicated in each subclause by the syntax for the expressions discussed therein.

operator associativity

Commentary

Every binary operator is specified to have an *associativity*, which is either to the left or to the right. In C the assignment operators and the conditional ternary operators associate to the right; all other binary operators associate to the left. Associativity controls how operators at the same precedence level bind to their operands. Operators with left-associativity bind to operands from left-to-right, Operators with right-associativity bind from right-to-left.

943 operator precedence

Most syntax productions for C operators follow the pattern $X_n \Rightarrow X_n\, op\, X_{n+1}$ where X_n is the production for the operator, op, having precedence n (i.e., they associated to the left); for instance, `i / j / k` is equivalent to `(i / j) / k` rather than `i / (j / k)`. The pattern for *`conditional-expression`* (and similarly for *`assignment-expression`*) is $X_n \Rightarrow X_{n+1}?X_{n+1} : X_n$ (i.e., it associates to the right); for instance, `a ? b : c ? d : e` is equivalent to `a ? b : (c ? d : e)` rather than `(a ? b : c) ? d : e`.

Other Languages

Most algorithmic languages have similar associativity rules to C. However, operators in APL always associate right-to-left.

Coding Guidelines

Like precedence, possible developer misunderstandings about how operators associate can be solved using parentheses. Expressions, or parenthesized expressions that consist of a sequence of operators with the same precedence, might be thought to be beyond confusion. If the guideline recommendation specifying the use of parentheses is followed, associativity will not be a potential source of faults. However, some of the deviations for that guideline recommendation allow consideration for multiplicative operators to be omitted from the enforcement of the guideline. For the case of adjacent multiplicative operators, this deviation should not be applied.

expression shall be parenthesized 943.1

Cg 955.1

If the result of a multiplicative operator is the immediate operand of another multiplicative operator, then the two operators shall be separated by at least one parenthesis in the source.

If an expression consists solely of operations involving the binary plus operator, it might be thought that the only issue that need be considered, when ordering operands, is their values. However, there is a second issue that needs to be considered— their type. If the operand types are different, the final result can depend on the order in which they were written (which defines the order in which the usual arithmetic conversions are applied).

usual arithmetic conversions 706

Cg 955.2

If the result of an additive operator is the immediate operand of another additive operator, and the operands have different promoted types, then the two operators shall be separated by at least one parenthesis in the source.

Example

In the following the fact that `j` is added to `i` before `k` is added to the result is not of obvious interest until it is noticed that their types are all different.

```
1  extern float i;
2  extern short j;
3  extern unsigned long k;
4
5  void f(void)
6  {
7  int x, y;
8
9  x = i + j + k;
10
11 y = i / j / k; /* / associates to the left: (i / j) / k */
12
13 i /= j /= k;   /* /= associates to the right: i /= (j /= k) */
14 }
```

Associativity requires that `j` be added to `i`, after being promoted to type **`float`**. The result type of `i+j` (**`float`**) causes `k` to be converted to **`float`** before it is added. The sequence of implicit conversions would

have been different had the operators associated differently, or the use of parentheses created a different operand grouping. Dividing `i` by `j`, before dividing the result by `k`, gives a very different answer than dividing `i` by the result of dividing `j` by `k`.

---

956 73) Allocated objects have no declared type. footnote 73

Commentary

The library functions that create such objects (`malloc` and `calloc`) are declared to return the type pointer to **`void`**.

C90

The C90 Standard did not point this fact out.

C++

The C++ operator **`new`** allocates storage for objects. Its usage also specifies the type of the allocated object. The C library is also included in the C++ Standard, providing access to the `malloc` and `calloc` library functions (which do not contain a mechanism for specifying the type of the object created).

Other Languages

Some languages require type information to be part of the allocation request used to create allocated objects. The allocated object is specified to have this type. Other languages provide library functions that return the requested amount of storage, like C.

---

957 DR287) A floating-point status flag is not an object and can be set more than once within an expression. footnote DR287

Commentary

Processors invariably set various flags after each arithmetic operation, be it floating-point or integer. For instance, in `w*x + y*z` after each multiplication flags status flags denoting *result is zero* or *result overflows* may be set. Floating-point status flags differ from integer status flags in that Standard library functions are available for accessing and setting their value, which makes visible the order in which operations take place.

Implementations that support floating-point state are required to treat changes to it as a side-effect. But, by not treating floating-point status flags as an object, the undefined behavior that occurs when the same object is modified between sequence points does not occur. 199 side effect floating-point state 941 object modified once between sequence points

This footnote was added by the response to DR #287.

Example

```
1  /*
2   * set/clear or clear/set one of the floating-point exception flags:
3   */
4  (feclearexcept)(FE_OVERFLOW) + (feraiseexcept)(FE_OVERFLOW);
```

---

958 If a value is copied into an object having no declared type using **`memcpy`** or **`memmove`**, or is copied as an array of character type, then the effective type of the modified object for that access and for subsequent accesses that do not modify the value is the effective type of the object from which the value is copied, if it has one.

Commentary

In the declarations of the library functions `memcpy` and `memmove`, the pointers used to denote both the object copied to and the object copied from have type pointer to **`void`**. There is insufficient information available in either of the declared parameter types to deduce an effective type. The only type information available is the effective type of the object that is copied. Another case where the object being copied would not have an

effective type, is when it is storage returned from a call to the `calloc` function which has not yet had a value of known effective type stored into it.

Here the effective type is being treated as a property of the object being copied from. Once set it can be carried around like a value. (From the source code analysis point of view, there is no requirement that this information be represented in an object during program execution.)

Use of character types to copy one object to another object is a common idiom. Some developers write their own object copy functions, or simply use an inline loop (often with the mistaken belief of improved efficiency or reduced complexity). The usage is sufficiently common that the standard needs to take account of it.

Other Languages

Many languages only allow object values to be copied through the use of an assignment statement. Few languages support pointer arithmetic (the mechanism needed to enable objects to be copied a byte at a time). While many language implementations provide a mechanism for calling functions written in C, which provides access to functions such as `memcpy`, they do not usually provide any additional specifications dealing with object types.

In some languages (e.g., awk, Perl) the type of a value is included in the information represented in an object (i.e., whether it is an integer, real, or string). This type information is assigned along with the value when objects are assigned.

Common Implementations

There are a few implementations that perform localized flow analysis, enabling them to make use of effective type information (even in the presence of calls to library functions). While performing full program analysis is possible in theory, for nontrivial programs the amount of storage and processor time required is far in excess of what is usually available to developers. There are also implementations that perform runtime checks based on type information associated with a given storage location.[866]

A few processors tag storage with the kinds of value held in it[1389] (e.g., integer or floating-point). These tags usually represent broad classes of types such as pointers, integers, and reals. This functionality might be of use to an implementation that performs runtime checks on executing programs, but is not required by the C Standard.

Example

```
1  #include <stdlib.h>
2  #include <string.h>
3
4  void *obj_copy(void *obj_p, size_t obj_size)
5  {
6  void *new_obj_p = malloc(obj_size);
7
8  /*
9   * It would take some fancy analysis to work out, statically,
10  * the effective type of the object being copied here.
11  */
12 memcpy(new_obj_p, obj_p, obj_size);
13
14 return new_obj_p;
15 }
```

effective type
lvalue used for access

For all other accesses to an object having no declared type, the effective type of the object is simply the type of the lvalue used for the access. 959

Commentary

This is the effective type of last resort. The only type available is the one used to access the object. For instance, an object having allocated storage duration that has only had a value stored into it using lvalues of character type will not have an effective type. This wording does not specify that the type used for the access is the effective type for subsequent accesses, as it does in previous sentences.

Coding Guidelines

The question that needs to be asked is why the object being accessed does not have an effective type. An access to the storage returned by the `calloc` function before another value is assigned to it, is one situation that can occur because of the way a particular algorithm works. Unless the access is via an lvalue having a character type, use is being made of representation information; this is discussed elsewhere.

569.1 representation information using

---

960 An object shall have its stored value accessed only by an lvalue expression that has one of the following types:[74)]

object value accessed if type

Commentary

This list is sometimes known as the *aliasing rules* for C. Any access to the stored value of an object using a type that is not one of those listed next results in undefined behavior. To access the same object using one of the different types listed requires the use of a pointer type. Reading from a different member of a union type than the one last stored into is unspecified behavior.

589 union member when written to

The standard defines various cases where types have the same representation and alignment requirements, they all involve either signed/unsigned versions of the same integer type or qualified/unqualified versions of the same type. The intent is to allow objects of these types to interoperate. These cases are reflected in the rules listed in the following C sentences. There are also special access permissions given for the type **`unsigned char`**.

486 signed integer corresponding unsigned integer
495 positive signed integer type subrange of equivalent unsigned type
556 qualifiers representation and alignment
573 value copied using unsigned char

C90

In the C90 Standard the term used in the following types was *derived type*. The term *effective type* is new in the C99 Standard and is used throughout the same list.

Other Languages

Most typed languages do not allow an object to be accessed using a type that is different from its declared type. Accessing the stored value of an object through different types requires the ability to take the addresses of objects or to allocate untyped storage. Only a few languages offer such functionality.

Common Implementations

The only problem likely to be encountered with most implementations, in accessing the stored value of an object, is if the object being accessed is not suitably aligned for the type used to access it.

39 alignment

Coding Guidelines

The guideline recommendation dealing with the use of representation information may be applicable here.

569.1 representation information using

Example

The following is a simple example of the substitutions that these aliasing rules permit:

```
1   extern int glob;
2   extern double f_glob;
3
4   extern void g(int);
5
6   void f(int *p_1, float *p_2)
7   {
8   glob = 1;
9   *p_1 = 3;            /* May store value into object glob. */
10  g_1(glob);           /* Cannot replace the argument, glob, with 1. */
11
```

```
12  glob = *p_1;
13  *p_2 = f_glob * 8.6; /* Undefined behavior if store modifies glob. */
14  g_2(glob);           /* Translator can replace the argument, glob, with 2. */
15  }
```

Things become more complicated if an optimizer attempts to perform statement reordering. Moving the generated machine code that performs floating-point calculations to before the assignment to `glob` is likely to improve performance on pipelined processors. Alias analysis suggests that the objects pointed to by `p_1` and `p_2` must be different and that statement reordering is possible (because it will not affect the result). As the following invocation of `f` shows, this assumption may not be true.

alias analysis 1491

```
1  union {
2         int i;
3         float f;
4        } u_g;
5
6  void h(void)
7  {
8  f(&u_g.i, &u_g.f);
9  }
```

---

object stored value accessed only by

— a type compatible with the effective type of the object,

compatible type 632 additional rules

Commentary

Accessing an object using a different, but compatible type(i.e., an enumerated type and its compatible integer type) is thus guaranteed to deliver the same result.

C++

3.10p15

— *the dynamic type of the object,*

1.3.3 dynamic type

the type of the most derived object (1.8) to which the lvalue denoted by an lvalue expression refers. [Example: if a pointer (8.3.1) `p` whose static type is "pointer to class `B`" is pointing to an object of class `D`, derived from `B` (clause 10), the dynamic type of the expression `*p` is "`D`." References (8.3.2) are treated similarly.] The dynamic type of an rvalue expression is its static type.

The difference between an object's dynamic and static type only has meaning in C++.

compatible type 631 if

Use of effective type means that C gives types to some objects that have no type in C++. C++ requires the types to be the same, while C only requires that the types be compatible. However, the only difference occurs when an enumerated type and its compatible integer type are intermixed.

Coding Guidelines

The two objects having compatible types might have been declared using one or more typedef names, which may depend on conditional preprocessing directives. Ensuring that such types remain compatible is a software engineering issue that is outside the scope of these coding guidelines.

enumeration 1447 type compatible with

The issue of making use of enumerated types and the implementation's choice of compatible integer type is discussed elsewhere.

Example

```
1   extern int f(int);
2
3   void DR_053(void)
4   {
5   int (*fp1)(int) = f;
6   int (**fpp)() = &fp1;
7
8   /*
9    * In the following call the value of fp1 is being accessed by an
10   * lvalue that is different from its declared type, but is compatible
11   * with its effective type: (int (*)()) vs. (int (*)(int)).
12   */
13  (**fpp)(3);
14  }
```

962 — a qualified version of a type compatible with the effective type of the object,

Commentary

Qualification does not alter the representation or alignment of a type (or of pointers to it), only the translation-time semantics. Adding qualifiers to the type used to access the value of an object will not alter that value. The **volatile** qualifier only indicates that the value of an object may change in ways unknown to the translator (therefore the quality of generated machine code may be degraded because a translator cannot make use of previous accesses to optimize the current access).

556 qualifiers representation and alignment
746 pointer converting qualified/unqualified

Other Languages

Languages containing a qualifier that performs a function similar to the C **const** qualifier (i.e., a read-only qualifier) usually allow objects having that type to access other objects of the same, but unqualified, type.

Example

```
1   extern int glob;
2
3   void f(const int *p_i)
4   {
5   /*
6    * Only ever read the value pointed to by p_i, but may
7    * directly, or indirectly, cause glob to be modified.
8    */
9   }
10
11  void g(void)
12  {
13  const int max = 33;
14
15  f(&max);
16  f((const int *)&glob);
17  }
```

963 — a type that is the signed or unsigned type corresponding to the effective type of the object,

Commentary

The signed/unsigned versions of the same type are specified as having the same representation and alignment requirements to support this kind of access. The standard places no restriction here on the values represented by the stored value being accessed. The intent of this list is to specify possible aliasing circumstances, not possible behaviors.

footnote 509 31
footnote 971 74

Other Languages

Few languages support an unsigned type. Those that do support such a type do not require implementations to support the inter-accessing of signed and unsigned types of the form available in C.

Coding Guidelines

The range of nonnegative values of a signed integer type is required to be a subrange of the corresponding unsigned integer type. However, it cannot be assumed that this explicit permission to access an object using either a signed or unsigned version of its effective type means that the behavior is always defined. The guideline recommendation on making use of representation information is applicable here.

positive 495 signed integer type
subrange of equivalent unsigned type
representation information using 569.1
footnote 509 31

If an argument needs to be passed to a function accepting a pointer to the oppositely signed type, an explicit cast will be needed. The issues involved in such casts are discussed elsewhere.

— a type that is the signed or unsigned type corresponding to a qualified version of the effective type of the object, 964

Commentary

This is the combination of the previous two cases.

— an aggregate or union type that includes one of the aforementioned types among its members (including, recursively, a member of a subaggregate or contained union), or 965

Commentary

A particular object may be an element of an array or a member of a structure or union type. Objects having one of these derived types can be accessed as a whole; for instance, using an assignment operator (the array object will need to be a member of a structure or union type). It is this access as a whole that in turn accesses the stored value(s) of the members.

Common Implementations

A great deal of research has been invested in analyzing the pattern of indexes into arrays within loops, with a view to parallelizing the execution of that loop. But, for array objects outside of loops, relatively little research effort has been invested in attempting to track the contents of particular array's elements. There are a few research translators that break structure and union objects down into their constituent members when performing flow analysis. This enables a much finer-grain analysis of the aliasing information.

data dependency 988
array element held in register 1369

Example

```
#include <string.h>

extern long *p_l;

union U {
          int i;
          long l;
         } uil;
struct S {
           int i;
           long l;
          } sil_1,
            sil_2;
```

```
14  long a_l[3];
15
16  void f(void)
17  {
18  *p_l = 33;
19
20  /*
21   * The following four statements may all cause the value
22   * pointed to by p_l to be modified.
23   */
24  memset(&uil, 0, sizeof(uil));
25  memset(&sil, 0, sizeof(sil_1));
26  memset(&a_l, 0, sizeof(a_l));
27  sil_2 = sil_1;
28
29  if (*p_l == 33) /* This test is not guaranteed to be true. */
30     a_l[0] = 9;
31  }
```

966 — a character type.

Commentary

Prior to the invention of the **void** type (during the early evolution of C[1180]), pointer to character types were used as the generic method of passing values having different kinds of pointer types as arguments to function calls.

Although library functions have always been available for copying any number of bytes from one object to another (e.g., `memcpy`), many developers have preferred to perform inline copying (writing the loop at the point of copy) or to call their own functions. These preferences show no signs of dying out and the standard needs to continue to support the possibility of objects having character types being aliases for objects of other types.

C++

— *a* **char** *or* **unsigned char** *type.* 3.10p15

The C++ Standard does not explicitly specify support for the character type **signed char**. However, it does specify that the type **char** may have the same representation and range of values as **signed char** (or **unsigned char**). 516 char range, representation and behavio

It is common practice to access the subcomponents of an object using a **char** or **unsigned char** type. However, there is code that uses **signed char**, and it would be a brave vendor whose implementation did not assume that objects having type **signed char** were not a legitimate alias for accesses to any object.

Other Languages

While other languages may not condone the accessing of subcomponents of an object, their implementations sometimes provide mechanisms for making such accesses at the byte level.

Coding Guidelines

Accessing objects that do not have a character type, using an lvalue expression that has a character type is making use of representation information, which is covered by a guideline recommendation. The special case of the type **unsigned char** is discussed elsewhere. 569.1 representation information 573 value copied using unsigned char

967 A floating expression may be *contracted*, that is, evaluated as though it were an atomic operation, thereby omitting rounding errors implied by the source code and the expression evaluation method.[75)] contracted

Commentary

This defines the term *contracted*.

Some processors have instructions that perform more than one operation before delivering a result. The most commonly seen instance of such a multiple operation instruction is the multiply/add pair; taking three operands and delivering the result of evaluating `x + y * z`. This so-called *fused* multiply/add instruction reflects the kinds of operations commonly seen in numerical computations— for instance, matrix multiple and FFT calculations. A fused instruction may execute more quickly than the equivalent two separate instructions and may return a result of greater accuracy (because there are no conversions or rounding performed on the intermediate result).

This wording in the standard explicitly states that the use of such fused instructions is permitted (subject to the use of the `FP_CONTRACT` pragma) by the C Standard, even if it means that the final result of an expression is different from what it would have been had several independent instructions been used.

C90

This explicit permission is new in C99.

C++

The C++ Standard, like C90, is silent on this subject.

Other Languages

Very few languages get involved in the instruction level processor details when specifying the behavior of programs. Fortran does not explicitly mention contraction but some implementations make use of it.

Common Implementations

Some implementations made use of fused multiply/add instructions in their implementation of C90.

Coding Guidelines

An expression that is contracted by an implementation may be thought to deliver the double advantage of faster execution and greater accuracy. However, in some cases the accuracy of the complete calculation may be decreased. The issues associated with contracting an expression are discussed elsewhere.

contraction 974 undermine predictability

The **`FP_CONTRACT`** pragma in **`<math.h>`** provides a way to disallow contracted expressions. 968

Commentary

The `FP_CONTRACT` pragma also provides a way to allow contracted expressions if they are supported by the implementation.

C90

Support for the `FP_CONTRACT` pragma is new in C99.

C++

Support for the `FP_CONTRACT` pragma is new in C99 and not specified in the C++ Standard.

---

contracted how implementation-defined

Otherwise, whether and how expressions are contracted is implementation-defined.[76)] 969

Commentary

Contraction requires support from both the processor and the translator. (Even although fused instructions may be available on a processor, a translator may not provide the functionality needed to make use of them.) For instance, in `a*b+c*d` there are a number of options open to an implementation that supports a contracted multiply/add. The instruction sequence used to evaluate this expression is likely to be affected by the values from previous operations currently available in registers.

C++

The C++ Standard does not give implementations any permission to contract expressions. This does not mean they cannot contract expressions, but it does mean that there is no special dispensation for potentially returning different results.

Common Implementations

The operator combination multiply/add is the most commonly supported by processors because of the frequency of occurrence of this pair in FFT and matrix operations (these invariably occur in signal processing applications). Other forms of contraction have been proposed for other specialist applications (e.g., cryptography[1484]).

The floating-point units in the Intel i860[624] can operate in pipelined or scalar mode, with a variety of options on how the intermediate results are fed into the different units. Depending on the generated code it is possible for the evaluation of `a*b+z` to differ from `c*d+z`, even when the products `a*b` and `c*d` are equal (this issue is discussed in WG14 document N291).

Coding Guidelines

Even in those cases where a developer is aware that expression contraction may occur, there is no guarantee that it will be possible to estimate its impact. For complex expressions the implementation-defined behavior may be sufficiently complex that developers may have difficulty deducing which, if any, subexpression evaluations have been contracted. (One way of finding out the translator's behavior is to examine a listing of the generated machine code.) Once known, what use is this information, on contracted expressions, to a developer? Probably none. The developer needs to look at the issue from a less-detailed perspective.

The only rationale for supporting contracted expressions is improved runtime performance. In those situations where the possible improvement in performance offered by contraction is not required it only introduces uncertainty, a cost for no benefit. Because the default behavior is implementation-defined (no contraction unless requested might have been a better default choice by the C Committee), it is necessary for the developer to ensure that contraction is explicitly switched off, unless it is explicitly required to be on.

Rev 969.1

Unless there is a worthwhile cost/benefit in allowing translators to perform contraction, any source file that evaluates floating-point expressions shall contain the preprocessing directive:
`#pragma STDC FP_CONTRACT off`
near the start of the source file, before the translation of any floating-point expressions.

When using the `FP_CONTRACT` pragma developers might choose to minimize the region of source code over which it is in the "ON" state (i.e., having a matching pragma directive that switches it to the "OFF" state) or have it the "ON" state during the translation of an entire translation unit. Until more experience is gained with the use of `FP_CONTRACT` pragma it is not possible to evaluate whether any guideline recommendation is worthwhile.

---

970 **Forward references:** the **`FP_CONTRACT`** pragma (7.12.2), copying functions (7.21.2).

---

971 74) The intent of this list is to specify those circumstances in which an object may or may not be aliased.

footnote 74 object aliased

Commentary

An object may be aliased under other circumstances, but the standard does not require an implementation to support any other circumstances. Aliasing is discussed in more detail in the discussion of the **`restrict`** type qualifier.

1491 alias analysis

Other Languages

The potential for aliasing is an issue in the design of most programming languages, although this term may not explicitly appear in the language definition. There is a family of languages having the major design aim of preventing any aliasing from occurring— functional languages.

Coding Guidelines

Although some coding guideline documents warn about the dangers of creating aliases (e.g., developers need to invest effort in locating, remembering, and taking them into account), their cost/benefit in relation to alternative techniques (e.g., moving the declaration of an object from block to file scope rather than passing

its address as an argument in what appears to be a function call) is often difficult to calculate (experience suggest that developers rarely create aliases unless they are required). Given the difficulty of calculating the cost/benefit of various alternative constructs these coding guidelines are silent on the issue of alias creation.

```
1  extern int glob;
2
3  int f(int *valu)
4  {
5  return ++(*valu) + glob; /* Can valu ever refer to glob? */
6  }
```

---

footnote 75

75) A contracted expression might also omit the raising of floating-point exceptions. 972

Commentary

exception 947
condition
NaN 340
raising an exception

For instance, an exception might be raised when the evaluation of an expression is not mathematically defined, or when an operand has a NaN value. To obtain the performance improvement implied by fused operations, a processor is likely to minimize the amount of checking it performs on any intermediate results. Also any difference in the value of the intermediate result (caused by different rounding behavior or greater intermediate accuracy) can affect the final result, which might have raised an exception had two independent instructions been used.

C++

The contraction of expressions is not explicitly discussed in the C++ Standard.

---

footnote 76

76) This license is specifically intended to allow implementations to exploit fast machine instructions that combine multiple C operators. 973

Commentary

The difference between machine instructions that combine multiple operators taking floating-point operands and those taking integer operands is that in the former case the final result may be different. While an infinite number of combined processor instructions are possible, only a few combinations occur frequently in commercial applications. Also, while many combinations occur frequently, there are rarely any worthwhile performance advantages to be had from fusing them into a single instruction.

C90

Such instructions were available in processors that existed before the creation of the C90 Standard and there were implementations that made use of them. However, this license was not explicitly specified in the C90 Standard.

C++

The C++ Standard contains no such explicit license.

Other Languages

Although this implementation technique is not explicitly discussed in the Fortran Standard, some of its implementations make use of it.

Common Implementations

Some processors do have special integer instructions for handling graphics processing. However, these are not usually sufficiently general purpose (i.e., they are algorithm-specific) to be used for the combined evaluation of C operators. Combined arithmetic operations on integer data types do not appear in any processor known to your author.

While processors may have fused instructions available, implementations vary in their support for such instructions. The reason for this is that many of the processors providing such instructions are designed with

particular kinds of applications in mind and often have an irregular architecture. Even if fused instructions are generated by a translator, its pattern of register usage may be far from optimal because of the difficulties of mapping sequences of operators in a coherent way.

A study by Arnold and Corporaal[58] looked for frequently occurring sequences of operations in DSP applications. The results found that three operand arithmetic and load/store with prior address calculation occurred reasonably frequently (i.e., may be worth creating a single instruction to perform them).

---

974 As contractions potentially undermine predictability, and can even decrease accuracy for containing expressions, their use needs to be well-defined and clearly documented.

contraction undermine predictability

Commentary

This sentence applies to implementations. What exactly is a *well-defined* use? For instance, the intent of fused operations is increased performance. How much additional information is needed? Developers need information on the circumstances under which a translator will make use of such instructions and the impact of any surrounding subexpression evaluations (i.e., their potential impact on the generation of exceptions, NaNs, and underflow/overflow). Requiring developers to read listings of generated machine code probably does not count as clearly documented.

Algorithms created by floating-point experts take account of the rounding that will take place during the evaluation of an expression. If the expected rounding does not occur, the results may be less accurate than expected. This difference in rounding behavior need not be restricted to the contracted subexpression; one part of an expression may be contracted and another related part not contracted, leading to an imbalance in the expected values. (The decision on whether to contract can depend on the surrounding context, the same expression being contracted differently in different contexts, undermining predictability.)

Many developers do not have the mathematical sophistication needed to perform an error analysis of an algorithm containing one or more expressions that have been contracted (or not). The behavior of an implementation for particular algorithms is likely to be found, by developers, by measuring how it handles various test cases.

Other Languages

This is an issue that applies to all language implementations that make use of fused instructions to contract expressions.

Coding Guidelines

A clear, fully documented implementation provides no more rationale for allowing translators to contract expressions than a poorly documented one is a rationale for disallowing them. The guideline recommendations on contraction to apply whatever the state of the implementation's documentation.

Example

If the intermediate result of some operator is (with four additional bits of internal accuracy, shown using binary representation, with an underscore after position 53):

```
1.00000000000000000000001011111111111111111111111111111_0111
```

it would be rounded to:

```
1.00000000000000000000001011111111111111111111111111111
```

However, if the original result were not rounded, but immediately used as the operand of some form of fused add instruction with the other operand having the value (in practice the decimal point would be implicitly shifted right):

```
0.00000000000000000000000000000000000000000000000000000_0100
```

the result would be:

```
1.00000000000000000000011000000000000000000000000000
```

In the nonfused instruction case, where rounding occurred, the result of the add would be the value of the first operand.

6.5.1 Primary expressions

primary-expression syntax

975

```
primary-expression:
                identifier
                constant
                string-literal
                ( expression )
```

Commentary

A primary expression may be thought of as the basic unit from which a value can be read, or into which one can be stored. There is no simpler kind of expression (parentheses are a way of packaging up a complex expression).

C++

The C++ Standard (5.1p1) includes additional syntax that supports functionality not available in C.

Other Languages

Many languages treat a wider range of constructs as being primary expressions (because they do not define array selection, `[]`, structure and union member accesses, and function calls as operators).

Common Implementations

compound expression 1313

`gcc` supports what is calls *compound expressions* as a primary expression.

Semantics

identifier is primary expression if

976

An identifier is a primary expression, provided it has been declared as designating an object (in which case it is an lvalue) or a function (in which case it is a function designator).[77)]

Commentary

An identifier that has not been declared cannot be a *primary-expression*. So references to undeclared identifiers are a violation of syntax (a less through reading of the standard had led many people to believe that such usage was implicitly undefined behavior; the footnote was added in C99 to highlight this point) and must be diagnosed. Whether the identifier denotes a value or refers to an object depends on the operator, if any, of which it is an operand.

lvalue converted to value 725

C++

The C++ definition of identifier (5.1p7) includes support for functionality not available in C. The C++ Standard uses the term *identifier functions*, not the term *function designator*. It also defines such identifier functions as being lvalues (5.2.2p10) but only if their return type is a reference (a type not available in C).

Other Languages

Some languages implicitly declare identifiers that are not explicitly declared. For instance, Fortran implicitly declares identifiers whose names start with one of the letters `I` through `N` as integers, and all other identifiers as reals.

Common Implementations

Using current, high-volume, commodity technology, accessing an object's storage can be one of the slowest operations. Since 1986 CPU performance has increased by a factor of 1.55 per annum, while DRAM (one of the most common kinds of storage used) performance has only increased at 7% per annum[560] (see Figure 0.6). Many modern processors clock at a rate that is orders of magnitude faster than the random access memory chips they are interfaced to. This can result in a processor issuing a load instruction and having to wait 100 or more clock cycles for the value to be available for subsequent instructions to use. The following are a number of techniques are used to reduce this time penalty:

- Translators try to keep the values of frequently used objects in registers. 1369 register storage-class
- Hardware vendors add caches to their processors. In some cases there can be an on-chip cache and an off-chip cache, the former being smaller but faster (and more expensive) than the latter. 0 cache
- Processors can be designed to be capable of executing other instructions, which do not require the value being loaded, while the value is obtained from storage. This can involve either the processor itself deciding which instructions can be executed or its designers can expose the underlying operations and allow translators to generate code that can be executed while a value is loaded. For instance, the MIPS processor has a delay slot immediately after every load instruction; this can be filled with either a NOP instruction or one that performs an operation that does not access the register into which the value is being loaded. It is then up to translator implementors to find the sequence of instructions that minimizes execution time.[788]

Studies have found that a relatively small number of load instructions, so called *delinquent loads*, account for most of the cache misses (and therefore generate the majority of memory stalls). A study by Panait, Sasturkar, and Wong[1048] applied various heuristics to the assembler generated from the SPEC benchmarks to locate those 10% of load instructions that accounted for over 90% of all data cache misses. When basic bock profiling was used they were able to locate the 1.3% of loads responsible for 82% of all data cache misses.

Many high-performance processors now support a 64-bit data bus, while many programs continue to use 32-bit scalar types for the majority of operations. This represents a 50% utilization of resources. One optimization is to load (store is less common) two adjacent 32-bit quantities in one 64-bit operation. Opportunities for such optimizations are often seen within loops performing calculations on arrays. One study[13] was able to significantly increase the efficiency of memory accesses and improve performance based on this optimization.

Predicting the value of an object represented using a 32-bit word might be thought to have a 1 in 4×10^9 chance of being correct. However, studies have found that values held in objects can be remarkably predictable.[189,859]

Given that high-performance processors contain a cache to hold the value of recently accessed storage locations, the predictability of the value loaded by a particular instruction might not be thought to be of use. However, high-performance processors also pipeline the execution of instructions. The first stages of the pipeline perform instruction decoding and pass the components of the decoded instruction on to later stages, which eventually causes a request for the value at the specified location to be loaded. The proposed (no processors have been built— the existing results are all derived from the behavior of simulations of existing processors modified to use some form of value prediction tables) performance improvement comes from speculatively executing[466] other instructions based on a value looked up (immediately after an instruction is decoded and before it passes through other stages of the pipeline) in some form of *load value locality* table (indexed by the address of the load instruction). If the value eventually returned by the execution of the load instruction is the same as the one looked up, the results of the speculative execution are used; otherwise, the results are thrown away and there is no performance gain. The size of any performance gain depends on the accuracy of the value predictors used and a variety of algorithms have been proposed.[186,992] It has also been proposed that some value prediction decisions be made at translation time.[187]

value locality 0 cache 0 processor pipeline

Coding Guidelines

Some coding guidelines documents require that all identifiers be declared before use. This requirement arises from the C90 specification that an implicit declaration be provided for references to identifiers, which had not been declared, denoting function designators. Such an implicit declaration is not required in C99 and a conforming implementation will issue a diagnostic for all references to undeclared identifiers. This issue is discussed elsewhere.

operator 1000 ()

Usage

A study by Yang and Gupta[1489] found, for the SPEC95 programs, on average eight different values occupied 48% of all allocated storage locations throughout the execution of the programs. They called this behavior *frequent value locality*. The eight different values varied between programs and contained small values (zero was often the most frequently occurring value) and very large values (often program-specific addresses of objects and string literals).

Table 976.1: Dynamic percentage of load instructions from different *classes*. The *Class* column is a three-letter acronym: the first letter represents the region of storage (Stack, Heap, or Global), the second denotes the kind of reference (Array, Member, or Scalar), and the third indicates the type of the reference (Pointer or Nonpointer). For instance, *HFP* is a load of pointer-typed member from a heap-allocated object. There are two kinds of loads generated as a result of internal translator housekeeping: *RA* is a load of the return address from a function-call, and any register values saved to memory prior to the call also need to be reloaded when the call returns, *CS* callee-saved registers The figures were obtained by instrumenting the source prior to translation. As such they provide a count of loads that would be made by the abstract machine (apart from *RA* and *CS*). The number of loads performed by the machine code generated by translators is likely to be optimized (evaluation of constructs moved out of loops and register contents reused) and resulting in fewer loads. Whether these optimizations will change the distribution of loads in different classes is not known. Adapted from Burtscher, Diwan and Hauswirth.[187]

function leaf/non-leaf

A common program design methodology specifies that all the work should be done in the leaf functions (a *leaf function* is one that doesn't call any other functions). The nonleaf functions simply forms a hierarchy that calls the appropriate functions at the next level. In their study of the characteristics of C and C++ programs (using SPECint92 for C), Calder, Grunwald, and Zorn[192] made this leaf/nonleaf distinction when reporting their findings (see Table 976.2).

instruction 0 profile for different processors

The issue of dynamic instruction characteristics varying between processors and translators is discussed elsewhere. In the case of load instructions, Table 976.3 compares runtime percentages for two different processors.

Table 976.2: Occurrence of load instructions (as a percentage of all instructions executed on HP–was DEC– Alpha). The column headed *Leaf* lists percentage of calls to leaf functions, *NonLeaf* is for calls to nonleaf functions. Adapted from Calder, Grunwald, and Zorn.[192]

Program	Mean	Leaf	NonLeaf	Program	Mean	Leaf	Non-Leaf

977 A constant is a primary expression.

Commentary

A constant is a single token. A constant expression is a sequence of one or more tokens.

1322 constant expression syntax

Common Implementations

The numeric values of most constants that occur in source code tend to be small. Processor designers make use of this fact by creating instructions that contain a constant value within their encoding. In the case of RISC processors, these instructions are usually limited to loading constant values into a register (the constant zero occurs so often that many of them dedicate a, read-only, register to holding this value). Many CISC processors having instructions to perform arithmetic and logical operations, the constant value being treated as one of the operands. For instance, the Motorola 68000[968] had an optimized add instruction (`ADDQ`, add quick) that included three bits representing values between 1 and 8, in addition to the longer instructions containing 8-, 16-, and 32-bit constant values.

Coding Guidelines

Guidelines often need to distinguish between constants that are visible in the source code and those that are introduced through macro replacement. The reason for this difference in status is caused by how developers interact with source code; they look at the source code prior to translation phase 1, not as it appears after preprocessing. The issues involved in giving symbolic names to constants are discussed elsewhere.

macro replacement
822 symbolic name

Usage

Usage information on the distribution of all constant values occurring in the source is given elsewhere.

825 integer constant syntax

978 Its type depends on its form and value, as detailed in 6.4.4.

Commentary

Syntactically all constants have an arithmetic type (the null pointer constant either has the form of an octal constant, or a cast of such a constant, which is not a primary expression).

822 constant syntax

979 A string literal is a primary expression.

Commentary

The only context in which a string literal can occur in source code is as a primary expression.

Usage

string literal 895 syntax

Usage information on string literals is given elsewhere.

It is an lvalue with type as detailed in 6.4.5. 980

Commentary

lvalue 721 string literal 904 type

It is an lvalue because it has an object type and its type depends on the lexical form of the string literal.

---

parenthesized expression

A parenthesized expression is a primary expression. 981

Commentary

Parentheses can be thought of as encapsulating the expression within them.

expression 189 evaluation abstract machine base document 1

Implementations are required to honor the operator/operand pairings of an expression implied by the presence of parentheses. The base document differs from the standard in allowing implementations to rearrange expressions, even in the presence of parentheses.

Common Implementations

An optimizer may want to reorder the evaluation of operands in an expression to improve the performance or size of the generated code. For instance, in:

```
1  extern int i, j, k;
2
3  void f(void)
4  {
5  int x = i + k,
6      y = 21 + i + j + k;
7  /* ... */
8  }
```

it may be possible to improve the generated machine code by rewriting the subexpression `21 + i + j + k` as `i + k + j + 21`. Perhaps the result of the evaluation of `i + k` is available in a register, or is more quickly obtained via the object `x`.

However, such expression rewriting by a translator may not preserve the intended behavior of the expression evaluation. The expression may have been intentionally written this way because the developer knew that the evaluation order specified in the standard would guarantee that the intermediate and final results were always representable (`i + k` may be a large negative value, with `j` sometimes having a value that would cause this sum to overflow).

In the above case, rewriting as `((21 + i) + j) + k` would stop most optimizers from performing any reordering of the evaluation. However, if an optimizer can deduce that reordering the evaluation through parentheses would not affect the final result, it can invoke the as-if rule (on processors where signed integer arithmetic wraps and does not signal an overflow, reordering the evaluation of the expression would not cause a change of behavior). The only visible change in external behavior might be a change in program performance, or a smaller program image.

as-if rule 122

For floating-point types wrapping behavior cannot come to an optimizer's rescue (by enabling overflows to be ignored). However, some implementations may chose to consider overflow as a rare case, preferring the performance advantages in the common cases. Overflow is not the only issue that needs to be considered when operands have a floating-point type, as the following example shows:

```
1  extern double i, j, k;
2
3  void f(void)
```

```
{
double x = i + k,
       y = i + j + k;
/* ... */
}
```

assuming the objects have the following values:

```
i = 1.0E20
j = -1.0E20
k = 6.0
```

then the value that is expected to be assigned to `y` is `6.0`. Rewriting the expression as `i + k + j` would result in the value `0.0` being assigned (because of limited accuracy, adding `6.0` to `1.0E20` gives the result `1.0E20`).

Coding Guidelines

There is a guideline recommendation specifying that expressions shall be parenthesized.

943.1 expression shall be parenthesized

Use of parentheses makes the intentions of the developer clear to all. Objections raised, by developers, against the use of unnecessary parentheses are often loud and numerous. Many developers consider that use of parentheses needs to be justified on a case-by-case basis. Others take the view that there are no excuses for not knowing the precedence of all C operators and that all developers should learn them by heart. These coding guidelines accept that many developers do not know the precedence of all C operators and that exhortations to learn them will have little practical effect. Parenthesizing all binary (and some unary) operators and their associated operands is considered to be the solution (to the problem of developers' incorrect deduction of the grouping of operands within an expression). In some instances a case can be made for not using parentheses, which are discussed in the Syntax sections of the relevant operators.

943 operator precedence

As the discussion in Common Implementations showed, the use of parentheses can sometimes reduce the opportunities available to an optimizer to generate more efficient machine code. These coding guidelines consider this to be a minor consideration in the vast majority of cases, and it is not given any weight in the formulation of any guideline recommendations.

Some coding guideline documents recommend against redundant parentheses; for instance, in `((x))` the second set of parentheses serves no purpose. Occurrences of redundant parentheses are rare and there is no evidence that they have any significant impact on source code comprehension. These coding guidelines make no such recommendation.

Usage

Usage information on parentheses usage is given elsewhere.

281 parenthesized expression nesting levels

---

982 Its type and value are identical to those of the unparenthesized expression.

Commentary

But, for the use of expression rewriting by an optimizer, the generated machine code will also be identical.

Common Implementations

Some early implementations considered that parentheses 'hid' their contents from subsequent operators. This created a difference in behavior between `sizeof("0123456")` and `sizeof(("0123456"))`— one returning the **`sizeof`** of an array operand, the other the size of a pointer operand. The C Standard makes no such distinction.

729 array converted to pointer

---

983 It is an lvalue, a function designator, or a void expression if the unparenthesized expression is, respectively, an lvalue, a function designator, or a void expression.

Commentary

This means that `(a) = (f)(x)` and `a = f(x)` are equivalent constructs.

Other Languages

In many languages a function call is a primary expression, so it is not possible to parenthesize a function designator.

Forward references: declarations (6.7). 984

6.5.2 Postfix operators

postfix-expression syntax

985

```
postfix-expression:
                primary-expression
                postfix-expression [ expression ]
                postfix-expression ( argument-expression-list_opt )
                postfix-expression .  identifier
                postfix-expression -> identifier
                postfix-expression ++
                postfix-expression --
                ( type-name ) { initializer-list }
                ( type-name ) { initializer-list , }
argument-expression-list:
                assignment-expression
                argument-expression-list , assignment-expression
```

Commentary

The token pairs `[ ]` and `( )` are not commonly thought of as being operators.

C90

Support for the forms (compound literals):

```
( type-name ) { initializer-list }
( type-name ) { initializer-list , }
```

is new in C99.

C++

Support for the forms (compound literals):

```
( type-name ) { initializer-list }
( type-name ) { initializer-list , }
```

is new in C99 and is not specified in the C++ Standard.

Other Languages

Many languages do not treat the array subscript (`[]`), structure and union member accesses (`.` and `->`), or function calls (`()`) as operators. They are often included as part of the syntax (as punctuators) for primary expressions. The syntax used in C for these operators is identical or very similar to that often used by other languages containing the same construct.

Many languages support the use of comma-separated expressions within an array index expression. Each expression is used to indicate the element of a different dimension— for instance, the C form `a[i][j]` can be written as `a[i, j]`.

Some languages use parentheses, `()`, to indicate an array subscript. The rationale given for using parentheses in Ada[619] is based on the principle of *uniform referents*— a change in the method (i.e., a function call or array index) of evaluating an operand does not require a change of syntax.

Cobol uses the keyword **OF** to indicate member selection. Fortran 95 uses the **%** symbol to represent the `->` operator.

Perl allows the parentheses around the arguments in a function call to be omitted if there is a declaration of that function visible.

Common Implementations

The question of whether using the postfix or prefix form of the `++` and `--` operators results in the more efficient machine code crops up regularly in developer discussions. The answer can depend on the processor instruction set, the translator being used, and the context in which the expression occurs. It is outside the scope of this book to give minor efficiency advice, or to list all the permutations of possible code sequences that could be generated for specific operators.

Coding Guidelines

There is one set of cases where developers sometime confuse the order in which prefix operators and *unary-operators* are applied to their operand. The expression `*p++` is sometimes assumed to be equivalent to `(*p)++` rather than `*(p++)`. A similar assumption can also be seen for the postfix operator `--`. The guideline recommendation dealing with the use of parenthesis is applicable here.

1080 unary-expression syntax

Dev 943.1 A postfix-expression denoting an array subscript, function call, member access, or compound literal need not be parenthesized.

Dev 943.1 Provided the result of a postfix-expression, denoting a postfix increment or postfix decrement operation, is not operated on by a unary operator it need not be parenthesized.

Example

```
1  struct s {
2           struct s *x;
3           };
4  struct s *a,
5           *x;
6
7  void f(void)
8  {
9  a>x;
10 a->x;
11 a-->x;
12 a--->x;
13 }
```

Table 985.1: Occurrence of postfix operators having particular operand types (as a percentage of all occurrences of each operator, with **[** denoting array subscripting). Based on the translated form of this book's benchmark programs.

Operator	Type	%	Operator	Type	%
v++	**int**	54.0	**[**	**unsigned char**	5.1
v--	**int**	52.5	**[**	other-types	4.7
[	*****	38.0	**[**	**int**	4.1
v++	*****	25.7	**v++**	**unsigned long**	3.1
v--	**long**	15.9	**v--**	**unsigned short**	2.7
[	**struct**	14.5	**v--**	**unsigned char**	2.6
v++	**unsigned int**	13.3	**[**	**const char**	2.4
[	**float**	12.0	**[**	**unsigned long**	1.2
v--	**unsigned int**	11.5	**v++**	**long**	1.1
[	**union**	10.2	**[**	**unsigned int**	1.1
v--	*****	7.1	**v++**	**unsigned short**	1.0
[	**char**	6.8	**v++**	**unsigned char**	1.0
v--	**unsigned long**	6.1	**v--**	**short**	1.0

Table 985.2: Common token pairs involving `.`, `->`, `++`, or `--` (as a percentage of all occurrences of each token). Based on the visible form of the `.c` files.

Token Sequence	% Occurrence of First Token	% Occurrence of Second Token	Token Sequence	% Occurrence of First Token	% Occurrence of Second Token
identifier `->`	9.8	97.5	`v++ )`	41.4	1.4
identifier `v++`	0.9	96.9	`v++ ;`	39.9	1.4
identifier `v--`	0.1	96.1	`v++ ]`	4.6	1.3
identifier `.`	3.6	83.8	`v++ =`	7.6	0.7
`] .`	20.3	15.4	`v-- ;`	58.4	0.3
`->` identifier	100.0	10.1	`v-- )`	29.1	0.1
`.` identifier	100.0	4.2			

footnote 77

77) Thus, an undeclared identifier is a violation of the syntax. 986

Commentary

This fact was not explicitly pointed out in the C90 Standard, which led some people to believe that the behavior was undefined. The response to DR #163 specified the order in which requirements, given in the standard, needed to be read (to deduce the intended behavior).

C++

The C++ Standard does not explicitly point out this consequence.

Other Languages

Some languages regard a reference to an undeclared identifier as a violation of the language semantics that is required to be diagnosed by an implementation.

Common Implementations

Most implementations treat undeclared identifiers as primary expressions. It is during the subsequent semantic processing where the diagnostic associated with this violation is generated. The diagnostic often points out that the identifier has not been declared rather than saying anything about syntax.

6.5.2.1 Array subscripting

Constraints

subscripting

One of the expressions shall have type "pointer to object *type*", the other expression shall have integer type, and the result has type "*type*". 987

Commentary

Surprisingly there is no requirement that the pointer type be restricted to occurring as the left operand (because such a requirement invariably exists in other computer languages).

Other Languages

Most languages require that the left operand have an array type. The implicit conversion of arrays to pointers is unique to C (and C++). A few languages (e.g., Awk, Perl, and Snobol 4) support the use of strings as indexes into arrays (they are called *table*s in Snobol 4).

Coding Guidelines

Although the C Standard permits the operands to occur in any order, the pointer type nearly always appears (in source) as the left operand. Developers have not gotten into the habit of using any other operand ordering. Introductory books on C teach this operand order and many don't even mention that another order is permitted. There is nothing to be gained by specifying a particular operand order in a coding guideline; the alternative is very rarely seen.

Example

The following all conform to this requirement:

```
1   extern int arr[10];
2   extern int glob;
3
4   void f(void)
5   {
6   (glob++)[arr] = 9;
7   arr[glob-1]=10;
8   (arr+2)[3]=4["abcdefg"];
9   "abc"[2]='z';           /* Ok, undefined behavior. */
10  }
```

Semantics

988 A postfix expression followed by an expression in square brackets `[]` is a subscripted designation of an element of an array object.

Commentary

Many developers do not think of square brackets, `[]`, as being an operator. A single token would be sufficient to indicate an array subscript. However, existing practice in other languages and the advantages of the bracketing effect of using two tokens (it removes the need to use parentheses when the subscript expression is more complex than a *unary-expression*) were more important considerations.

Subscripted arrays are not as commonly seen in C source code as they are in programs written in other languages. Using pointers where arrays would be used in other languages, seems like a more natural fit in C. Among the reasons for this might be the support for pointer arithmetic available in C but not many other languages, and the automatic conversion of arrays to pointers to their first element.

1165 additive operators pointer to object

Other Languages

Many languages allow all of the subscripts in a multidimensional array access to appear within a single pair of square brackets (or parentheses for some languages), with each subscript being separated by a comma (rather like the arguments in a function call). In some languages subscripting an array is implied by the appearance of an expression to the right of an object having an array type.

1577 footnote 121

Common Implementations

Most processor instruction sets support one or more forms of addressing that is designed to handle the accessing of storage via array subscripting. In practice the *pointer-to object type* is often a value that is known at translation time (e.g., a file scope array object whose address is decided at link time). In this case the subscript value can be loaded into a register and a *register with displacement* addressing mode used (an almost universally available addressing mode).

Values contained within arrays are often accessed sequentially, one at a time. A common C practice is to assign the base address of the array to a pointer, access each element through that pointer, incrementing the pointer to move onto the next element.

```
1   #define NUM_ELEMS (20)
2
3   extern int a[NUM_ELEMS];
4
5   void f(void)
6   {
7   int *p = a;
8
9   while (p != a+NUM_ELEMS)
10     /*
```

```
11       * Do something involving:
12       *
13       *         *p
14       *
15       * p will need to be incremented before the loop goes around again.
16       */
17      ;
18
19   for (int a_index=0; a_index < NUM_ELEMS; a_index++)
20      /*
21       * Do something involving:
22       *
23       *         a[a_index]
24       */
25      ;
26   }
```

data dependency

Depending on the processor instruction set and the surrounding source code context, use of a pointer may result in more or less efficient machine code than an array access. However, looking at the code in a wider perspective, the use of pointers rather than arrays makes some optimizations significantly more difficult to implement. The problem is one of possible data dependencies— an optimizer needs to know what they are; and the analysis is significantly more difficult to perform when pointers rather than arrays are involved.

Scientific and engineering programs often spend a large amount of time within loops reading and writing array elements. Such programs tend to loop through elements of different arrays, performing some calculation involving each of them. When a processor can execute more than one instruction at the same time, finding the most efficient ordering is technically very difficult. The problem is knowing when the value read from an array element is going to be affected by the writing of a value to the same array. Knowing that there is no dependency between two accesses allows an optimizer to order them as it sees fit. (If there is a dependency, the operations must occur in the order as written.) The sequence of statements within a loop may also have been unrolled, exposing dependencies between accesses in what were different iterations. The patterns of array reference usage have been studied in an attempt to generate faster machine code. The three types of array reference patterns are:

loop unrolling 1774

Flow-dependent

```
1   for (index = 1; index < 10; index++)
2      {
3      A[index-1] = B[index];
4      C[index] = A[index];
5      }
```

Anti-dependent

```
1   for (index = 1; index < 10; index++)
2      {
3      B[index] = A[index-1];
4      A[index] = C[index];
5      }
```

Output-dependent

```
1   for (index = 1; index < 10; index++)
2      {
3      A[index-1] = B[index];
4      A[index] = C[index];
5      }
```

It is not necessary to be targeting a special-purpose parallel processor to want to try to optimize these loops. Modern processors have multiple execution integer and floating-point arithmetic units.[6, 350, 627, 1342] Keeping all units busy can result in significant performance improvements.

For the flow-dependent case: Unrolling the loop once, we see the order of execution for the assignment statements is:

Time step	Operation
t=1	A[0] = B[1]
t=2	C[1] = A[1]
t=3	A[1] = B[2]
t=4	C[2] = A[2]

Attempting to perform these two iterations in parallel, we get:

Time step	Thread 1	Thread 2
t=1	A[0] = B[1]	A[1] = B[2]
t=2	C[1] = A[1]	C[2] = A[2]

There is an assignment to `A[1]` in execution thread 2 at time *t=1* before that value is used in execution thread 1 at time *t=2*. Executing this code in parallel would cause the array element value to be given a new value before its previous value had been used. A modification to the loop, known as *preloading*, removes this flow dependency:

```
1  for (index = 1; index < 10; index++)
2     {
3     T = A[index];
4     A[index-1] = B[index];
5     C[index] = T;
6     }
```

For the anti-dependency case: Unrolling the loop once, we see the order of execution for the assignment statements is:

Time step	Operation
t=1	B[1] = A[0]
t=2	A[1] = C[1]
t=3	B[2] = A[1]
t=4	A[2] = C[2]

Attempting to perform these two iterations in parallel, we get:

Time step	Thread 1	Thread 2
t=1	B[1] = A[0]	B[2] = A[1]
t=2	A[1] = C[1]	A[2] = C[2]

Here the value assigned to `B[2]` in execution thread 2 at time *t=1* is the old value of `A[1]`, before it is updated in execution thread 1 at time *t=2*. Executing this code in parallel would cause the array element value to be given a value that is incorrect, the correct one not yet having been calculated. Reordering the sequence of assignments removes this anti-dependency:

```
1  for (index = 1; index < 10; index++)
2     {
3     A[index] = C[index];
4     B[index] = A[index-1];
5     }
```

For the output dependent case: Unrolling the loop once, we see the order of execution for the assignment statements is:

Time step	Operation
t=1	A[0] = B[1]
t=2	A[1] = C[1]
t=3	A[1] = B[2]
t=4	A[2] = C[2]

Attempting to perform these two iterations in parallel, we get:

Time step	Thread 1	Thread 2
t=1	A[0] = B[1]	A[1] = B[2]
t=2	A[1] = C[1]	A[2] = C[2]

Here the correct assignment to `A[1]` in execution thread 2 at time *t=1* is overwritten by an assignment in execution thread 2 at time *t=2*. Executing the code in parallel causes the final value of the array element to be incorrect. Reordering the sequence of assignments removes this output dependency:

```
1  for (index = 1; index < 10; index++)
2     {
3     A[index] = C[index];
4     A[index-1] = B[index];
5     }
```

It is not usually intuitively obvious if a dependency exists between elements of an array in different iterations of a loop. A number of tests based on the mathematics of number theory are known; for instance, in:

```
1  for (index = 5; index < 10; index++)
2     {
3     A[2*index - 1] = C[index];
4     B[index] = A[4*index - 7];
5     }
```

if a dependency exists, there must be values of `x` and `y` such that the element accessed in statement `S(x)` is the same as that in statement `S(y)`. For this to occur the relation $2x - 1 = 4y - 7$ must hold. This occurs when x and y equal 3, which is not within the bounds of the loop, so there is no dependency in this case.

Equations such as these, known as *Diophantine* equations, are usually written with the variable terms on the left and the constant value on the right (e.g., $4y - 2x = 6$). It is known that a solution to such an equation, in integer values, exists if and only if the greatest common divisor of the constants on the left hand side divides the constant on the right-hand side (which it does in this case). This test, known as the *GCD* test, is very simple to apply and will determine whether there is a dependency between accesses to an array. However, the problem with the GCD test is that it does not fully take advantage of the known information (the bounds of the loop). The *Banerjee* test[89] is a much more sophisticated test that is often performed (others have also been proposed).

Even with these sophisticated tests, it is still only possible to deduce whether dependencies exist for a fraction of the cases commonly seen in industrial applications.[1224] Allen and Kennedy[17] discuss data dependency in detail, specifically algorithms for optimizing the ordering of array accesses within loops (Fortran-based). For calculations involving sparse matrices, it is sometimes possible to improve performance and reduce storage overhead by mapping the representation of the nonzero array elements to another kind of data structure.[123]

Example

```
1  extern int a[3][4];
2  extern int (*p1)[];
3  extern int *p2;
4  extern int p3;
```

```
5
6   void f(void)
7   {
8   p1=a;    /* An array of array of int becomes a pointer to an array of int. */
9
10  p2=a[1]; /* Indexing exposes the array of int, which is converted to pointer to int. */
11
12  p3=a[1][2]; /* Indexing again reveals an int. */
13
14  if (a[1][2] != p2[2]) /* p2 points at the start of a[1] */
15     printf("Something wrong here\n");
16  }
```

---

989 The definition of the subscript operator **[]** is that **E1[E2]** is identical to **(*((E1)+(E2)))**.

array subscript identical to

Commentary

This explains the symmetry between the operands of the **[]** operator. In their equivalent form, operand order is irrelevant. This equivalence also highlights the point that C requires as much checking on the bounds of array subscripts by implementations as it requires on pointer differencing.

Other Languages

This equivalence relationship is unique to C (and C++).

Common Implementations

Some translators rewrite array accesses into this form in their internal representation. It reduces the number of different cases that need to be considered during code generation.

The degree to which the use of subscripted arrays or pointers affects the quality of generated machine code will depend on the sophistication of the analysis performed by a translator. Simpler translators usually generate higher-quality machine code when pointers are used. More sophisticated optimizers can make use of the information provided by a subscripted array (the name of the object being accessed) to generate higher-quality code. A study by Franke and O'Boyle[441] obtained up to 14% improvement in execution time (for several DSPstone benchmarks[1395] using the same translator) by source-to-source transformation, converting pointer accesses to explicit array accesses prior to processing by the compiler proper.

Coding Guidelines

Some guidelines documents recommend against the use of pointer arithmetic. Such a recommendation overlooks the equivalence between array subscripting and pointer arithmetic. While, it could be argued that this equivalence relationship is purely a specification detail in the C Standard, this would not correspond to how many developers think about array subscripting. This stated equivalence shows the extent to which the use of pointers, rather than arrays, are embedded within the C language. Coding guidelines that simply recommend against the use of pointer arithmetic are generally unworkable in practice. If developers are using C, guidelines need to work within the framework of that language.

---

990 Because of the conversion rules that apply to the binary + operator, if **E1** is an array object (equivalently, a pointer to the initial element of an array object) and **E2** is an integer, **E1[E2]** designates the **E2**-th element of **E1** (counting from zero).

Commentary

It is sometimes claimed that having arrays zero based results in more efficient machine code being generated. Basing the array at zero can result in a small efficiency improvement for those cases where the address of the array is not known at translation (or link) time (machine code does not need to be generated to subtract one from the index expression). However, this analysis ignores the impact of the algorithm on the index expression. Any algorithm which naturally uses an array indexed from one, requires the developer to either

adjust the index expression to make it zero-based or to ignore the zero'th element (the array will contain an unused element). Whether more algorithms are naturally one-based rather than zero-based is not known.

Given the general interchangeability of arrays and allocated storage, the only practical option is for arrays to be zero-based. Arrays based at one would require that all allocated storage also have an implied base of one. In a language supporting pointer arithmetic, nonzero based arrays and pointers would significantly complicate the generated machine code and the developer's conception of where pointers actually pointed.

```
1  void f(void)
2  {
3  char a[10];
4  char *p = a;
5
6  a[1] = 'q';
7  p[1] = 'q';
8  *p = 'q';
9  p++;
10 *p = 'q';
11 }
```

Other Languages

Some languages base their array at one (e.g., Fortran). Languages in the Algol family allow the developer to specify both the lower and upper bounds of an array. For instance, in Pascal the definition `a[4..9] :Integer;` would define an array of integers that was to be subscripted with values between four and nine, inclusive (the underlying implementation would be zero-based, the translator generating code to subtract four from the index expression).

Coding Guidelines

Off-by-one coding errors may be the most common problems associated with array subscripting. This problem seems to be generic to all programming languages, independent of whether arrays start at zero, one, or a user defined value.

Successive subscript operators designate an element of a multidimensional array object. 991

Commentary

footnote 121 1577 Just like using the structure member selection operator (`.`) to access successive members of a nested structure, the `[]` operator can be used to select successive elements of a multidimensional array. A two-dimensional array can be thought of as adjacent slices of a single dimension array. As suggested by the mathematical terminology *dimension*, an array subscript can be thought of as the coordinates of the element being accessed in the defined array object.

For an array of arrays the word *object* denotes the specific object determined directly by the pointer's type and value, not other objects related to that one by contiguity. Therefore, if an array index exceeds the declared bounds, the behavior is undefined.

```
1  void DR_017_Q16(void)
2  {
3  int a[4][5];
4
5  a[1][7] = 0; /* Undefined behavior. */
6  }
```

Other Languages

Many languages require that all subscripts be given inside one pair of `[]` brackets. Such languages do not usually treat `[]` as an operator. A few languages provide operators that enable subsets of an array's elements to be selected. For instance, the Fortran 95 array selection `B(1:4, 6:8:2, 3)` specifies the set of elements whose first subscript varies between 1 and 4, the second subscript is either 6 or 8 (the third value, 2, in the index is a stride), and the third subscript is 3.

Common Implementations

Accesses to a multidimensional array requires that the translator calculate the address of the indexed element within the array object. In:

```
1  extern int a[3][5][7];
2  extern int j,
3             k,
4             l;
5
6  void f(void)
7  {
8  int i = a[j][k][l];
9  }
```

the array reference is equivalent to `(*(a+((((j*3)+k)*5)+l)))`. The value of this expression will also need to be multiplied by `sizeof(int)` to calculate the start of the element address.

When accesses to a multidimensional array occur within a nested loop, the evaluation of the indexing expression can often be optimized. For instance, in the following:

```
1  for (j=0; j<MAX_X; j++)
2     for (k=0; k<MAX_Y; k++)
3        for (l=0; l<MAX_Z; l++)
4           a[j][k][l]=formula;
```

parts of the array index calculation are the same for each iteration of some of the loops (e.g., `j*3` has a constant value during the iteration of the two nested loops, as does `((j*3)+k)*5` during the iteration of the innermost loop). It may be worthwhile to keep one or both of these values in a register, or save either of them to a temporary storage location (which at worst is likely to be faster than loading the loop control variable and performing a multiply).

1774 loop control variable

Coding Guidelines

Accessing the elements of a multidimensional array requires additional instructions to scale the index. A technique sometimes used by developers to reduce this overhead, when accessing all the elements (e.g., to assign an initial value), is to treat the array as if it had a single dimension.

```
1  #define NUM_1 10
2  #define NUM_2 20
3
4  int a[NUM_1][NUM_2];
5
6  void init(void)
7  {
8  int *q = (int *)a;
9
10 /*
11  * Some developers prefer using pointer arithmetic here.
12  */
13 for (int index=0; index < NUM_1*NUM_2; index++)
14    q[index]=0;
15 }
```

Use of this technique can be an indicator of an unnecessary interest in efficiency by developers. The guideline recommendation dealing with use of representation information is applicable here.

569.1 representation information using

Table 991.1: Occurrence of object declarations having an array type with the given number of dimensions (as a percentage of all array types in the given scope; with local scope separated into parameters and everything else). Based on the translated form of this book's benchmark programs.

Dimensions	Parameters	Local	non-parameter
Scope	File Scope		
1	100.0	97.9	91.9
2	0.0	2.0	7.5
3	0.0	0.1	0.6

array
n-dimensional
reference

If **E** is an *n*-dimensional array (*n*≥*2*) with dimensions $i \times j \times \cdots \times k$ then **E** (used as other than an lvalue) is converted to a pointer to an (*n*-1)-dimensional array with dimensions $j \times \cdots \times k$ 992

Commentary

Because this conversion does not occur when E is used as an lvalue, it is not possible to simultaneously assign multiple array elements. For instance, in:

```
int a[10][20];
int b[20];

/*
 * The left operand has type array of int.
 * The right operand has type pointer to int.
 */
a[4]=b;
```

there is a type mismatch. It is not possible to assign all of b's elements in one assignment statement.

C++

Clause 8.3.4p7 uses the term *rank* to describe $i \times j \times \cdots \times k$, not *dimensions*.

Other Languages

In most languages arrays are never converted to a pointer to their first element. Like C++, some other languages use the term *rank*.

Coding Guidelines

The equivalence relationship between array subscripting and pointer accesses sometimes leads to developer confusion over when arrays and pointers types can be interchanged. A multidimensional array is not the same as an array of pointers or a pointer-to pointer. Both of these are common, incorrect assumptions made by inexperienced developers. In:

```
int a[10][20];
int (*q)[];
int **p;

void f(void)
{
q=a;        /* a is a pointer to int, the first element of the first row. */
p=a;        /* Incompatible types, a is not a pointer to pointer to int.  */
p=(int *)a; /* Translator is not required to issue a diagnostic here.     */
}
```

Mixing these different types will result in diagnostic messages being generated. While developers have been known to use explicit casts to stop these diagnostics from appearing, it is likely that the resulting programs will fail to work correctly and a guideline recommendation addressing this usage is not considered worthwhile.

Example

```
1  int a[10][20][30];
2
3  void f(void)
4  {
5  int (*p1)[20][30] = a;
6  int (*p2)[30] = a[0];
7  /* ... */
8  }
```

---

993 If the unary * operator is applied to this pointer explicitly, or implicitly as a result of subscripting, the result is the pointed-to (*n - 1*)-dimensional array, which itself is converted into a pointer if used as other than an lvalue.

Commentary

This process can continue for as many dimensions as there are in the array type. The last dereference yields the value of the pointed-to element (if used as other than an lvalue). The unary * operator has the same effect as subscripting the array with a zero index, `[0]`. This fact can be deduced from the definition of the subscript operator.

989 array subscript identical to

C++

*If the * operator, either explicitly or implicitly as a result of subscripting, is applied to this pointer, the result is the pointed-to ($n-1$)-dimensional array, which itself is immediately converted into a pointer.* 8.3.4p7

While the C++ Standard does not require the result to be used "as other than an lvalue" for it to be converted to a pointer. This difference does not result in any differences for the constructs available in C.

Coding Guidelines

While, technically, the forms * and `[0]` are interchangeable in many contexts, developers rarely think of them as such. For instance, many developers do not seem to separate out the components of an array definition as being both an allocation of storage and a creation of a reference to it (the array name). Are there any costs or benefits of only using the array subscript operator, **[]**, for operands having an array type and only the unary * operator for operands having a pointer type? Are there any costs or benefits of using one of these operators for both cases? The following are some of the issues:

- The notation `*a` is visually more compact than `a[0]`, while `a[index]` is shorter than `*(a+index)`.
- The unary * occurs much more frequently in C source code than the array subscript operator. It is possible that developers will be more practiced in the use of this form.
- In many contexts arrays are implicitly converted to pointers and arguments are always passed by value (not address). Less developer effort is needed to structure source code that uses pointers rather than arrays (which require decisions to be made on the number of elements to be specified in their declarations).

Example

Taking the example from the previous sentence, we have:

```
1  int a[10][20][30];
2
3  void f(void)
```

```
4  {
5  int (*p1)[30] = *a;
6  int (*p2) = *a[0];
7  /* ... */
8  }
```

array
row-major storage order

It follows from this that arrays are stored in row-major order (last subscript varies fastest). 994

Commentary

That is, the following equalities hold: `&a[i][j+1] == (&a[i][j]+1)` and `&a[i+1][j] == &a[i][j]+(sizeof(a[i][j]))`. Figure 994.1 illustrates the difference between row and column major storage layouts.

Figure 994.2 illustrates the difference in data structures used to represent the following two initialized object definitions in storage:

```
1  char day_arr[][10] = {
2                        "Monday", "Tuesday", "Wednesday", "Thursday", "Friday",
3                        "Saturday", "Sunday"
4                        };
5  char *day_ptr[] =  {
6                     "Monday", "Tuesday", "Wednesday", "Thursday", "Friday",
7                     "Saturday", "Sunday"
8                     };
```

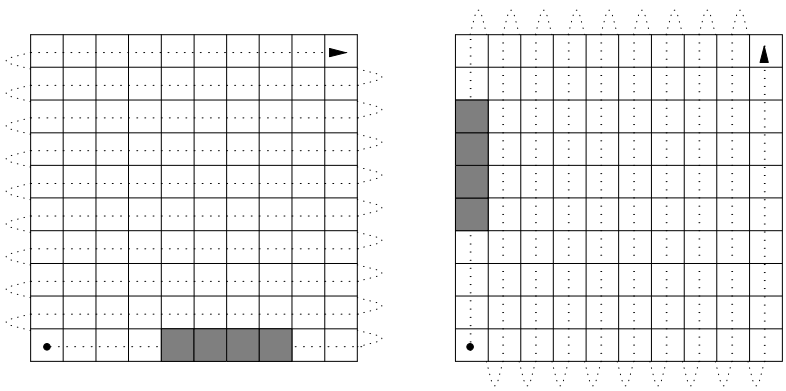

Figure 994.1: Row (left) and column (right) major order. The dotted line indicates successively increasing addresses for the two kinds of storage layouts, with the gray boxes denoting the same sequence of index values.

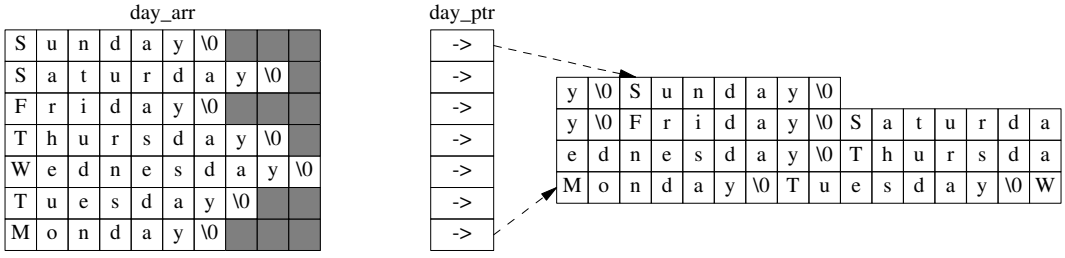

Figure 994.2: Difference in storage layout between an array of array of characters (left) and array of pointer to characters (right; not all pointers shown and the relative storage locations of the strings is only one of many that are possible).

The order in which array elements are organized can have significant performance implications. Processors use caches because their designers are aware that many data accesses exhibit spatial locality. If array elements are accessed in the order they are held in storage, maximum advantage can be taken of any available processor cache. The conditions under which the order of array element access might have an effect on program performance are discussed in the Common implementation section that follows. 0 cache

Other Languages

Some languages store arrays in column-major order (the first subscript varies the fastest). The most well-known being Fortran. One of the first things that developers of scientific and engineering applications, using Fortran, are told about is the importance of nesting loops to maintain spatial locality of reference.

Common Implementations

A processor's storage hierarchy can include a paged memory management system and often a cache. The performance of both of these can be affected by the order in which array elements are accessed. 0 cache

In a paged memory management system the amount of storage available for use by programs is usually greater than physically available. Memory is divided up into pages, usually 4 K or 8 K chunks, the less frequently used pages being swapped out to large, lower-cost storage (most often a hard disk). A large array can occupy many pages. Accessing noncontiguous array elements can require different pages needing to be in memory for each access. This can significantly impact performance because a swapped-out page consumes a lot of resources being swapped back into memory. Accessing elements in a contiguous order can significantly reduce the amount of paging activity.

A processor cache is usually structured to hold lines of data from memory. Each cache line holds a fixed number of bytes, usually some small power of 2 (but invariably larger than any scalar type). A load from an address will result in a complete cache line being fetched if the data at that address is not already in the cache. Accesses to sequential locations in storage can often be satisfied from data already in the cache.

```
1  #define INNER 1000
2  #define OUTER 2000
3
4  extern int a[INNER][OUTER];
5
6  void f(void)
7  {
8  /*
9   * This loop could execute more quickly than the one below
10  */
11 for (int i=0; i < INNER; i++)
12    {
13    /*
14     * Each access will be adjacent, in storage, to the previous one.
15     */
16    for (int j = 0; j < OUTER; j++)
17       a[i][j]+=1;
18    }
19
20 for (int j=0; j < OUTER; j++)
21    {
22    /*
23     * Each access will be disjoint, in storage, to the previous one.
24     */
25    for (int i = 0; i < INNER; i++)
26       a[i][j]+=1;
27    }
28 }
```

The preceding example illustrates spatial locality. A program's use of arrays can also show temporal locality. In the following example (function g), each element of the array c is accessed in the inner loop. If the number

of bytes in the array c is greater than the total size of the cache, then on the next iteration of the outer loop the values from the first elements will not be in the cache. Loading these values will cause other elements' values of c to be flushed from the cache.

A performance-driven solution is to introduce a nested loop. This loop iterates over a smaller range of values, sufficiently small that all the elements fit within the cache. This transform is known as *strip-mine and interchange* and is one of a family of so-called *cache blocking* transforms. Function h shows such a rewritten form of the calculation in function g. For optimal performance, the program needs to take account of the processor cache size.

```
1  #define INNER 1000
2  #define OUTER 2000
3  #define STRIP_WIDTH 32
4
5  extern int b[OUTER],
6             c[INNER];
7
8  void g(void)
9  {
10 for (int i=0; i < OUTER; i++)
11    for (int j = 0; j < INNER; j++)
12       b[i] += c[j];
13 }
14
15 void h(void)
16 {
17 for (int j = 0; j < INNER; j+=STRIP_WIDTH)
18    for (int i=0; i < OUTER; i++)
19       for (int k=j; k < MIN(INNER, j+STRIP_WIDTH-1); k++)
20          b[i] += c[k];
21 }
```

When the calculation within the loop involves both one- and two-dimensional arrays, the order of loop nesting can depend on how the arrays are indexed. The following code gives an example where the two outer loops are in the opposite order suggested by spatial locality, but temporal locality is the dominant factor here.

```
1  #define INNER 1000
2  #define OUTER 2000
3  #define STRIP_WIDTH 32
4
5  extern int b[OUTER],
6             c[INNER][OUTER];
7
8  void h(void)
9  {
10 /*
11  * for (int i=0; i < INNER; i++)
12  *    for (int j = 0; j < OUTER; j++)
13  *       b[j] += c[i][j];
14  *
15  * is transformed in to the following:
16  */
17 for (int j = 0; j < OUTER; j+=STRIP_WIDTH)
18    for (int i=0; i < INNER; i++)
19       for (int k=j; k < MIN(OUTER, j+STRIP_WIDTH-1); k++)
20          b[k] += c[i][k];
21 }
```

An extensive discussion of the issues involved in taking account of the cache, when ordering array accesses within loops is given in Chapter 9 of Allen and Kennedy.[17]

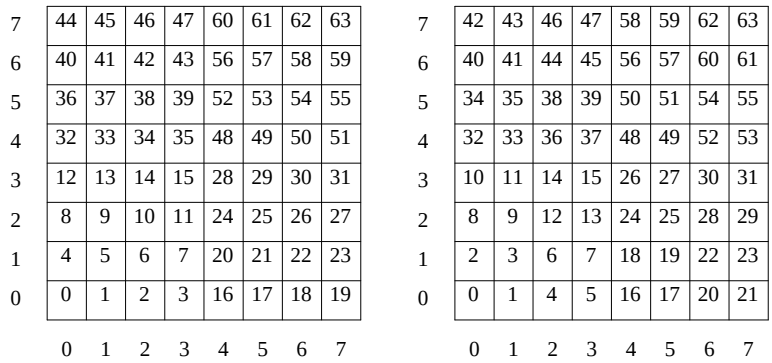

Figure 994.3: Two possible element layouts of an $8 * 8$ array; Blocked row-major layout (left) and Morton element layout (right). Factors such as efficiency of array index calculation, whether array size can be made a power of two, or array shape (e.g., non-square) drive layout selection.[1348]

Provided a multi-dimensional array is accessed through indexing (i.e., not via a pointer whose value has been explicitly calculated) an implementation can use any algorithm it chooses to layout elements in storage. One such algorithm is Morton layout,[1474] which has the advantage that element access performance is independent of whether the elements are accessed in row-major or column-major order, see Table 994.1.

Table 994.1: Cache hit-rate for sequentially accessing, in row-major order, a two-dimensional array stored using various layout methods. If the same array is accessed in column-major order the figures given in the Row-major and Column-major columns are swapped and the Morton layout figure remains unchanged. These figures ignore the impact that accessing other objects might have on cache behavior, and so denote the best hit-rate that can be achieved. Based on Thiyagalingam et al.[1349]

Cache size	Row-major	Morton	Column-major
32 byte cache line	75%	50%	0%
128 cache byte	93.75%	75%	0%
8K byte cache page	99.9%	96.875%	0%

Coding Guidelines

As the preceding discussion in Common implementations showed, the optimal nesting of loops is not always obvious. If all of the elements of a multidimensional array are to be accessed, some choice has to be made about the order in which the associated loops are nested. There is no evidence to suggest that always using the same ordering, rather than say varying the ordering, can lead to a worthwhile reduction in the cost of comprehending source. The use of multidimensional arrays is rarely seen outside of applications that perform some kind of numerical analysis, where developers are often willing to invest effort in tuning performance (and these coding guidelines are not intended to provide efficiency recommendations).

---

995 EXAMPLE Consider the array object defined by the declaration

```
int x[3][5];
```

Here **x** is a 3 × 5 array of **int**s; more precisely, **x** is an array of three element objects, each of which is an array of five **int**s. In the expression **x[i]**, which is equivalent to **(*((x)+(i)))**, **x** is first converted to a pointer to the initial array of five **int**s. Then **i** is adjusted according to the type of **x**, which conceptually entails multiplying **i** by the size of the object to which the pointer points, namely an array of five **int** objects. The results are added and indirection is applied to yield an array of five **int**s. When used in the expression **x[i][j]**, that array is in turn converted to a pointer to the first of the **int**s, so **x[i][j]** yields an **int**.

---

996 **Forward references:** additive operators (6.5.6), address and indirection operators (6.5.3.2), array declarators (6.7.5.2).

6.5.2.2 Function calls

Constraints

function call

The expression that denotes the called function[78)] shall have type pointer to function returning **void** or returning an object type other than an array type. 997

Commentary

function designator converted to type

An occurrence of a function designator in an expression is automatically converted to pointer-to function type.

function declarator return type identifier is primary expression if

A declaration of a function returning an array type is a constraint violation. Since identifiers denoting functions must be declared before they are referenced, the restriction on the object type being other than an array type is superfluous. Declaring a function to return a structure or union type, which contains a member having an array type, is sometimes used to get around the constraint on returning arrays from functions.

C++

5.2.2p3 *This type shall be a complete object type, a reference type or the type* ***void****.*

Source developed using a C++ translator may contain functions returning an array type.

Other Languages

Many languages usually distinguish between a *function* that has a return type and a *procedure* (or *subroutine*), which has no return type (they do not have an explicit **void** type). Some languages restrict functions to returning scalar types, while others allow functions to return any types, including function and array types.

function call arguments agree with parameters

If the expression that denotes the called function has a type that includes a prototype, the number of arguments shall agree with the number of parameters. 998

Commentary

That is, the prototype is visible at the point of call. It is not enough for it simply to exist in some translated file.

C++

C++ requires that all function definitions include a prototype.

5.2.2p6 *A function can be declared to accept fewer arguments (by declaring default arguments (8.3.6)) or more arguments (by using the ellipsis, . . . 8.3.5) than the number of parameters in the function definition (8.4). [Note: this implies that, except where the ellipsis (. . .) is used, a parameter is available for each argument.]*

A called function in C++, whose definition uses the syntax specified in standard C, has the same restrictions placed on it by the C++ Standard as those in C.

Other Languages

Those languages that support some form of function declaration that includes parameter information, often require that the number of arguments in the call agree with the declaration. Some languages (e.g., C++ and Ada) support default values for parameters. In these cases it is possible to omit arguments from the function call.

Coding Guidelines

function declaration use prototype 1810.1

If the guideline recommendation specifying use of function prototypes is followed, all called functions will have a prototype in scope.

argument type may be assigned

Each argument shall have a type such that its value may be assigned to an object with the unqualified version of the type of its corresponding parameter. 999

Commentary

The assignment of the argument value to the parameter is similar to an initializer for an object definition. The qualifier is ignored. It only has meaning inside the body of the function that defines the parameter list. Developers sometimes use the term *assignment compatible*, however, the standard does not define this term.

1649 initializer initial value

C++

The C++ language permits multiple definitions of functions having the same name. The process of selecting which function to call requires that a list of viable functions be created. Being a viable function requires:

> *. . . , there shall exist for each argument an implicit conversion sequence that converts that argument to the corresponding parameter . . .* 13.3.2p3

A C source file containing a call that did not meet this criteria would cause a C++ implementation to issue a diagnostic (probably complaining about there not being a visible function declaration that matched the type of the call).

Other Languages

Other languages that contain some kind of type qualifier usually have a rule similar to C.

Semantics

1000 A postfix expression followed by parentheses `()` containing a possibly empty, comma-separated list of expressions is a function call.

operator ()

Commentary

Many developers do not think of `()` as an operator. In theory, a single token would be sufficient to indicate a function call (and the same for the `[]` operator). However, existing practice in other languages, and the bracketing effect of using two tokens (it removes the need to use parentheses in those cases where there is more than one parameter), were more important considerations.

An identifier having pointer-to function type that is not followed by parentheses returns the value of the pointer. No function is called.

The first step in improving the execution time of a program is often to measure how much time is spent in each function. Such measurements may or may not include the time spent in any functions that are themselves called by each function (some tools try to provide an estimate of the amount of time spent in any nested calls). Such measurements provide no context information; for instance, the time spent in function `D` may differ between the call chains `A`⇒`B`⇒`D` and `X`⇒`Y`⇒`D`. Call path refinement[535] provides measurements for each set of call paths. The amount of information gathered is much greater and more detailed, but it does allow special cases to be detected (which could then be appropriately specialized), such as the different call paths to `D`.

Understanding the relationship between functions in terms of which one calls, or is called, by another one provides a useful means of comprehending the structure of a program. A call graph is a practical way of displaying this calling/called information. The term *call graph* is usually taken to mean the static call graph. Information on the calls is obtained without executing the program. (Tools that build dynamic call graphs also exist.)

call graph

The C language contains two features that complicate the building of a call graph— a preprocessor and the ability to assign functions and later call them via the object assigned to.

The preprocessor is sometimes used to hide implementation details, such as calls to system libraries, that developers are not expected to be aware of, treating the macro invocation as if it were a function call. At other times a macro is used for efficiency reasons, and any function calls in its body are likely to be of interest to the developer. The preprocessor can also be used to provide conditional compilation. A function call may appear in the program image if certain macros are defined during translation. This raises the question of whether a call graph should only include function calls that are visible in the unpreprocessed source code, or

should it only include function calls that appear in the token stream after preprocessing, or some combination of the two?

When a function is called through an object, having a pointer-to function type, the number of functions that could possibly be called is likely to be greater than one. Depending on the sophistication of the call graph analysis tool, it might show all functions having the pointed-to type of the object, all functions assigned to the object, or those functions that could possibly be pointed to at a given call site (although a recent study[933] was able to obtain some precise results on some of the GNU tools, using relatively inexpensive analysis).

An empirical study of static call graph tools by Murphy, Notkin, Griswold, and Lan[981,982] found that the call graphs they built were all different (in the set of called functions they each created). All tools individually listed called-functions that were not listed as called by any of the other tools, no call graph being a proper subset of another. One tool looked at the source code prior to preprocessing, one tool extracted information from program images that had been built with debugging information switched on, and the other tools operating in various in other ways.

C90

The C90 Standard included the requirement:

> *If the expression that precedes the parenthesized argument list in a function call consists solely of an identifier, and if no declaration is visible for this identifier, the identifier is implicitly declared exactly as if, in the innermost block containing the function call, the declaration*
>
> *extern int identifier();*
>
> *appeared.*

A C99 implementation will not perform implicit function declarations.

Other Languages

The use of `()` as the symbol, or operator, indicating a function call is widely used in computer languages. In some languages function calls are implicitly indicated by the type of an identifier and the context in which it occurs; use of `()` are not necessary. Other languages (e.g., Fortran) require the keyword **`call`** to appear before subroutine calls, but not before function calls that appear in an expression. In Lisp the name of the function being called appears as the first expression inside the parentheses. In functional languages it is even possible to invoke a function with an incomplete list of arguments, resulting in the partial evaluation of the called function. A few languages (e.g., ML) allow the function name to appear as an infix operator.

There is a standard for procedure calling: ISO/IEC 13886:1996 *Information technology— Language Independent Procedure Calling (LIPC)*. Quoting from the Introduction: "The purpose of this International Standard is to provide a common model for language standards for the concept of procedure calling.".

Common Implementations

Implementation limits 804

The Implementation limits clause does not specify any minimum requirements on the depth of nested function calls. On most implementations the maximum function-call depth is set by the amount of storage available for the stack to grow into. Some processors have dedicated call stacks and the maximum nesting depth can be as low as 20.[1128]

As processors have continued to evolve, the techniques for calling functions have come full circle. They started out simple, got very complex, and RISC brought them back to being simple (now they are starting to get complicated again). The complex processor instructions of the late 1970s and 1980s tried to perform all of the housekeeping actions associated with a function call. In practice, compiler writers often found it difficult to map the language semantics onto these complex instructions.[1000.1] In many cases it was possible to use alternative instructions that executed more quickly. (Some profiling studies showed that the complex instructions were rarely, if ever, encountered during program execution[1232,1460]). The RISC approach

[1000.1] Measurements of assembly language usage by developers[292] has found that they use a subset of the instructions available to them.

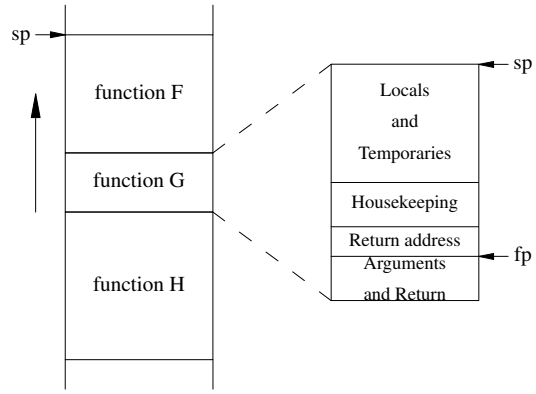

Figure 1000.1: Common storage organization of a function call stack.

simplified everything, going back to very basic support for function calls (which is what low cost processors had been doing all the time, the resources needed to implement complex instructions being too costly).

The minimum requirement for a function-call machine code instruction is that it alters the flow of control (so that the processor starts executing the instructions of the called function), and that there is a mechanism for returning to the instructions after the call (so that execution can resume where it left off).

Processors use a variety of techniques for saving the return address. Some push it onto a stack or a specified storage location (the caller takes responsibility for saving the value); others load it into a register (the called function takes responsibility for saving it). The requirement to call functions recursively restricts the possible mechanisms that can be used to save the return address. An analysis by Miller and Rozas[940] showed that allocating storage on a stack to hold information associated with function calls was more time efficient than allocating it on the heap (even when the cost of garbage collection was minimal).

1026 function call recursive

In most implementations the housekeeping needed to store the arguments is performed in the function performing the call, and the housekeeping needed to allocate storage for locals is handled by the called function. A very common implementation technique is to use a function-call stack, each function call taking storage from this stack to satisfy its requirements, when called, and freeing it up on return. Because function calls properly nest, all operations are performed on the current top of stack.

The address of the start of the stack storage for a function is known as its *frame pointer*. It is often held in a register and a *register + offset* addressing mode is used to access parameters and local objects. The *register + offset* addressing mode is not usually supported by DSP processors,[623] whose only indirect addressing modes are sometimes only pre-/postincrement/decrement of an address register performed as part of a storage access. A number of techniques have been proposed to optimize the generated machine code for processors having these following addressing mode characteristics:

register + offset

- Emulating the *register + offset* addressing mode by using a frame pointer and arithmetic operations to create the address of the object is one possibility[857] (using a peephole optimizer on the resulting code).
- Using a floating frame pointer, arranging the ordering of objects in storage to maximize the likelihood that adjacent accesses in the generated code will be adjacent-locations in storage (so that an increment/decrement will create an address ready for the next access).[375]
- Using algebraic transformations on expression trees to obtain the least cost of access sequence.[1144]
- Genetic algorithms have been proposed[842] as a general solution to the problem. (They are capable of adapting to the different numbers of addressing registers and the different autoincrement ranges available on different processors.)

Another technique is for translators to make use of the characteristics of the applications written for these processors; for instance, recursion is almost unknown, and allocating fixed-storage locations for local objects is often feasible. By building a call graph at link-time, linkers can deduce dependencies between calls and overlay storage for objects, defined in functions, whose functions are not simultaneously active.

The functional programming style of implementing algorithms creates a particular kind of function-call optimization[99] known as *tail calls*. Here the last statement executed in a function is a call to another function (a call to the same function is known as *tail recursion*). Such a recursive call can be replaced by a branch instruction to the start of the function that contains it. This tail recursion optimization idea can be extended to handle calls to other functions, as long as they occur as the last statement executed in a function. A call to another function can be replaced by a branch instruction (it may also be necessary to adjust the stack allocation for the amount of local storage). This optimization saves the creation of a new stack frame by reusing the existing one and can be worthwhile in target environments that have limited storage capacity.

Maintaining a general-purpose stack is an overhead that is not needed for some applications. Vendors of processors designed for use in freestanding environments have come up with a number of alternatives. For instance, the Microchip PIC 18CXX2 processor[931] call instruction pushes the return address onto a dedicated, 31-entry stack. Once this stack is full, the setting of the STVREN (stack overflow reset enable) flag determines the behavior; the processor will either reset or the current top of stack is overwritten with the latest return address. The STKFUL bit will have been set after entry 31 is used, allowing software to detect the pending problem.

One of the methods used by software viruses to gain control of a program is to overwrite a function's stack frame; for instance, changing the return address to point at malicious code that has been copied into some area of storage. A number of techniques to prevent such attacks have been proposed.[294, 443, 1463]

There is often a significant difference in performance overhead between function calls that involve system calls (i.e., calls into the host operating system, such as `fread`, and `fwrite`) and other calls (a factor of 20 has been reported[1137]). Merging multiple system calls into a single call can produce performance improvements.[1137]

Coding Guidelines

cognitive 0 switch

An occurrence of the `()` operator is likely to cause the reader to make at least one cognitive task switch. In some cases (e.g., a call to one of the trigonometric functions) readers may be able to immediately associate a return value with the call and its argument. In more complex cases, readers may have to put some thought into how the arguments passed will affect the return result. They may also need to take into account the fact that the call causes the values of some objects to be modified. There is nothing that can be done at the point of call to reduce the cognitive effort needed for these tasks.

The conditional `if (f)` is sometimes written when `if (f())` had been intended. However, this usage is a fault and these coding guidelines are not intended to recommend against the use of constructs that are obviously faults.

guidelines 0 not faults

sequential nesting ()

macro 1933 function-like

The nesting of function calls (i.e., the result of one function call being used as the argument to another function call) raises a comprehension issue. In (which uses function-like macros to reduce the volume of code):

```
1  struct TREE_NODE {
2                    int data;
3                    struct TREE_NODE *left,
4                                     *right;
5                   };
6
7  #define LEFT_NODE(branch) ((branch)->left)
8  #define RIGHT_NODE(branch) ((branch)->right)
9
10 extern struct TREE_NODE *root;
11
12 void f(void)
```

```
{
struct TREE_NODE *leaf;

leaf = LEFT_NODE(RIGHT_NODE(LEFT_NODE(root))).data;
}
```

the expression has to effectively be read from the inside out (given that arguments occur to the right of the function name, the direction of reading is right-to-left). Studies have found that people have difficulty interpreting sentences containing more than two levels of nesting, for instance, "The mouse the cat the dog chased bit died." Speakers of natural language have the same limitations as their listeners, so don't produce such sentences. However, when writing, people do not have to deal with the constraints of realtime communications and consequently tend to write more complex sentences. Writers of source code rarely consider the issue of comprehension by future readers.

1707 statement syntax

Although there are often many ways of phrasing the same natural language sentence ("the mouse died which was bitten by the cat which the dog chased"), the C language rarely offers such flexibility at the expression level. One option is to break an expression into two parts; for instance:

```
left_right = RIGHT_NODE(LEFT_NODE(root));
leaf = LEFT_NODE(left_right).data;
```

An important issue to consider when breaking up an expression into separate components is the application semantics associated with each component. The identifier `left_right` suggests an implementation detail, not a semantic association (the issue of identifier name semantics is discussed elsewhere).

792 Identifier semantic usability

While nested function calls may have a high-comprehension cost, there is no evidence to suggest that in general a guideline recommendation limiting the depth of nesting (and therefore requiring additional code to be written elsewhere) will have a worthwhile benefit (by any reduction in the required cognitive effort in this one case being greater than any increase in effort that occurs elsewhere). Similar human comprehension cost issues affect other operators.

1031 member selection
1095 sequential nesting *

Example

```
typedef int (*p_f)(int);

extern p_f f(float);

void g(void)
{
int loc = f(1.0)(2);
}
```

Usage

How frequent are function calls? The machine code instructions used to call a function may be generated by translators for reasons other than a function call in the source code. Some operators may be implemented via a call to an internal system library routine; for instance, floating-point operations on processors that do not support such operators in hardware. Such usage will vary between processors (see Figure 0.5).

Table 1000.1: Static count of number of calls: to functions defined within the same source file as the call, not defined in the file containing the call, and made via pointers-to functions. Parenthesized numbers are the corresponding dynamic count. Adapted from Chang, Mahlke, Chen, and Hwu.[216]

1001 The postfix expression denotes the called function.

Commentary

The symmetry seen in the `[]` operator does not also apply in the case of the `()` operator. The left operand always denotes the called function.

989 array subscript identical to

An analysis by Zhang and Ryder[1509] found that, for programs using only a single level of pointer-to function indirection (the simplest kind of pointers), statically determining the possible called functions at a call site is NP-hard.

Other Languages

Many languages do not support pointers to functions. For these languages the postfix expression is required to be an identifier.

Coding Guidelines

When the postfix expression is not an identifier denoting the name of a function but an object having a pointer-to function type it can be difficult to deduce which function is being is called. The possibility that the value has been cast from a different pointer-to function type complicates matters even more. Some coding guideline documents adopt a simple solution to the problem of knowing which function is actually being called. They ban the use of nonconstant function pointers.

If the use of nonconstant function pointers is prohibited, what are the alternative constructs available to developers? A sequence of *selection-statement*s could be used to select the function that is to be called. These alternatives do simplify the task of deducing the set of functions that could be called. However, they also potentially increase the effort needed to maintain the source. If any of the functions called changes, it could be necessary to edit more than one location in the source code. (All the **if** statements or **switch** statements referencing the changed function will need to be looked at, unless it is possible to locate the sequence of **if** statements, or **switch** statements in a macro, or inline function.)

1526 inline function

Declaring an array of pointers, initialized with function pointers, creates a single maintenance point in the source.

While use of nonconstant pointers to functions may increase the cognitive effort needed to comprehend source code, the use of alternative constructs could not be said to reduce the effort, and could increase it.

Example

```
1  extern int f_1(void);
2  extern int f_2(void);
3
4  extern int (* const p_f[])(void) = { f_1, f_2 };
5
6  void g(void)
7  {
8  p_f[0]();
9  }
```

Table 1001.1: Static count of functions defined, library functions called, direct and indirect calls to them and number of functions that had their addresses taken in SPECint95. Adapted from Cheng.[222]

Benchmark	Lines Code	Functions Defined	Library Functions	Direct Calls	Indirect Calls	& Function

The list of expressions specifies the arguments to the function. 1002

Commentary

This defines what the arguments to a C function are.

Usage

function call 289 number of arguments

Usage information on the number of arguments in calls to functions is given elsewhere.

An argument may be an expression of any object type. 1003

Commentary

If the visible function declaration does not include a prototype, this sentence makes passing an argument having an incomplete type undefined behavior. The case where a function prototype is in scope is covered by an earlier constraint.

argument 999 type may be assigned

Only object types have values and a value is needed to assign to the parameter.

Other Languages

Some languages support the use of labels as arguments. While others, particularly functional languages, support the use of types as arguments.

Common Implementations

The undefined behavior of most translators, on encountering an argument that does not have an object type in a call to a function whose declaration does not include a prototype, is to issue a diagnostic. The base document did not support the passing of structure or union types as parameters; a pointer to them had to be passed.

base document 1

Usage

Information on parameter types is given elsewhere (see Table 1831.1).

Table 1003.1: Occurrence of various argument types in calls to functions (as a percentage of argument types in all calls). Based on the translated form of this book's benchmark programs.

Type	%	Type	%
`struct *`	26.8	`void *`	4.0
`int`	16.5	`union *`	3.4
`const char *`	9.7	`unsigned char`	2.5
`char *`	8.4	`enum`	2.1
other-types	8.0	`unsigned short`	1.9
`unsigned int`	7.1	`const void *`	1.8
`unsigned long`	6.3	`long`	1.4

1004 In preparing for the call to a function, the arguments are evaluated, and each parameter is assigned the value of the corresponding argument.[79)]

function call preparing for

Commentary

This form of argument-passing is known as *call by value*. The standard does not specify any order for the evaluation of the arguments.

1025 function call sequence point

In some cases there may not be a parameter to assign the argument to. C supports the passing of variable numbers of arguments in a function call. The C90 Standard introduced the variable arguments mechanism for accessing the values of these arguments. Prior to the publication of C90, a variety of implementation-specific techniques were used by developers. These techniques relied on knowing the argument-passing conventions (which invariably involved taking the address of a parameter and incrementing, or decrementing, walking through the stack to access any additional arguments).

C++

The C++ Standard treats parameters as declarations that are initialized with the argument values:

> *When a function is called, each parameter (8.3.5) shall be initialized (8.5, 12.8, 12.1) with its corresponding argument.* 5.2.2p4

The behavior is different for arguments having a class type:

> *A class object can be copied in two ways, by initialization (12.1, 8.5), including for function argument passing (5.2.2) and for function value return (6.6.3), and by assignment (5.17).* 12.8p1

This difference has no effect if a program is written using only the constructs available in C (structure and union types are defined by C++ to be class types).

Other Languages

Many languages support a form of argument-passing known as *call by reference*. Here the address of the argument is passed and become the address through which parameter accesses occur. Inside the called function the parameters have the same type as the arguments; they are not pointers to that type. An assignment to the parameter stores the value into the corresponding object passed as the argument. The parameter is effectively an alias for the argument.

A similar, but slightly different, argument-passing mechanism is in/out passing. Here the argument value is copied into the parameter, but modifications to the parameter do not immediately affect the value of the object used as the argument. Just before the function (or procedure) returns, the current value of the parameter is copied into the corresponding object argument. In this case the parameters are not aliases of the corresponding argument objects, but values can still be passed back to the calling function.

Java passes arguments that have primitive type (the C arithmetic type) by value. Arguments having any other type are passed by reference.

Some languages do not (e.g., Haskell, Miranda, sometimes Lisp, Scheme) evaluate the arguments to a function before it is called. They are only evaluated on an as-needed basis, inside the called function, when they are accessed. Such a mechanism is known as *lazy*, or *normal-order evaluation*.

Algol 60 used what is known as *call by name* argument-passing. When this language was designed, developers were familiar with the use of assembly language macros. The arguments to these macros were expanded out in the body of the macro, just like the C preprocessor. The designers of Algol 60 decided that arguments to functions should have the same semantics. Algol 68, and other languages derived from Algol 60, did not duplicate this design decision.

Some languages (e.g., Ada, C++, and Fortran 90) support *named* parameters. Here the name of the parameter appears in the argument list to the left of the argument value. By using names it is possible to list the arguments in any order rather than relying on a default order implicit in the function definition.

Ichbiah, Barnes, Firth, and Woodger[619] discuss the rationale behind the selection of argument-passing mechanisms in Ada.

Common Implementations

One of the simplest, and commonly seen, techniques is to push arguments onto the stack used to hold the function return address and local object definitions. The addresses of each parameter in the called function are the stack locations holding the corresponding argument.

Different methods of passing arguments are seen on different processors and in different operating systems (Johnson[675] discusses the original thinking behind the C calling sequence). In a hosted environment there are usually strong commercial incentives for all translator vendors to use the same conventions (it enables calls to libraries written using different translators and languages to be intermixed). Since the early 1990s it has become common practice for processor vendors to publish a document called an ABI (Applications Binary Interface).[613, 1345–1347, 1517] One of the details specified by this document are the argument-passing conventions.

Calling conventions can also depend on how functions are defined. Functions defined using prototypes and the static storage class are good candidates for aggressive optimization of their calling sequence. Because they are not externally visible, the translator does not have to worry about calls where the prototype might not be visible. In the case of functions that are externally visible, translators have to play safe and follow documented calling conventions (unless using a link-time optimizer[985]).

The IAR PICmicro compiler[612] supports the **__bankN_func** specifier (where N is a decimal literal denoting particular storage banks), which can be used by developers to indicate, to the translator, which storage bank should be used to pass arguments in calls to functions (defined using this specifier).

function call 289
number of arguments

Analysis of function calls shows that it is rare for many arguments to be passed. This usage suggests the optimization of passing the first few arguments in registers and pushing any subsequent arguments onto the stack. In practice this is an optimization, which at first sight looks very simple, but turns out to be potentially very complex and sometimes not even an optimization at all. For instance, if the called function itself calls a function, the contents of the reserved registers need to be saved before the new arguments for the call are loaded into them.

register
function call
housekeeping

There is one task that needs to be performed, before performing a function call, that the standard does not mention. The contents of registers holding values that will be used after the call returns need to be saved. Implementations tend to adopt one of two strategies for saving these registers— caller saves registers (it only needs to save the ones that contain values that are accessed after the call returns) or callee saves registers (it only needs to save the registers it knows it modifies). Caller saves is commonly seen. An analysis by Davidson and Whalley[327] compared various methods and concluded that a hybrid scheme was often the best. It has been proposed that processors include an instruction that, when executed, tells the processor that the contents of a particular register will not be read again before another value is loaded, so called *dead value* information.[899] An overall performance increase of 5% is claimed from not having to save/restore values across function calls or process context switches.

In the 1990s researchers started to investigate link-time optimizations. The linker has information on register usage available to it, by function, across all translation units; thus, it is possible to work out exactly, not make worst-case assumptions, which registers need to be saved and restored. Measurements from one such tool[985] showed context-sensitive interprocedural register liveness analysis reducing the total number of load instructions performed during program execution by 2.5% to 5% (the context-insensitive figure was 2.5–3%).

Processor vendors have also attempted to design instructions that reduce the overhead associated with saving register contents. Some CISC processors[284] include call instructions which automatically save the contents of some registers. An alternative processor architectural technique, adopted by Sun in their SPARC architecture[1450] and more recently by Intel in the Itanium processor family,[1139] is to use overlapping register windows. Here the processor supports a large internal register file (often 128 or more registers) of which a subset (usually 32, the *register window*) are available to the program. Execution of a *call* instruction

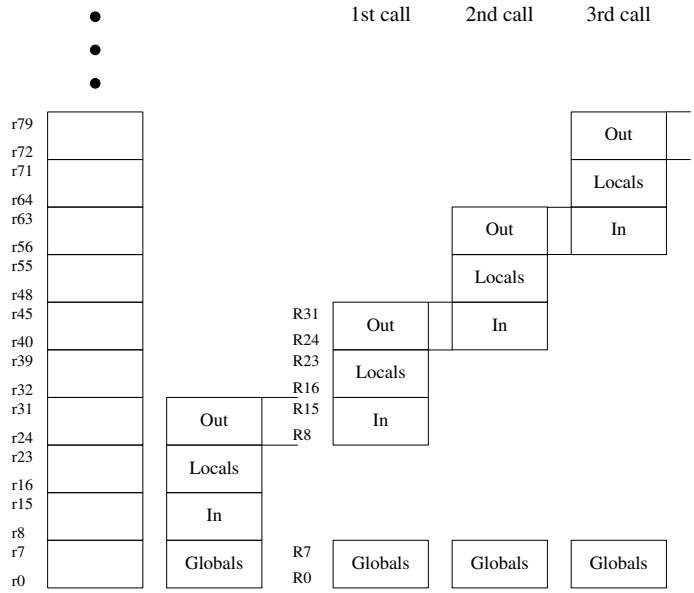

Figure 1004.1: A processor's register file (on the left) and a mapping to register windows for registers accessible to a program, after 0, 1, 2, and 3 *call* instructions have been executed. The mapping of the first eight registers is not affected by the *call* instruction.

causes the register window to slide up the internal register file such that, for instance, 16 *new* registers become available and 16 registers contents are *saved* (instructions always refer to registers numbered between 0 and 31, in the case of registers numbered between 8 and 31 the actual internal register referenced depends on the current depth of call instructions). Up to eight arguments in the *output* registers become available in the called function via its parameters in the *input* registers (see Figure 1004.1). Executing a return instruction slides the register window back, making the previous register contents available again. If there are sufficient nested call instructions the register file fills up and some of its contents have to be spilled to storage (a time consuming process). The performance advantage of registers windows comes from typical program behavior, where call depth does not vary a great deal during program execution (i.e., register file contents rarely have to be spilled and reloaded from storage). The optimal size of register window to use involves trade-offs among several hardware design factors.[461]

1005 If the expression that denotes the called function has type pointer to function returning an object type, the function call expression has the same type as that object type, and has the value determined as specified in 6.8.6.4.

Commentary

This defines the type of the function call expression (to which the **( )** operator is applied) and the type of its value (created by the evaluation of an expression appearing in a **return** statement in the called function's body).

C90

A rather embarrassing omission from the original C90 Standard was the specification of the type of a function call. This oversight was rectified by the response to DR #017q37.

C++

Because C++ allows multiple function definitions having the same name, the wording of the return type is based on the type of function chosen to be called, not on the type of the expression that calls it.

The type of the function call expression is the return type of the statically chosen function . . .

Other Languages

Some languages use the convention that a function call always returns a value, while procedure (or subroutine) calls never return a value.

Common Implementations

Although not explicitly specified in the C90 Standard, all implementations effectively used the above definition (and did not regard the omission of a definition in the standard as implying undefined behavior).

Table 1005.1: Occurrence of various return types in calls to functions (as a percentage of the return types of all function calls). Based on the translated form of this book's benchmark programs.

Type	%	Type	%
`void`	35.8	`union *`	3.2
`int`	30.5	`unsigned long`	3.1
`struct *`	9.1	`char *`	3.1
`void *`	6.3	`unsigned int`	2.1
other-types	5.2	`char`	1.6

Otherwise, the function call has type **`void`**. 1006

Commentary

In this case it has no value.

C++

C++ also supports functions returning reference types. This functionality is not available in C.

---

function result attempt to modify

If an attempt is made to modify the result of a function call or to access it after the next sequence point, the behavior is undefined. 1007

Commentary

The result referred to here is any actual storage returned by the function call. This situation can only occur if the function return type is a structure or union type (see Examples that follow).

C90

This sentence did not appear in the C90 Standard and had to be added to the C99 Standard because of a change in the definition of the term lvalue. lvalue 721

C++

The C++ definition of lvalue is the same as that given in the C90 Standard, however, it also includes the wording:

5.2.2p10 *A function call is an lvalue if and only if the result type is a reference.*

In C++ it is possible to modify an object through a reference type returned as the result of a function call. Reference types are not available in C.

Common Implementations

The implementation of functions that return a structure or union type usually involves the use of, translator allocated, temporary storage. This storage is usually allocated in the stack frame of the calling function and passed to the called function as an additional, hidden from the developer, argument. The C Standard only requires that the lifetime of the temporary storage used to hold the return value exist until the next sequence point after the return. Reuse of any part of this temporary storage by developers (e.g., to hold other temporary values) could overwrite any previous contents.

Coding Guidelines

By continuing to access the result of a function call, developers are relying on undefined behavior for what is essentially an efficiency issue (they are manipulating the returned result directly rather than assigning it to a declared object). However, on the basis that occurrences of this usage are likely to be rare, a guideline recommendation is not considered cost effective.

Example

In the following the temporary used to hold the value returned by `f` may, or may not be used for other purposes after the function has returned.

```
1  struct S {
2            int m1;
3            unsigned char m2[10];
4           };
5
6  extern struct S f(void);
7
8  void g(void)
9  {
10 int *pi = &(f().m1); /* Get hold of the address of part of the result. */
11 unsigned char uc_1,
12               uc_2;
13
14 *pi = 11; /* Undefined behavior. */
15
16 /*
17  * In the following there is a sequence point after the comma operator.
18  */
19 uc_1 = f().m2[uc_2=0, 2]; /* Also undefined, and probably surprising to readers. */
20
21 /*
22  * Depending on the unspecified order of evaluation, the
23  * following may also be undefined.
24  */
25 uc_1 = f().m2[f().m1];
26 }
```

1008 If the expression that denotes the called function has a type that does not include a prototype, the integer promotions are performed on each argument, and arguments that have type **float** are promoted to **double**.

called function no prototype

Commentary

This sentence applies when an old-style function declaration is visible at the point of call. If no prototype is visible, there is no information on the expected type of the argument available to the translator. On many processors the minimum-size object that can be pushed onto the stack (the most common argument-passing mechanism) has type **int**. The integer promotion rules for arguments match how their value is likely to be passed to the function, even if they had a type whose size was smaller than **int**. This behavior also matches the case where an argument expression contains operators, causing the integer promotions to be performed on the operands.

485 int natural size

A consequence of performing the integer promotions on arguments is that the translator needs to generate matching machine code for accessing the parameters in the called function. It is possible that it may need to implicitly convert a value back to its original type.

1011 function definition ends with ellipsis

The conversion of real type **float** to **double** does not apply to complex types. The following wording was added to the Rationale by the response to DR #206:

Rationale

float _Complex is a new type with C99. It has no need to preserve promotions needed by pre-ANSI-C. It does not break existing code.

C++

In C++ all functions must be defined with a type that includes a prototype.

A C source file that contains calls to functions that are declared without prototypes will be ill-formed in C++.

Other Languages

Most languages do not contain multiple integer types. Those languages that do contain multiple floating-point types do not usually specify that arguments having these types need be converted prior to the call.

Coding Guidelines

function declaration use prototype 1810.1

If the guideline recommendation specifying use of function prototype declarations is followed the integer promotions will not be performed.

---

default argument promotions

These are called the *default argument promotions*. 1009

Commentary

integer promotions 675

This defines the term *default argument promotions*. They are a superset of the integer promotions in that they also promote the type **float** to **double**.

C++

The C++ Standard always requires a function prototype to be in scope at the point of call. However, it also needs to define default argument promotions (Clause 5.2.2p7) for use with arguments corresponding to the ellipsis notation.

Coding Guidelines

The term *argument promotions*, or the *arguments are promoted*, are commonly used by developers. There is no obvious benefit in investing effort in changing this existing usage.

---

arguments same number as parameters

If the number of arguments does not equal the number of parameters, the behavior is undefined. 1010

Commentary

Prior to the C90 Standard no prototypes using the ellipsis notation were available. However, developers still expected to be able to pass variable numbers of arguments to functions. The C Committee added the ellipsis notation for passing variable numbers of arguments to functions. However, the Committee could not make it a constraint violation for the number of arguments passed to disagree with the number of parameters in a nonprototype function definition. It would have invalidated a large body of existing source code.

Other Languages

Most languages require that the number of arguments agree with the number of parameters. Some classes of languages (e.g., functional) are specifically intended to support function invocations where fewer arguments than parameters are passed.

Common Implementations

Passing the incorrect number of parameters is both a common mistake, a programming technique that continues to be used by some developers, and something that occurs within long-existent source code. Being able to handle this case is usually seen as commercially essential for an implementation.

If the argument-passing conventions are such that the leftmost argument is nearest the top of the stack (if the stack grows down it will have the lowest address, if the stack grows up it will have the highest address), then the address of a particular parameter in the called function does not have a dependency on the number of arguments given in the call. The address of the parameter is known at translation time and can be accessed by indexing off the stack pointer (or the frame pointer, if the implementation uses one, see Figure 1000.1).

There are a number of implementation techniques for passing arguments to functions. These techniques all rely, to some degree, on the caller performing some of the housekeeping. As well as assigning arguments to parameters, this housekeeping also usually includes popping them off the stack when the called function returns (assuming this is the argument-passing convention used).

Coding Guidelines

Given the guideline recommendation dealing with the use of function prototypes this situation is only likely to occur when developers are modifying existing code that does not use function prototypes. Mismatches between the number and types of arguments in function calls, when no prototype is visible, and the corresponding function definition are a very common source of programming error (experience shows that once developers who use the non-prototype form are introduced to the benefits of using prototypes, they rarely want to switch back to using the non-prototype form). These mismatches are not required to be diagnosed by a translator if no prototype is visible at the point of call.

1810.1 function declaration use prototype

46 undefined behavior

Developers do not usually provide the incorrect number of arguments in a function call on purpose (an existing developer practice is to call the Unix system function `open` with 2 or 3 arguments depending on the value of the second). A guideline recommending that the expected number of arguments always be passed serves no purpose. The solution to the underlying problem is to use prototypes. The extent to which it is cost effective to modify existing code to use prototypes is discussed elsewhere.

1810 prototypes cost/benefit

1011 If the function is defined with a type that includes a prototype, and either the prototype ends with an ellipsis (`, ...`) or the types of the arguments after promotion are not compatible with the types of the parameters, the behavior is undefined.

function definition ends with ellipsis

Commentary

This C sentence applies when calling a function, defined using a prototype, when an old-style declaration (not the prototype) is visible at the point of call.

When translating a function whose definition uses a prototype an implementation knows the types of the parameters and can make use of this information. In particular it need not implicitly convert a reference to a parameter that does not have a type that is the same as its promoted type. It may also choose to assign different storage addresses to such parameters, when declared with and without the use of prototype notation.

1019 function call prototype visible

There are advantages to requiring implementations to make sure this case is well defined. (It would enable developers to slowly migrate their source code over to using prototypes, changing definitions to use prototypes, and eventually getting around to ensuring that a prototype is visible from all calls to that function.) The disadvantage of such an approach is that it would have tied implementations to backward compatibility, removing the possibility of most of the optimizations that prototypes enable translators to perform.

The occurrence of an ellipsis in a function's definition does not automatically require an implementation to guarantee that all calls to that function have well-defined behavior. In some implementations the argument/parameter mechanism used when a function is defined using ellipsis is completely different from when an ellipsis is not used. If, at the point of call, it is not known that the function definition contains an ellipsis (because no prototype is visible), the generated code may be incorrect.

Other Languages

Most languages either specify that some form of prototype declarations always be used, or do not provide any mechanism for specifying the types of parameters. However, it is not uncommon for a language to evolve into supporting both kinds of function definition (provided it originally supported the nonprototype form only). For instance, the ability to declare subroutines taking arguments was added in release 5.003 of Perl.

Common Implementations

There are two commonly seen cases: (1) the parameter has an integer type whose rank is less than that of **`int`**; (2) the type of the argument, after promotion, is not compatible with the parameter type. It is not uncommon for implementations to give unexpected results when reading a parameter having a character type in a function defined using a prototype, when that function has been called in a context where no prototype

is visible. In some cases the machine code generated by a translator for the called function, accesses the value of the parameter using an instruction that reads more than eight bits (the typical number of bits in a character type). The assumption being made by the translator is that at the point of call the argument will have been converted to the character type, bringing it into the representable range of that type (the typical implementation behavior for all character types). If no prototype is visible at the point of call, this conversion will not have occurred, and it is possible for a value outside of the representable range of a character type to be assigned to the parameter.

Assuming that arguments are passed by pushing values onto a stack, the number of bytes pushed onto the stack will depend on the number of bytes in the promoted argument type. If the types **int** and **long**, for instance, have the same size, then mixing their usage in arguments is likely to have no surprising results. However, if these two types have different sizes, it is likely that after an argument having the other type is evaluated, any subsequent arguments (which will depend on the order of evaluation) will be pushed at addresses that are different from where their corresponding parameters expect them to be.

Coding Guidelines

function declaration use prototype 1810.1

If a function is defined using a prototype, the only reason for not having this prototype visible at the point of call is that the translator being used does not support prototypes (i.e., it is different from the one that translated the function definition). The guideline recommendation dealing with the use of function prototypes is applicable here.

Example

The handling of parameters inside a function definition can be different from when a prototype is used than when it is not used. In:

file_1.c

```
int f_np(a, b)
signed char a;
int b;
/*
 * Function body assumes that any call will perform the default argument
 * promotions.  So it will insert casts, where necessary, on parameters.
 */
{
return a + b;
}

int f_pr(signed char a, int b)
/*
 * Function body assumes that a prototype is visible at the point of call.
 * Hence the arguments will have been cast at the point of call.  So there
 * is no need to insert an implicit conversion on any parameter reference.
```

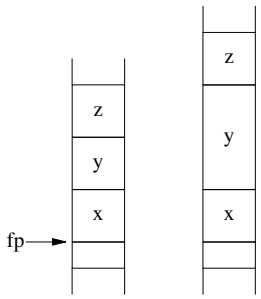

Figure 1011.1: An example of the impact, on relative stack addresses, of passing an argument having a type that occupies more storage than the declared parameter type. For instance, the offset of z, relative to the frame pointer *fp*, might be changed by passing an argument having a type different from the declared type of the parameter y (this can occur when there is no visible prototype at the point of call to cause the type of the argument to be converted).

```
 */
{
return a + b;
}
```

file_2.c

```
extern int f_np();
extern int f_pr();

extern signed char sc;
extern int i;
extern int glob;

int g(void)
{
glob = f_np(sc, i);
glob = f_pr(sc, i);
}
```

at the call to `f_np` there is no visible information on the function parameter types. If there had been, the first argument would have been cast to type **`signed char`**.

So what is the value of the parameter `a` inside the function `f_pr`? No implicit conversion need occur. If machine code to load one byte is generated by the translator, the value will only ever be in the range of the type **`signed char`**. However, if the generated code loads a larger unit of storage, it may be quicker to load a word, making the assumption that the top bits are all zero rather than to load a byte and zeroing the top bits. In the load word case the possible range of values is that of type **`int`**, not **`signed char`**.

1012 If the function is defined with a type that does not include a prototype, and the types of the arguments after promotion are not compatible with those of the parameters after promotion, the behavior is undefined, except for the following cases:

argument in call incompatible with function definition

Commentary

The rationale for this compatibility requirement is the same as that for the prototype case (the only difference is that the compatibility check is against the promoted type of the parameter). The call and definition need to agree on how the type of the argument affects how and where values are passed to the called function.

1011 function definition ends with ellipsis

C90

The C90 Standard did not include any exceptions.

C++

All functions must be defined with a type that includes a prototype.

A C source file that contains calls to functions that are declared without prototypes will be ill-formed in C++.

Common Implementations

The undefined behavior for these cases of all known C90 implementations is as defined in C99.

Coding Guidelines

Passing an argument having the incorrect type is a fault and these coding guidelines are not intended to recommend against the use of constructs that are obviously faults. The two cases listed in the following C sentences are intended to codify practices that are relatively common in existing code, not for use in newly written code. Adhering to the guideline recommendation on using function prototypes enables translators to implicitly perform any necessary conversion or to issue a diagnostic is none is available.

0 guidelines not faults

1810.1 function declaration use prototype

Example

Here both the function definition and the point of call must agree on how they treat the type of the argument. In the following:

file_1.c
```
#include <stdio.h>

void f(a)
short a;
{
printf("a=%d\n", a);
}
```

file_2.c
```
extern void f();

void g(void)
{
f(10);  /* First call. */
f(10L); /* Second call. */
}
```

the argument passed in the first call to `f` is compatible with the promoted type of the parameter in the definition of `f`. In the second call the argument is not compatible, even though the value is representable in the promoted parameter type (and also the unpromoted parameter type).

---

footnote 78

78) Most often, this is the result of converting an identifier that is a function designator. 1013

Commentary

A self-evident, to experienced developers, piece of information is carried over from the C99 document.

C++

The C++ language provides a mechanism for operators to be overloaded by developer-defined functions, creating an additional mechanism through which functions may be called. Although this mechanism is commonly discussed in textbooks, your author suspects that in practice it does not account for many function calls in C++ source code.

Other Languages

This statement is true in most programming languages.

Common Implementations

The implicit conversion of a function designator to a pointer-to function is optimized away by most implementations, generating a machine code instruction to perform a function call to a known (at link-time) address.

Usage

In most programs an identifier is converted in more than 99% of cases, although a lower percentage is occasionally seen (see Table 1001.1).

---

footnote 79

79) A function may change the values of its parameters, but these changes cannot affect the values of the arguments. 1014

Commentary

operator () 1000

The storage used for parameters is specific to the function invocation. The final value of a parameter is never copied back to the corresponding argument. The storage used for parameters is released when the invocation of the function, that defines, them returns.

C++

The C++ reference type provides a call by address mechanism. A change to a parameter declared to have such a type will immediately modify the value of its corresponding argument.

This C behavior also holds in C++ for all of the types specified by the C Standard.

Other Languages

In languages that support various forms of argument passing (e.g., call by value, call by reference, or **OUT** style parameters) changes to the value of a parameter may or may not affect the value of the argument, or may be a violation of the language semantics (e.g., parameters defined using **IN** in Ada).

1004 function call preparing for

Coding Guidelines

Some coding guideline documents do not permit parameters to be modified within the function definition. They are considered to be read-only objects. The rationale for such a guideline often draws parallels with other languages, where a modification of a parameter also modifies the corresponding argument. Should a set of C coding guidelines take into account the behavior seen in other languages, and if so, which others languages need to be considered? Would a guideline recommendation against modifying parameters reduce or increase faults in programs? would it reduce or increase the effort needed to comprehend a function? Are the alternatives more costly than the original problem, if there is one? Without even being able to start answering these questions, there is no point in attempting to create a guideline recommendation.

1015 On the other hand, it is possible to pass a pointer to an object, and the function may change the value of the object pointed to.

Commentary

Parameters can have any object type (which include pointer types). Assigning the value of an argument, having a pointer type, to a parameter, having a pointer type, has the same effective semantics as assigning any pointer value to an object. Both pointers point at the same object. A modification of the value of the pointed-to object through either pointer reference will be visible via the other pointer reference.

C++

This possibility is not explicitly discussed in the C++ Standard, which supports an easier to use mechanism for modifying arguments, reference types.

Other Languages

This statement is generally true in languages that support pointers. In some languages (e.g., function languages) it is never possible to have two pointers (or references as they are usually known) to the same object. An assignment, or argument, would cause the pointed-to object to be copied. The pointer assigned would then point at a different object that had the same value.

Coding Guidelines

One of the issues overlooked by coding guideline documents which recommend against the use of pointers, is that argument-passing in C uses pass by value. If pointers cannot be used, the only way for a function to pass information back to its caller is via a returned value, or by modifying file scope objects. The alternatives could be worse than what they are replacing.

Usage

Pointer types are the most commonly occurring kind of parameter type (see Table 1831.1).

1016 A parameter declared to have array or function type is adjusted to have a pointer type as described in 6.9.1.

Commentary

This adjustment is made to the types of the parameters in a function definition. The arguments are similarly adjusted.

1821 function definition syntax
729 array converted to pointer
732 function designator converted to type

Coding Guidelines

The benefit of defining parameters using array types rather than the equivalent pointer type comes from the additional information provided (the expected number of elements) to tools that analyze source code (enabling them to potentially be more effective in detecting likely coding faults). There is new functionality in C99 that allows developers to specify a lower bound on the number of elements in the object passed as an argument and to specify that after conversion, the pointer rather than the pointed-to object is qualified.

1599 function declarator static

— one promoted type is a signed integer type, the other promoted type is the corresponding unsigned integer type, and the value is representable in both types; 1017

Commentary

Many argument expressions are integer constants, often having type **signed int**. A requirement that all such arguments be explicitly cast, or contain a suffix, in those cases where the corresponding parameter has type **unsigned int** was considered onerous. This exception allows unsuffixed integer constants to be used as arguments where the corresponding parameter has type **unsigned int**.

This exception requires that the rank of the signed and unsigned integer types be the same. It does not provide an exception for the case where an integer constant argument has a different type from the corresponding parameter type, but is representable in the parameter type. There are two requirements specified elsewhere that ensure implementations meet this requirement: (1) identical values of corresponding signed/unsigned integer types, and (2) storage and alignments requirement.

signed 486
integer
corresponding
unsigned integer
footnote 509
31

Other Languages

Most languages do not contain both signed and unsigned integer types.

Coding Guidelines

Most integer constants that appear in source code have small positive values (98% of decimal literals and 88% of hexadecimal literals are less than 32,768) of type **signed int** (only 2% of constants are suffixed). In these cases there is no obvious benefit to using a cast/suffix when the corresponding parameter has an unsigned type. For other kinds of arguments, more information on the cost/benefit of explicit casts/suffixes for arguments is needed before it is possible to estimate whether any guideline recommendation is worthwhile.

integer 825
constant
usage

Example

In the following values of type **unsigned int** and **int** are passed as arguments. Prior to C99, the C90 Standard specified that this was undefined behavior.

```
1  extern unsigned int ui;
2
3  extern void f();
4
5  void g(void)
6  {
7  f(ui);
8  f(22);
9  }
```

— both types are pointers to qualified or unqualified versions of a character type or **void**. 1018

Commentary

Requiring that arguments having type pointer-to unqualified character type be explicitly cast to the parameter type (to remove an undefined behavior that another part of the standard specifies, although not normatively) was regarded as being excessive. A commonly used argument of type pointer-to unqualified character type is a string literal. Some functions in the C library have parameters whose type is `const char *`. A large amount of existing code uses the pre-C Standard definition of these functions, which does not include the **const** qualifier.

footnote 565
39
Normative 18
references

Other Languages

Some languages have generic pointer types that can be passed as arguments where the corresponding parameter type is a pointer to some other type.

Coding Guidelines

What kind of pointer argument types and pointer parameter types, in an old-style function definition, are likely to occur in existing code? It is unlikely that parameters having a pointer type will be qualified (these were introduced into C at the same as prototypes), and they are probably more likely to be pointers to character type than pointer to **void**. The only constant pointer type is the null pointer constant, whose type is not under developer control. If this exception case is invoked, the argument type is likely to either have a pointer-to qualified type or be a pointer to **void**.

More information on the cost/benefit of explicit casts, for arguments, is needed before it is possible to evaluate whether any guideline recommendation is worthwhile.

1019 If the expression that denotes the called function has a type that does include a prototype, the arguments are implicitly converted, as if by assignment, to the types of the corresponding parameters, taking the type of each parameter to be the unqualified version of its declared type.

function call prototype visible

Commentary

When a prototype is visible, argument conversion occurs at the point of call. (For functions defined without a prototype, parameters are converted inside the function definition.) A constraint requires that the conversion path exist. The implicit conversion rules, for assignment, simply specify that the value being assigned is converted to the object assigned to. There are constraints that ensure that this conversion is possible.

1011 function definition ends with ellipsis
999 argument type may be assigned
1303 simple assignment

C90

The wording that specifies the use of the unqualified version of the parameter type was added by the response to DR #101.

C++

The C++ Standard specifies argument-passing in terms of initialization. For the types available in C, the effects are the same.

> *When a function is called, each parameter (8.3.5) shall be initialized (8.5, 12.8, 12.1) with its corresponding argument.* 5.2.2p4

Other Languages

This is how call by value is usually specified to work in languages that support some form of function prototypes.

Common Implementations

Passing an argument is not always the same as performing an assignment. In the case of arguments, the storage used to pass the value may be larger than the type being passed because of alignment requirements. For instance, arguments may always be passed in storage units that start at an even address. If characters occupy 8 bits, the unused portion of the parameter storage unit may need to be set to zero.

Coding Guidelines

The issues involved in any implicit conversion of arguments are the same as those that apply in other contexts.

653 operand convert automatically

1020 The ellipsis notation in a function prototype declarator causes argument type conversion to stop after the last declared parameter.

Commentary

Type conversion does not stop; as such, there are no available parameter types to convert to. However, the standard does specify another rule that may cause argument type conversions (see following C sentence).

C++

There is no concept of starting and stopping, as such, argument conversion in C++.

Other Languages

Common Lisp supports functions taking a variable number of arguments. However, it uses dynamic typing and it is not necessary to perform type checking and conversion during translation.

Common Implementations

Some implementations treat the arguments corresponding to the ellipsis notation differently from other arguments. The ellipsis notation makes it very difficult to specify, in advance, optimal passing conventions for those arguments. Some implementations put the arguments corresponding to the ellipsis notation in a dedicated block of storage that makes them easy to access using the `va_*` macros. Other implementations simply push these arguments onto the stack, along with all other arguments.

The default argument promotions are performed on trailing arguments. 1021

Commentary

default argument promotions called function no prototype 1009 1008

The rationale for performing the default argument promotions on trailing arguments is the same as that for performing them on arguments of calls to functions where no prototype is visible. There is also the added benefit of simplifying the implementation of the `va_*` macros by permitting them to assume that these promotions have occurred; for instance, an implementation can rely on an object having type **`short`** having been converted to type **`int`** when passed as a trailing argument. These macros are specified to have undefined behavior if one of their arguments has a type that is not compatible with its promoted type.

Coding Guidelines

Some developers incorrectly assume that because a prototype is visible the arguments corresponding to the ellipsis notation are passed as is; that is, no implicit conversions are applied to them at the point of call (this assumption only leads to a fault is a certain combinations of events occur). Other than developer training, there is no obvious worthwhile guideline recommendation.

Example

```
1  extern unsigned char uc;
2
3  extern void f(int, char, float, ...);
4
5  void g(void)
6  {
7  f(1, uc, 1.2F, 99, 3.4F);
8  f(1, uc, 1.2F, 5.6, 'w', 0x61, 'y');
9  }
```

No other conversions are performed implicitly; 1022

Commentary

This C sentence specifies what happens when there is no function prototype in scope at the point of call.

C++

In C++ it is possible for definitions written by a developer to cause implicit conversions. Such conversions can be applied to function arguments. C source code, given as input to a C++ translator, cannot contain any such constructs.

Common Implementations

base document 1

The base document required that arguments having a structure or union type be converted to pointers to those types. This conversion was performed because the passing of arguments having structure or union types was not supported. It was assumed that, if an argument had such a type, a pointer to it had been intended and the translator implicitly took its address.

1023 in particular, the number and types of arguments are not compared with those of the parameters in a function definition that does not include a function prototype declarator.

Commentary

No comparison occurs even if the function definition, that does not use a prototype, is contained in the same source file as the call and occurs lexically before it in that file. The number and types of arguments are only compared with those of the parameters in a function definition if it uses a prototype and occurs lexically prior to the call in the same source file. In all other cases it is the visible declaration that controls what checks are made on the arguments in the call. The C Standard does not require any cross-translation unit checks against function definitions.

C++

All function definitions must include a function prototype in C++.

Other Languages

This behavior is common in languages that do not have a construct similar to a function prototype declarator. Without any parameter information to check against, there is little that implementations can do. The behavior for the case where a function call appears in the source textually before a definition of the function occurs varies between languages. Some (e.g., Algol 68) require that argument and corresponding parameter types be compared, which requires the implementation to operate in two passes, while others (e.g., Fortran) have no such requirement.

Common Implementations

Translators and static analysis tools sometimes perform checks on the arguments to functions that have been defined using the old-style definition. This checking can include the following:

- *Comparing the number and type of arguments against the corresponding parameters.* This can be done if the called function is defined in the same source file as the call, or by performing cross translation unit checks during translation phase 8.
- *Comparing the types of the arguments in different calls to the same function.* Often more than one call to the same function is made from the same source file. Flagging differences in argument types between these different calls provides a consistency check, although it will not detect differences between argument types and their corresponding parameter types.

1024 If the function is defined with a type that is not compatible with the type (of the expression) pointed to by the expression that denotes the called function, the behavior is undefined.

function call not compatible with definition

Commentary

766 pointer to function converted 1611 function compatible types

For this situation to occur either a pointer-to function type has to be explicitly cast to an incompatible pointer to function type, or the declaration visible at the point of call is not compatible with the function definition it refers to. A cast could occur at the point of call, or when a function designator is assigned to a pointer-to function type.

Note: Calling a function, where the visible declaration does not include a prototype, with a particular set of argument types does not affect the type pointed to by the expression that denotes the called function (there is no creation of a composite type).

C++

In C++ is it possible for there to be multiple definitions of functions having the same name and different types. The process of selecting which function to call requires that a list of viable functions be created (it is possible that this selection process will not return any matching function).

It is possible that source developed using a C++ translator may contain pointer-to function conversions that happen to be permitted in C++, but have undefined behavior in C.

Common Implementations

Implementations usually treat such a call like any other. They generate machine code to evaluate the arguments and perform the function call. Unexpected behavior is likely to occur if the argument types differ from the corresponding parameter types and the two types have different sizes.

Differences in the return type can result in unexpected behavior, depending on the implementation technique used to handle function return values. In some implementations the return value, from a function, is passed back in a specific register. A difference in function return type can result in the value being passed back in a different register (or a storage location). Other implementations pass the return value back to the caller on the stack. A difference in the number of bytes actually occupied by the return value and the number of bytes it is expected to occupy can result in a corrupt stack (which often holds function return addresses) leading to completely unpredictable program behavior.

stack 449

Coding Guidelines

Intentionally calling a function defined with a type that is not compatible with the pointed-to function type, visible at the point of call, is at best relying on an implementation's undefined behavior being predictable (for argument-passing and values being returned). This usage may deliver different results if the source is translated using different implementations, or even different versions of the same implementation. If this usage occurs within existing code, it potentially ties any retranslation of that source to the translator originally used.

There is a programming technique that relies on the arguments in a function call depending on the context in which they occur. For instance, an array of pointers to function may have elements pointing at more than one function type.

```
1  extern int f0(), f2(), f4();
2  extern int f1(), f3();
3
4  int (*(a[5]))() = {f0, f1, f2, f3, f4};
5
6  void g(int p)
7  {
8  if (p % 2)
9     a[p](1, 2);
10 else
11    a[p](1);
12 }
```

ellipsis 1601
supplies no information
identifier 422.1
declared in one file
identifier 422.2
with extern linkage
reference shall #include

An alternative technique that does not rely on implementation-defined behavior is to declare the various `f` functions and the array element type using a function prototype that contains an ellipsis. Adhering to the guideline recommendations on defining an external declaration in one source file, which is visible at the point where its corresponding function is defined prevents a visible function declaration from being incompatible with its definition.

---

function call sequence point

The order of evaluation of the function designator, the actual arguments, and subexpressions within the actual arguments is unspecified, but there is a sequence point before the actual call. 1025

Commentary

The sequence point before the call guarantees that any side effects in the evaluation of the arguments, or the function designator, will have occurred prior to the call. When a value is returned, there is also a sequence point immediately before the called function returns.

return expression 1719
sequence point

C++

5.2.2p8

All side effects of argument expression evaluations take effect before the function is entered.

While the requirements in the C++ Standard might appear to be a subset of the requirements in the C Standard, they are effectively equivalent. The C Standard does not require that the evaluation of any other operands, which may occur in the expression containing the function call, have occurred prior to the call and the C++ Standard does not prohibit them from occurring.

Other Languages

A few languages do specify an evaluation order for the arguments in a function call; for instance, Java specifies a left-to-right order.

Common Implementations

Most implementations evaluate the arguments in the order that they are pushed onto the call stack, with the function designator evaluated last (this behavior usually minimizes the amount of temporary storage needed for argument evaluation). The most common order for pushing arguments onto the call stack implies a right-to-left evaluation order. Using this order makes it possible to pass variable numbers of arguments, the address of the last argument (the rightmost one in the argument list) in a call to a function may not be known when its definition is translated. However, the address of the first argument, in the argument list, can always be made the same relative to the frame pointer of the called function by pushing it last (see Figure 1000.1). By being pushed last the value of the first argument is always closest to the local storage, and successive arguments further way.

Coding Guidelines

This unspecified behavior is a special case of an issue covered by a guideline recommendation. Function calls are sometimes mapped to function-like macro invocations. In this case an argument that contains side effects may be evaluated more than once (in the body of the macro replacement). This issue is discussed elsewhere.

187.1 sequence points
all orderings give same value
1939 macro
arguments separated by comma

Example

```
1  #include <stdio.h>
2
3  int glob = 0;
4
5  int f(int value, int *ptr_to_value)
6  {
7  if (value != *ptr_to_value)
8     printf("first argument evaluated before assigned to glob\n");
9  if (value == *ptr_to_value)
10    {
11    printf("value == pointer to value\n");
12    /*
13     * Between the previous equality test and here glob may
14     * have been assigned the value 1 (in main).  Let's check...
15     */
16    if (value != *ptr_to_value)
17       printf("value != pointer to value\n");
18    }
19 return 1;
20 }
21
22 int main(void)
23 {
24 (glob = 1) + f(glob, &glob);
25 }
```

function call recursive

Recursive function calls shall be permitted, both directly and indirectly through any chain of other functions. 1026

Commentary

object 272 storage outside function image

This is a requirement on the implementation. It is supported by a restriction on where storage for objects can be allocated. The standard does not specify any minimum limit on the depth of nested function calls that an implementation must support.

Other Languages

Some languages do not require implementations to support recursive function calls. Fortran (prior to Fortran 90) and some dialects of Basic do not support recursive calls (although some implementations of Fortran did allow recursion). Some languages (e.g., Fortran 90, and later PL/1 and CHILL) require that functions called recursively be declared using the keyword **`recursive`**.

Common Implementations

The implication of this requirement is that objects defined locally within each function definition must be allocated storage outside of the sequence of machine instructions implementing a function.

Recursive function calls are rare in most applications. Some implementations make use of this observation to improve the quality of generated machine code. The default behavior of the implementation being to assume that a program contains no recursive function calls. If a function is not called recursively, it is not necessary for the implementation to allocate storage for its local objects every time it is called— storage for these local objects could be allocated in a global area at a known, fixed address; these addresses can be calculated at link-time using the program's call tree to deduce which function lifetimes are mutually exclusive. Objects local to a set of functions whose lifetimes are mutually exclusive, can be overlaid with each other, minimizing the total amount of storage that is required.

Removing the need to support recursion removes the need to maintain a stack of return addresses. One alternative sometimes used is to store a function's return address within its executable code (ensuring that the surrounding instructions jump around this location).

Coding Guidelines

Many coding guideline documents ban recursive function calls on the basis that their use makes it impossible to calculate, statically, a program's maximum storage and execution requirements. (This is actually an overstatement; the analysis is simply very difficult and only recently formalized.[128, 129]) However, in some mathematical applications, recursion often occurs naturally and sometimes requires less effort to comprehend than a nonrecursive algorithm. Also, recursive algorithms are often easier to mathematically prove properties about than their equivalent iterative formulations.

Rather than provide a guideline recommendation and matching deviation, these coding guideline subsections leaves it to individual projects to handle this special case, if necessary.

EXAMPLE In the function call 1027

```
(*pf[f1()]) (f2(), f3() + f4())
```

the functions **`f1`**, **`f2`**, **`f3`**, and **`f4`** may be called in any order. All side effects have to be completed before the function pointed to by **`pf[f1()]`** is called.

Commentary

An order of execution could be guaranteed by using the comma operator:

```
1  (t4=f4(), t3=f3(), t2=f2(), t1=f1(),  (*pf[t1]) (t2, t3 + t4))
```

Common Implementations

Because its value is needed last, the function `f1` is likely to be called last.

1028 **Forward references:** function declarators (including prototypes) (6.7.5.3), function definitions (6.9.1), the **return** statement (6.8.6.4), simple assignment (6.5.16.1).

6.5.2.3 Structure and union members

Constraints

1029 The first operand of the . operator shall have a qualified or unqualified structure or union type, and the second operand shall name a member of that type.

operator . first operand shall

Commentary

The . operator effectively operates on the left operand to make its member names visible. The right operand indicates which one is to be accessed.

Other Languages

This notation is common to most languages that support some form of structure or union type. Cobol uses the keyword **OF** and reverses the order of the operands.

Common Implementations

The definition originally used in K&R allowed the right operand to belong to any visible structure or union type. This restricts member names to being unique; there was a single structure and union name space, not a separate one for each type. A member name was effectively treated as a synonym for a particular offset from a base address.

An extension sometimes seen in translators[717] for freestanding environments is to define the behavior when the left operand has an integer type and the right operand is an integer constant. In this case the . operator returns the value of the bit indicated by its right operand from the value of the left operand. Other extensions, seen in both environments, include anonymous unions and even unnamed members.[1350] In this case the right operand may be any member contained within the type of the left operand (translator documentation does not always specify the rules used to disambiguate cases where more than one member could be chosen).

```
1  void Plan_9(void)
2  {
3  typedef struct lock {
4                        int locked;
5                       } Lock;
6  struct {
7          union {
8                 int u_mem1;
9                 float u_mem2;
10               }; /* Constraint violation, but supported in some implementations. */
11         int s_mem2;
12         Lock;    /* Constraint violation, but supported in some implementations. */
13        } obj;
14
15 obj.u_mem1=3; /* Access member without any intermediate identifiers. */
16 obj.locked=4;
17 }
```

1030 The first operand of the -> operator shall have type "pointer to qualified or unqualified structure" or "pointer to qualified or unqualified union", and the second operand shall name a member of the type pointed to.

Commentary

The -> operator is really a shorthand notation that allows (*p).mem to be written as p->mem. Because many structure members' accesses occur via pointers this notational convenience makes for more readable source code.

Other Languages

Many languages do not need to provide a shorthand notation covering this case. In those languages where the indirection operator appears to the right of the operand, member selection does not require parentheses. In Pascal, for instance, `R.F` selects the field `F` from the record `R`, while `P_R^.F` selects the field from the record pointed to by `P_R`. However, it might be asked why it is necessary to use a different operator just because the left operand has a pointer type. The language designers could have chosen to specify that an extra indirection is performed, if the left operand has a pointer type. The Ada language designers took this approach (to access all of a pointed-to object the reserved word **`all`** needs to be used).

Semantics

member selection

A postfix expression followed by the `.` operator and an identifier designates a member of a structure or union object. 1031

Commentary

union 1427 members start same address

Members designated using the `.` operator are at a translation time known offset from the base of the structure (members of unions always have an offset of zero). This translation-time information is available via the `offsetof` macro.

Other Languages

Cobol and PL/1 support elliptical member references. One or more selection operators (and the corresponding member name) can be omitted, provided it is possible for a translator to uniquely determine a path to the specified member name. By allowing some selection operators to be omitted, a long chain of selections can be shortened (it is claimed that this improves readability).

Cobol and Algol 68 use the reverse identifier order (e.g., `name OF copper` rather than `copper.name`).

Coding Guidelines

Structure or union types defined in system headers are special in that development projects rarely have any control over their contents. The members of structure and union types defined in these system headers can vary between vendors. An example of the different structure members seen in the same structure type is provided by the `dirent` structure. The POSIX.1 Standard[636] requires that this structure type include the members `d_name` and `d_namelen`. The Open Groups Single Unix Specification[1487] goes further and requires that the member `d_ino` must also be present. Looking at the system header on Linux we find that it also includes the members `d_off` and `d_type`; that is

```
1  struct dirent {
2                  ino_t d_ino;                /* SUS */
3                  off_t d_off;                /* Linux */
4                  unsigned char d_type;       /* Linux */
5                  unsigned short int d_reclen; /* POSIX.1 */
6                  char d_name[256];           /* POSIX.1 */
7                 };
```

While developers cannot control the availability of members within structure types on different platforms, they can isolate their usage of those members that are vendor-specific. Encapsulating the use of specific members within functions or macro bodies is one solution. Most host development environments predefine a number of macros and these can be used as feature test macros by a development group.

feature test macro 96

Table 1031.1: Number of member selection operators of the same object (number of dot selections is indicated down the left, and the number of indirect selections across the top). For instance, `x.m1->m2` is counted as one occurrence of the dot selection operator with one instance of the indirect selection operator. Based on the translated form of this book's benchmark programs.

. \ ->	0	1	2	3	4	5
0	0	165,745	10,396	522	36	4
1	28,160	34,065	3,437	230	7	0
2	3,252	6,643	579	26	0	0
3	363	309	35	5	0	0
4	16	33	2	0	0	0
5	0	15	0	0	0	0

1032 The value is that of the named member [DR283)], and is an lvalue if the first expression is an lvalue.

Commentary

A member access that reads a value behaves the same as an access that reads from an ordinary identifier.

The number of constructs whose result has a structure, or union, type that is not an lvalue has been reduced to one in C99. The cast operator does not return an lvalue, but its operand cannot be a structure or union type.

The issue of members having a bit-field type is discussed elsewhere.

721 lvalue
1131 footnote 85
1134 cast scalar or void type
672 bit-field in expression

Common Implementations

The base address of file scope objects having a structure type may not be known until link-time. The offset of the member will then need to be added to this base address. Nearly all linkers support some kind of relocation information, in object files, needed to perform this addition at link-time. The alternative is to generate machine code to load the base address and add an offset to it, often a slower instruction (or even two instructions).

Example

```
1  struct s {
2            int m;
3           };
4
5  void f(void)
6  {
7  int *p_i;
8  struct s l_s;
9
10 p_i = &(l_s.m);
11 /*
12  * A strictly conforming program can only cast an object having
13  * a structure type to exactly the same structure type.
14  */
15 p_i = &(((struct s)l_s).m); /* Constraint violation, & not applied to an lvalue. */
16 }
```

1033 If the first expression has qualified type, the result has the so-qualified version of the type of the designated member.

struct qualified
result qualified

Commentary

The qualifiers on the result type are the union of the set of type qualifiers on the two operands.

Other Languages

The logic of an outer qualifier applying to all the members of a structure or union applies to qualifiers followed in most programming languages.

Example

```
1  void f(void)
2  {
3  const struct {
4                 const int mem_1;
5                 int mem_2;
6                } x;
7
8  x.mem_1; /* Has type const int, not const const int */
9  x.mem_2; /* Also has type const int */
10 }
```

EXAMPLE 1040 qualifiers Also see a C Standard example elsewhere.

A postfix expression followed by the -> operator and an identifier designates a member of a structure or union object. 1034

Commentary

A consequence of the pointer dereference operator, *, being a prefix rather than a postfix operator and having a lower precedence than the member selection operator, ., is that it is necessary to write (*p).mem to access a member of a pointed-to structure object. To provide a shorthand notation, the language designers could either have specified that one level of pointer indirection is automatically removed if the left operand of the . operator has pointer type (as Ada and Algol 68 do), or they could specify a new operator. They chose the latter approach, and the -> operator was created.

C++

The C++ Standard specifies how the operator can be mapped to the dot (.) form and describes that operator only.

5.2.5p3 *If E1 has the type "pointer to class X," then the expression E1->E2 is converted to the equivalent form (*(E1)).E2; the remainder of 5.2.5 will address only the first option (dot)[59].*

Common Implementations

In this case the base address of the pointed-to object is not usually known until program execution, although the offset of the member from that address is known during translation. Processors invariably support a *register+offset* addressing mode, where the base address of an object (the address referenced by the left operand) has already been loaded into register. It is common for more than one member of the pointed-to object to be accessed within a sequence of statements and this base address value will compete with other frequently used values to be held in a register. register + offset 1000

The time taken to load a value from storage can be significant and processors use a variety of techniques to reduce this performance overhead. Walking tree-like data structures, using the -> operator, can result in poor locality of reference and make it difficult for a processor to know which storage locations to prefect data from. A study by Luk and Mowry[872] investigated translator-controlled prefetching schemes. cache 0

Coding Guidelines

The issues common to all forms of member access are discussed elsewhere. There is a difference between the use of the . and -> operators that can have coding guideline implications. Accessing the member of a nested structure type within one object can lead to a series of successive . operators being applied to the result of preceding . operators. In this case the sequence of operators is narrowing down a particular member within a larger object; the member selections are intermediate steps toward the access of a particular member. It is likely that different members will have different types and if an incorrect member appears in the selection chain, a diagnostic will be issued by a translator. member selection 1031

The -> operator is often used to access members of a tree-like data structure whose nodes may have a variety of types and are independent objects. A sequence of -> operators represents a path to a particular node in this tree, relative to other nodes. The member selection path used to access a particular member is not limited to the depth of nesting of the structure types involved. To work out what the final node accessed represents, developers need to analyze the path used to reach it, where each node on the path is often a separate object. (An incorrect path is very unlikely to generate a diagnostic during translation)

In many cases developers are not interested in the actual path itself, only what it represents. When there is a sequence of -> operators in the visible source code, developers need to deduce, or recognize, the algorithmic semantics of the operation sequence. This deduction can require significant developer cognitive resources. There are a number of techniques that might be used to reduce the total resources required, or reduce the peak load required. The following example illustrates the possibilities:

```
typedef struct TREE_NODE *TREE_PTR;
struct TREE_NODE {
                  int data;
                  TREE_PTR left,
                           right;
                  };

#define LEFT_NODE(branch) ((branch)->left)
#define RIGHT_NODE(branch) ((branch)->right)
#define Get_Road_Num(node) ((node)->left->right->left.data)

extern TREE_PTR root;

void f(void)
{
int leaf_valu;
TREE_PTR temp_node_1,
         temp_node_2,
         destination_addr,
         road_name;

leaf_valu = root->left->right->left.data;
leaf_valu = ((root->left)->right)->left.data;
/*
 * Break the access up into smaller chunks.  Is the access
 * above easier or harder to understand than the one below?
 */
temp_node_1 = root->left;
temp_node_2 = temp_node_1->right;
leaf_valu = temp_node_2->left.data;
/*
 * If the intermediate identifier names had a name that suggested
 * an association with what they represented, the effort needed,
 * by developers, to create their own associations might be reduced.
 */
destination_addr = root->left;
road_name = destination_addr->right;
leaf_valu = road_name->left.data;
/*
 * Does hiding the underlying access details, an indirection
 * operator, make any difference?
 */
leaf_valu = LEFT_NODE(RIGHT_NODE(LEFT_NODE(root))).data;
/*
 * The developer still has to deduce the meaning of the access from the path
 * used.  Why not hide the complete path behind a meaningful identifier?
 */
leaf_valu = Get_Road_Num(root);
```

```
49  }
```

sequential nesting () 1000
sequential nesting * 1095

Some of these issues also affect other operators. At the time of this writing there is insufficient experimental evidence to enable a meaningful cost/benefit analysis to be performed.

The value is that of the named member of the object to which the first expression points, and is an lvalue.[80)] 1035

Commentary

Unlike uses of the `.` operator, there are no situations where a pointer can refer to an object that is not an lvalue (although many implementations' internal processing of the `offsetof` macro casts and dereferences `NULL`).

lvalue 721

bit-field in expression 672

The issue of members having a bit-field type is discussed elsewhere.

If the first expression is a pointer to a qualified type, the result has the so-qualified version of the type of the designated member. 1036

Commentary

struct 1033
qualified result qualified
effective type 948

Qualification is based on the pointed-to type. The effective type of the object is not considered. The qualifiers on the result type are the union of the set of type qualifiers on the two operands.

---

union special guarantee

One special guarantee is made in order to simplify the use of unions: if a union contains several structures that share a common initial sequence (see below), and if the union object currently contains one of these structures, it is permitted to inspect the common initial part of any of them anywhere that a declaration of the complete type of the union is visible. 1037

Commentary

alias analysis 1491

value stored in union 586

At one level this guarantee is codifying existing practice. At another level it specifies a permission, given by the standard to developers, which a translator needs to take account of when performing pointer alias analysis. This guarantee is an exception to the general rule that reading the value of a member of a union type after a value has been stored into a different member results in unspecified behavior. It only applies when two or more structure types occur within the definition of the same union type. Being contained within the definition of a union type acts as a flag to the translator; pointers to objects having these structure types may be aliased.

Two or more structure types may share a common initial sequence. But if these types do not appear together within the same union type, a translator is free to assume that pointers to objects having these two structure types are never aliases of each other.

The existing C practice, which this guarantee codifies, is an alternative solution to the following problem. The structure types representing the nodes of a tree data structure (or graph) used by algorithms, sometimes have a number of members in common and a few members that differ. To simplify the processing of these data structures a single type, representing all members, is usually defined. The following example shows one method for defining this type:

```
1   struct REC {
2              int kind_of_node_this_is;
3              long common_2;
4              int common_3;
5              union {
6                     float differ_1;
7                     short differ_2[5];
8                     char *differ_3;
9                    } unique;
10             };
```

Use of a type built in this fashion can be inflexible. It creates a dependency between developers working with different types. The type will generally be contained in a single file with any modifications needing to

go through a change control mechanism. There is also the potential issue of wasted storage. One of the union members may use significantly more storage than any of the other members. Allocating storage based on the value of `sizeof(struct REC)` could be very inefficient. An alternative solution to defining a common type is the following:

```
struct REC_1 {
            int kind_of_node_this_is;
            long common_2;
            int common_3;
                  float differ_1;    /* Members that differ start here. */
            };
struct REC_2 {
            int kind_of_node_this_is;
            long common_2;
            int common_3;
                  short differ_2[5]; /* Members that differ start here. */
            };
struct REC_3 {
            int kind_of_node_this_is;
            long common_2;
            int common_3;             /* Members that differ start here. */
                  char *differ_3;
            };

union REC_OVERLAY {
                  struct REC_1 rec_1;
                  struct REC_2 rec_2;
                  struct REC_3 rec_3;
                  };
```

In this case the different structures (`REC_1`, `REC_2`, etc.) could be defined in different source files, perhaps under the control of different developers. When storage is allocated for a particular kind of node, the type appearing as the operand of **`sizeof`** can be the specific type that is needed; there is no wasted storage caused by the requirements of other nodes.

The wording " . . . anywhere that a declaration of the complete type of the union is visible." is needed to handle the following situation:

afile.c

```
#include <stdio.h>

union utag {
            struct tag1 {
                        int m1;
                        double d2;
                        } st1;
            struct tag2 {
                        int m1;
                        char c2;
                        } st2;
            } un1;

extern int WG14_N685(struct tag1 *pst1, struct tag2 *pst2);

void f(void)
{
if (WG14_N685(&un1.st1, &un1.st2))
   printf("optimized\n");
else
   printf("unoptimized\n");
}
```

tag 634 declared with same

If the two structure declarations did not appear within the same union declaration in the following translation unit, a translator would be at liberty to perform the optimization described earlier.

bfile.c

```
union utag {
            struct tag1 {
                        int m1;
                        double d2;
                        } st1;
            struct tag2 {
                        int m1;
                        char c2;
                        } st2;
            } un1;

int WG14_N685(struct tag1 *pst1, struct tag2 *pst2)
{
pst1->m1 = 2;
pst2->m1 = 0;   /* Could be an alias for pst1->m1 */
return pst1->m1;
}
```

C90

The wording:

> *anywhere that a declaration of the complete type of the union is visible.*

was added in C99 to handle a situation that was raised too late in the process to be published in a Technical Report. Another wording change relating to accessing members of union objects is discussed elsewhere.

EXAMPLE 1044 member selection value 586 stored in union

C++

Like C90, the C++ Standard does not include the words " . . . anywhere that a declaration of the complete type of the union is visible."

Other Languages

This kind of guarantee is unique to C (and C++). However, other languages support functionality that addresses the same problem. Two languages commonly associated with the software development of applications requiring high-integrity, Pascal and Ada, both support a form of the union type within a structure type supported by C.

Common Implementations

All implementations known to your author assign the same offset to members of different structure types, provided the types of all the members before them in the definition are compatible.

Coding Guidelines

The idea of overlaying members from different types seems to run counter to traditional thinking on how to design portable, maintainable programs. The C Standard requires an implementation to honor this guarantee so its usage is portable. The most common use of common initial sequences is in dynamic data structures. These involve pointers and pointers to different structure types which are sometimes cast to each others types. There can be several reasons for this usage, including:

- Sloppy programming, minimal change maintenance, or a temporary fix that becomes permanent; for instance, some form of tree data structure whose leafs have some structure type. An enhancement requires a new list of members representing completely different information, and rather than add these members to the existing structure, it is decided to create a new structure type (perhaps to save space). Changing the type of the member that points at the leafs, to have a union type (its members

having the types of the two structures), would require changing accesses to that member to include the name of the appropriate union member. Existing code could remain unchanged if the existing member types remained the same. Any references to the new structure type is obtained by casting the original pointer type.

- Support for subtyping, inheritance, or class hierarchies— constructs not explicitly provided in the C language.

The following discussion is based on the research of Stiff et al.,[1301, 1302] and others.[215] In:

```
typedef struct {
                 int x,
                     y;
                } Point;

void update_position(Point *);

typedef enum { RED, BLUE, GREEN } Color;

typedef struct {
                 int x,
                     y;
                 Color c;
                } Color_Point;
typedef struct {
                 Point where;
                 Color c;
                } CW_Point;
typedef struct {
                 char base[sizeof(Point)];
                 Color c;
                } CA_Point;

void change_color(Color_Point *);

void f(void)
{
Point a_point;
Point *some_point;
Color_Point a_color_point;
CW_Point a_c_point;
/* ... */
update_position((Point *)&a_color_point);
update_position(&a_c_point.where);
/* ... */
some_point = (Point *)&a_color_point;    /* An upcast.  */
/* ... */
change_color((Color_Point *)some_point); /* A downcast. */
}
```

the types `Color_Point`, `CW_Point` and `CA_Point` can be thought of as subtypes of `Point`, one having the same common initial sequence as `Point` (guaranteeing that the members `x` and `y` will have the same offsets) and the other making use of its definition. Both forms of definition are found in source code.

1038 common initial sequence

The issue is not about how the contents of structures are defined, but about how their usage may rely on layout of their members in storage. For instance, developers who depend on member layout to reinterpret an object's contents. In the above example a call to `update_position` requires an argument of type `Point *`. The design of the data structures for this program makes use of the fact that all members called `x` and `y` have the same relative offsets within their respective objects.

530 structure type sequentially allocated objects

Commonly seen object-oriented practice is to allow objects of a derived class to be treated as if they were objects of a base class. Sometimes called an *upcast* (because a subtype, or class, is converted to a type or class). A conversion in the other direction, known as a *downcast*, is seen less often.

Discussing how members in one structure might occupy the same relative (to the start of the structure) storage locations as members in another structure would normally bring howls of protest about unsafe practices. Rephrasing this discussion in terms of the object-oriented concepts of class hierarchies and inheritance lends respectability to the idea. The difference between this usage in C and C++ (or Java) is that there is no implicit language support for it in the former case; the details have to be looked after by the developer. It is this dependency on the developer getting the layout correct that is the weakest link.

Duplicating sequences of members within different structures, as in the declaration of `Color_Point`, violates the single location principle, but has the advantage of removing the need for an additional dot selection in the member reference. Using a single declared type within different structures, as in `CW_Point`, is part of the fabric of normal software design and development, but has the disadvantage of requiring an additional member name to appear in an access.

Stiff et al. base the definition of the term *physical type* on the layout of the members in storage. The form of the declarations of the members within the structure is not part of its physical type. Upcasting does leave open the possibility of accessing storage that does not exist; for instance, if a pointer to an object of type `Point` is converted to a pointer to an object of type `Color_Point`, and the member `c` is subsequently accessed through this pointer.

Usage

Measurements by Stiff et al.[1301] of 1.36 MLOC (the SPEC95 benchmarks, gcc, binutils, production code from a Lucent Technologies' product and a few other programs) showed a total of 23,947 casts involving 2,020 unique types. For the `void *` ⇔ `struct *` conversion, they found 2,753 upcasts (610 unique types), 2,788 downcasts (606 unique types), and 538 cases (60 unique types) where there was no matching between the associated up/down casts. For the `struct *` ⇔ `struct *` conversions, they found 688 upcasts (78 unique types), 514 downcasts (66 unique types), and 515 cases (67 unique types) where there was no relationship associated with the types.

---

common initial sequence

Two structures share a *common initial sequence* if corresponding members have compatible types (and, for bit-fields, the same widths) for a sequence of one or more initial members. 1038

Commentary

This defines the term *common initial sequence*.

The rationale given for the same representation and alignment requirements of signed/unsigned types given in footnote 31 does not apply to a common initial sequence. Neither is a special case called out, like that for arguments. Also the rationale given in footnote 39 for pointer to **`void`** does apply to a common initial sequence. There are additional type compatibility rules called out for pointer to **`void`** and other pointer types for some operators, but there are no rules called out for common initial sequences.

The requirement that successive members of the same structure have increasing addresses prevents an implementation from reordering members, in storage, to be different from how they appear in the source (unless it can deduce that such a reordering will not affect the behavior of the program). The common initial sequence requirement thus reduces to requiring the same amount of padding between members.

footnote 509 31
argument 1012 in call incompatible with function definition
footnote 565 39
member 1422 address increasing
structure 1424 unnamed padding

C++

3.9p11 *If two types T1 and T2 are the same type, then T1 and T2 are layout-compatible types.*

Two POD-structs share a common initial sequence if corresponding members have layout-compatible types (and, for bit-fields, the same widths) for a sequence of one or more initial members.

POD is an acronym for *Plain Old Data* type.

C++ requires that types be the same, while C requires type compatibility. If one member has an enumerated type and its corresponding member has the compatible integer type, C can treat these members as being part of a common initial sequence. C++ will not treat these members as being part of a common initial sequence.

Common Implementations

In choosing the offset from the start of the structure of each structure member, all implementations known to your author only consider the type of that member. Members that appear later in the structure type do not affect the relative offset of members that appear before them. Translators that operate in a single pass have to assume that the initial members of all structure types might be part of a common initial sequence. In the following example the body of the function `f` is encountered before the translator finds out that objects it contains have access types that are part of a common initial sequence.

10 implementation single pass

```
1  struct t_1 {
2              int mem_1;
3              double mem_2;
4              char mem_3;
5             } g_1;
6  struct t_2 {
7              int mem_4;
8              double mem_5;
9              long mem_6;
10            } g_2;
11
12 void f (void)
13 { /* Code accessing g_1 and g_2 */ }
14
15 union {
16        struct t_1 mem_7;
17        struct t_2 mem_8;
18       } u;
19
20 /* ... */
```

Coding Guidelines

A common initial sequence presents a number of maintenance problems, which are all derived from the same requirement— the need to keep consistency between textually different parts of source code (and no translator diagnostics if there is no consistency). The sequence of preprocessing tokens forming a common initial sequence could be duplicated in each structure definition, or the common initial sequence could be held in its own source file and **`#include`**d in all the structure type definitions that define the members it contains. Since the cost/benefit of the different approaches is unknown, and there is no established existing practice that addresses the software engineering issues associated with reliably maintaining a consistent common initial sequence, no recommendations are made here.

Example

```
1  typedef short int BUCKET;
2
3  struct R_1 {
4              short int mem_1;
5              int mem_2 : 1+1;
6              unsigned char mem_3;
7              };
```

```
8   struct R_2 {
9               short mem_1;
10              int mem_2 : 2;
11              short mem_3; /* Not a common initial sequence member. */
12              };
13  struct R_3 {
14              short int member_1;
15              int mem_2 : 3-1;
16              long mem_3;
17              };
18  struct R_4 {
19              BUCKET mem_1;
20              int mem_2 : 1+1;
21              float mem_3;
22              };
23  union node_rec {
24                  struct R_1 n_1;
25                  struct R_2 n_2;
26                  struct R_3 n_3;
27                  struct R_4 n_4;
28                  };
```

EXAMPLE 1 If **f** is a function returning a structure or union, and **x** is a member of that structure or union, **f().x** is a valid postfix expression but is not an lvalue. 1039

Commentary

lvalue 725
converted to value

It is not an lvalue because it occurs in a context where an lvalue is converted to a value.

EXAMPLE
qualifiers

EXAMPLE 2 In: 1040

```
struct s { int i; const int ci; };
struct s s;
const struct s cs;
volatile struct s vs;
```

the various members have the types:

```
s.i         int
s.ci        const int
cs.i        const int
cs.ci       const int
vs.i        volatile int
vs.ci       volatile const int
```

Commentary

derived type 557
qualification
qualified 1492
array type

Other examples are given elsewhere.

footnote
80

80) If **&E** is a valid pointer expression (where **&** is the "address-of" operator, which generates a pointer to its operand), the expression **(&E)->MOS** is the same as **E.MOS**. 1041

Commentary

Similarly, if `P` is a valid pointer expression, the expression `(*P).MOS` is the same as `P->MOS`. The term *address-of* is commonly used by developers to denote the **&** operator.

C++

The C++ Standard does not make this observation.

footnote DR283

1042 DR283) If the member used to access the contents of a union object is not the same as the member last used to store a value in the object, the appropriate part of the object representation of the value is reinterpreted as an object representation in the new type as described in 6.2.6 (a process sometimes called "type punning").

Commentary

The issue accessing overlapping union members and *type punning* is discussed elsewhere.

An object representation is the sequence of bytes that is interpreted, using a type, to form a value.

The member being accessed may include bytes that are not within the object last written to. These bytes may have an indeterminate or an unspecified value.

This footnote was added by the response to DR #283.

531 union type overlapping members
531 type punning union
574 object representation
461 object initial value indeterminate
586 value stored in union

1043 This might be a trap representation.

Commentary

The same object representation may be a value representation when interpreter using one type but a trap representation when interpreted using another type (e.g., a value of type **long** may be a trap representation when its object representation is reinterpreted as the type **float**). Accessing a trap representation causes undefined behavior.

This footnote was added by the response to DR #283.

574 object representation
595 value representation
579 trap representation reading is undefined behavior

1044 EXAMPLE 3 The following is a valid fragment:

EXAMPLE member selection

```
union {
        struct {
                int    alltypes;
        } n;
        struct {
                int    type;
                int    intnode;
        } ni;
        struct {
                int    type;
                double doublenode;
        } nf;
} u;
u.nf.type = 1;
u.nf.doublenode = 3.14;
/* ... */
if (u.n.alltypes == 1)
        if (sin(u.nf.doublenode) == 0.0)
                /* ... */
```

The following is not a valid fragment (because the union type is not visible within function **f**):

```
struct t1 { int m; };
struct t2 { int m; };
int f(struct t1 *p1, struct t2 *p2)
{
        if (p1->m < 0)
                p2->m = -p2->m;
        return p1->m;
}
int g()
{
        union {
                struct t1 s1;
                struct t2 s2;
        } u;
```

```
        /* ... */
        return f(&u.s1, &u.s2);
}
```

Commentary

The sense of "not a valid fragment" in the second example is unspecified behavior (because different members of a **union** type are being accessed without an intervening store). Given the arguments passed to the function `f`, the likely behavior is to return the absolute value of the member `m`.

value 586 stored in union

C90

In C90 the second fragment was considered to contain implementation-defined behavior.

C++

The behavior of this example is as well defined in C++ as it is in C90.

Common Implementations

An optimizer might assume that the objects pointed at by the parameters of `f` are disjoint (because there is no connection between the structure types `t1` and `t2` at the time the function `f` is first encountered during translation). There is a long history of C translators being able to operate in a single pass over the source code and in some cases the function `f` might be completely translated before moving on to the function `g` (the example could have put `g` in a separate file). Given the availability of sufficient registers, an optimizer (operating in a single pass) may hold the contents of `p1->m` in a different register to the contents of `p2->m`. So, although the member `m` will hold a positive value after the call to `f`, the value returned by both functions could be negative.

implementation 10 single pass

Forward references: address and indirection operators (6.5.3.2), structure and union specifiers (6.7.2.1). 1045

6.5.2.4 Postfix increment and decrement operators

Constraints

---

postfix operator constraint

The operand of the postfix increment or decrement operator shall have qualified or unqualified real or pointer type and shall be a modifiable lvalue. 1046

Commentary

C99 added complex types to the set of scalar types. However, the Committee did not define a meaning for the postfix increment and decrement operators for the complex types. (A natural result, had polar coordinates been chosen for the representation, would have been to increment or decrement the magnitude; one possibility in a cartesian coordinate representation would be to increment the real part, which is the effect in `C+=1`.)

The postfix `++` operator might be used in conjunction with an object of type **_Bool** to perform an atomic test-and-set operation. However, C99 does not require an implementation to support this usage, even if the Library typedef name `sig_atomic_t`, defined> has type **_Bool**.

C90

The C90 Standard required the operand to have a scalar type.

C++

D.1p1 *The use of an operand of type* ***bool*** *with the postfix* ++ *operator is deprecated.*

Other Languages

These operators are usually seen in languages that claim to be *C-like*.

Common Implementations

Many processors include instructions that are special cases of other instructions. For instance, addition and subtraction instructions that encode a small constant value as part of the instruction (removing the need to load the constant into a register before using it as an operand). The number of bits used for encoding this constant in an instruction tends to be greater for wider instructions. In some cases (usually 8-bit processors) the instruction may be simply an increment/decrement by one.

Looping constructs often involve incrementing or decrementing an objects value by one. The object may be a loop counter or a pointer into storage. Some processors combine a counting operation, comparison of modified value, and branch based on result of the comparison in a single instruction, while other processors support addressing modes that modify the contents of a register (or storage location) as part of the execution of the instruction.[968] In some cases these addressing modes can be used to efficiently access successive elements of an array. To be able to use these specialized instructions the appropriate constructs need to occur in the source and a translator needs to be capable of detecting it. For instance, the Motorola 68000[968] includes a postincrement and a predecrement addressing mode, which are only useful in some cases.

1763 iteration statement syntax

```
while (*p++ == *q++) /* Postincrement */
   ;
while (*--p == *--q) /* Predecrement */
   ;
/* Motorola 68000 addressing modes no use for the following */
while (*++p == *++q) /* Preincrement */
   ;
while (*p-- == *q--) /* Postdecrement */
   ;
```

Coding Guidelines

Incrementing or decrementing the value of an object by one is a relatively common operation. This usage created two rationales for the original inclusion of these postfix operators in the C language. It simplified the writing of a translator capable of generating reasonable quality machine code and it provided a shortened notation (in both the visual and conceptual sense) for developers. Another rationale for the use of these operators has come into being since they were first created— existing practice. Because they occur frequently in existing source developers have acquired extensive experience in recognizing their use in source. Their presence in existing code ensures that future developers will also gain extensive experience in recognizing their use. These operators are part of the culture of C.

912 punctuator syntax

The issue of translator optimization increment/decrement operators is not as straight-forward as it might appear; it is discussed elsewhere. The conclusions reached are even more applicable to the postfix operators because of their additional complexity.

1082 prefix ++ incremented

From the coding guideline perspective use of these operators can be grouped into the following three categories:

1. *The only operator in an expression statement.* In this context the result returned by the operation is ignored. The statement simply increments/decrements its operand. Use of the postfix, rather than the prefix, form follows the pattern seen at the start of most visible source code statement lines— an identifier followed by an operator (see Figure 940.2). For this reason the postfix operators are preferred over prefix operators, an expression statement context.

1082 prefix ++ incremented

2. *One of the operators in a full expression that contains other operators.* Experience shows that developers' strategy of scanning down the left edge of the source looking for objects that are modified sometimes results in them failing to notice object modifications that occur in other contexts (i.e., a postfix or prefix operation appearing in the right operand of an assignment, or the argument of a function call). It is possible to write the code so that a postfix operator does not occur in the same expression as other operators. Moving the evaluation back before the containing expression removes

1712 full expression

the need for duplicate operations in each arm of an **if/else** (an **else** arm will have to be created if one does not exist) or **switch** statement. For an expression statement the operation can be moved after the containing expression. (If the usage is part of an initializer, the first form is only available in C99, which permits the mixing of declarations and statements.)

```
...i++...
```

becomes the equivalent form:

```
t=i;
i++;
...t...
```

or:

```
...i...
i++;
```

The total cognitive effort needed to comprehend the first equivalent form may be more than the postfix form (the use of `t` has to be comprehended). However, the peak effort may be less (because the operations may have been split into smaller chunks in serial rather than nested form). The total cognitive effort needed to comprehend the second equivalent form may be the same as the original and the peak effort may be less. Are more faults likely to be introduced through miscomprehension, through a visual code scanning strategy that may fail to spot modifications, or through the introduction of a temporary object? There is insufficient evidence to answer this question at the time of this writing. Although in the case of expression statements there is the possibility of a benefit (at a very small initial, typing cost) to moving the modification operation to after the expression. The issue of side effects occurring within expressions containing operators that conditionally evaluate their operands is discussed elsewhere.

&& 1255 second operand

3. *The only operator in a full expression that is not an expression statement.* When the postfix operator is the only operator in a full expression it might be claimed that it will not be overlooked by readers. There is no evidence for, or against, this claim.

Your author has encountered other coding guideline authors, whose primary experience is with non-C like languages, who recommend against the postfix and prefix operators. These recommendations seem to be driven by unfamiliarity. Experience suggests that once the novelty has worn off, these developers become comfortable with and even prefer the shorter C forms.

By their very nature the **++** and **--** operators often occur in expressions used as indices to storage locations. The off-by-one mistake may be the most commonly occurring mistake associated with array subscripting. For some coding guideline authors, this has resulted in guilt by association. There is no evidence to show that the use of these operators leads to more, or less, mistakes being made than if an alternative expression were used.

prefix ++ 1082 incremented

The rationale for preferring prefix operators over postfix operators in some contexts is given elsewhere.

Cg 1046.1

A postfix operator shall not appear in an expression unless it is the only operator in an expression statement.

Semantics

postfix ++ result

The result of the postfix ++ operator is the value of the operand.

Commentary

That is, the value before the object denoted by the operand is incremented.

Common Implementations

Having to return the original value as the result, and to update the original value, requires at least one more register, or storage location, than the prefix form.

Coding Guidelines

An occurrence of the postfix ++ operator may cause the reader to make a cognitive task switch (between evaluating the full expression and evaluating the modification of a storage location). It also requires that two values be temporarily associated with the same object. Having to remember two values requires more memory resources than recalling one. There is also the possibility of interference between the two, closely semantically associated, values (causing one or both of them to be incorrectly recalled). As the previous C sentence discussed, rewriting the code so that a postfix operator is not nested within an expression evaluation may reduce the cognitive resources needed to comprehend that piece of source.

0 cognitive switch

1048 After the result is obtained, the value of the operand is incremented.

Commentary

That is, at the next sequence point the value of the object will be one larger than it was before the evaluation of this operator (assuming no other value is stored into the object before this sequence point is reached, which would result in undefined behavior).

C++

After the result is noted, the value of the object is modified by adding 1 to it, unless the object is of type ***bool****, in which case it is set to* ***true****. [Note: this use is deprecated, see annex D.]*

5.2.6p1

The special case for operands of type **bool** also occurs in C, but a chain of reasoning is required to deduce it.

476 _Bool large enough to store 0 and 1

Common Implementations

The two values created by the postfix operators (the value before and the value after) are likely to simultaneously require two registers, to hold them. The extent to which the greater call on available processor resources, compared to the corresponding prefix operators, results in less optimal generated machine code will depend on the context in which the operator occurs (i.e., a change to the algorithm to use a different operator may affect the quality of the machine code generated for other operators).

1049 (That is, the value 1 of the appropriate type is added to it.)

Commentary

If USHRT_MAX has the same value as INT_MAX, then the following increment would have undefined behavior, if the value 1 used has type **int**. However, it is defined if the value 1 used has type **unsigned int** (it is assumed that the phrase *appropriate type* is to be interpreted as a type for which the behavior is defined).

```
1  unsigned short u = USHRT_MAX;
2
3  u++;
```

1050 See the discussions of additive operators and compound assignment for information on constraints, types, and conversions and the effects of operations on pointers.

Commentary

addition 1154 operand types compound 1310 assignment constraints additive 1162 operators semantics compound 1312 assignment semantics prefix op- 1085 erators see also

The implication is that these constraints and semantics also apply to the postfix ++ operator. The same references are given for the postfix operators.

C++

5.2.6p1

The C++ Standard provides a reference, but no explicit wording that the conditions described in the cited clauses also apply to this operator.

See also 5.7 and 5.17.

The side effect of updating the stored value of the operand shall occur between the previous and the next sequence point. 1051

Commentary

sequence 187 points

This is a requirement on the implementation. It is a special case of a requirement given elsewhere. The postfix ++ operator is treated the same as any other operator that modifies an object with regard to updating the stored value. It is possible that the ordering of sequence points, during the evaluation of a full expression, is nonunique. It is also possible that the operand may be modified more than once between two sequence points, causing undefined behavior.

sequence 187 points

C++

sequence 187 points

The C++ Standard does not explicitly specify this special case of a more general requirement.

Common Implementations

assignment- 1288 expression syntax

Like the implementation of the assignment operators, there may be advantages to delaying the store operation (keeping the new value in a register), perhaps because subsequent operations may modify it again.

Coding Guidelines

sequence 187.1 points all orderings give same value

The applicable guideline recommendation is discussed elsewhere.

---

postfix -- analogous to ++

The postfix -- operator is analogous to the postfix ++ operator, except that the value of the operand is decremented (that is, the value 1 of the appropriate type is subtracted from it). 1052

Commentary

postfix ++ 1047 result

The effects of the -- operator are not analogous to the postfix ++ operator when the operand has type **_Bool** (otherwise the same Commentary and Coding guideline issues also apply). The -- operator always inverts the truth-value of its operand.

```
1  #include <stdio.h>
2
3  void f(_Bool p)
4  {
5  _Bool q = p;
6
7  q--; q++;
8  p++; p--;
9
10 if (p == q)
11    printf("This implementation is not conforming\n");
12 }
```

C++

5.2.6p2

. . . except that the operand shall not be of type **bool**.

A C source file containing an instance of the postfix `--` operator applied to an operand having type **_Bool** is likely to result in a C++ translator issuing a diagnostic.

1053 **Forward references:** additive operators (6.5.6), compound assignment (6.5.16.2).

6.5.2.5 Compound literals

C90

Support for compound literals is new in C99.

C++

Compound literals are new in C99 and are not available in C++.

Usage

No usage information is provided on compound literals because very little existing source code contains any use of them.

Constraints

1054 The type name shall specify an object type or an array of unknown size, but not a variable length array type.

Commentary

The type of the compound literal is deduced from the type name, not from the parenthesized list of expressions. Note that here *type name* refers to a syntactic rule.

1624 abstract declarator syntax

The number of elements in the compound literal are required to be known at translation time. This simplifies the handling of their storage requirements.

Compound literals are not usually thought of in terms of scalar types. In those cases where the address of an object is needed simply to fill an argument slot, using an unnamed object may be simpler than defining a dummy variable.

```
1  extern void glob(int, int, int *);
2
3  void f(void)
4  {
5  int loc = (int){9}; /* Surprising?  Unusual?  Machine generated? */
6  double _Complex C = (double _Complex){2.0 + I * 3.0};
7
8  glob(1, 2, &((int){0}));
9  }
```

Other Languages

Some languages do not require a type name to be given. The type of the parenthesized list of expressions is deduced from the context in which it occurs.

Example

```
1  extern int n;
2  struct incomplete_type;
3
4  void f(void)
5  {
6  typedef int a_n[n];
7  typedef int a_in[];
8
```

```
(a_n){1, 2, 3}; /* Constraint violation. */

/*
 * Number of elements in array deduced from number of
 * expressions in the parentheses; same as for initializers.
 */
(a_in){4, 5, 6, 7};

(void){1.3, 4};                   /* Constraint violation. */
(struct incomplete_type){'a', 3}; /* Constraint violation. */
}
```

initializer value not contained in unnamed object

No initializer shall attempt to provide a value for an object not contained within the entire unnamed object specified by the compound literal. 1055

Commentary

initializer 1642 value not contained in object

This is the compound literal equivalent of a constraint on initializers for object definitions. The object referred to here is the object being initialized, not other objects declared within the translation unit (or even unnamed object). For instance:

```
void f(int p)
{
struct s_r {
            int mem_1,
                mem_2;
            int *mem_3;
            };

(int []){ p = 1, /* Also provide a value for p. */
              2};

(struct s_r){1, 7,
             &(([2]){5, 6})}; /* Provide a value for an anonymous object. */
}
```

Example

```
struct TAG {
            int mem;
            };

void f(void)
{
/*
 * More expressions that do not have elements in the array.
 */
(int [3]){0, 1, 2, 3}; /* Constraint violation. */
(int [3]){0, [4] = 1}; /* Constraint violation. */
(struct TAG){5, 6};    /* Constraint violation. */
}
```

If the compound literal occurs outside the body of a function, the initializer list shall consist of constant expressions. 1056

Commentary

All objects defined outside the body of a function have static storage duration. The storage for such objects is initialized before program startup, so can only consist of constant expressions. This constraint only differs from an equivalent one for initializers by being framed in terms of "occurring outside the body of a function" rather than "an object that has static storage duration."

1065 compound literal
151 static storage duration
455 initialized before program startup
1644 initializer
static storage duration object

Semantics

1057 A postfix expression that consists of a parenthesized type name followed by a brace-enclosed list of initializers is a *compound literal*.

compound literal

Commentary

This defines the term *compound literal*. A compound literal differs from an initializer list in that it can occur outside of an object definition. Because their need be no associated type definition, a type name must be specified (for initializers the type is obtained from the type of the object being initialized).

1641 initialization
syntax

Other Languages

A form of compound literals are supported in some languages (e.g., Ada, Algol 68, CHILL, and Extended Pascal). These languages do not always require a type name to be given. The type of the parenthesized list of expressions is deduced from the context in which it occurs.

Coding Guidelines

From the coding guideline point of view, the use of compound literals appears fraught with potential pitfalls, including the use of the term *compound literal* which suggests a literal value, not an unnamed object. However, this construct is new in C99 and there is not yet sufficient experience in their use to know if any specific guideline recommendations might apply to them.

1066 compound literal
inside function body
1061 compound literal
is lvalue

1058 It provides an unnamed object whose value is given by the initializer list.[81)]

compound literal
unnamed object

Commentary

The difference between this kind of unnamed object and that created by a call to a memory allocation function (e.g., `malloc`) is that its definition includes a type and it has a storage duration other than allocated (i.e., either static or automatic).

Other Languages

Some languages treat their equivalent of compound literals as just that, a literal. For instance, like other literals, it is not possible to take their address.

Common Implementations

In those cases where a translator can deduce that storage need not be allocated for the unnamed object, the as-if rule can be used, and it need not allocate any storage. This situation is likely to occur for compound literals because, unless their address is taken (explicitly using the address-of operator, or in the case of an array type implicit conversion to pointer type), they are only assigned a value at one location in the source code. At their point of definition, and use, a translator can generate machine code that operates on their constituent values directly rather than copying them to an unnamed object and operating on that.

Coding Guidelines

Guideline recommendations applicable to the unnamed object are the same as those that apply to objects having the same storage duration. For instance, the guideline recommendation dealing with assigning the address of objects to pointers.

1088.1 object
address assigned

Example

The following example not only requires that storage be allocated for the unnamed object created by the compound literal, but that the value it contains be reset on every iteration of the loop.

```
1  struct s_r {
2             int mem;
3             };
4
5  extern void glob(struct s_r *);
6
7  void f(void)
8  {
9  struct s_r *p_s_r;
10
11 while (p_s_r->mem != 10)
12    {
13    glob(p = &((struct s_r){1});
14 /*
15  * Instead of writing the above we could have written:
16  *    struct s_r unnamed_s_r = {1};
17  *    glob (p_s_r = &unnamed_s_r);
18  * which assigns 1 to the member on every iteration, as
19  * part of the process of defining the object.
20  */
21    p_s_r->mem++; /* Increment value held by unnamed object. */
22    }
23 }
```

If the type name specifies an array of unknown size, the size is determined by the initializer list as specified in 6.7.8, and the type of the compound literal is that of the completed array type. 1059

Commentary

array of unknown size initialized 1683

This behavior is discussed elsewhere.

Coding Guidelines

array incomplete type 1573

The some of the issues involved in declaring arrays having an unknown size are discussed elsewhere.

Otherwise (when the type name specifies an object type), the type of the compound literal is that specified by the type name. 1060

Commentary

Presumably this is the declared type of the unnamed object initialized by the initializer list and therefore also its effective type.

effective type 948

---

compound literal is lvalue

In either case, the result is an lvalue. 1061

Commentary

lvalue 721

lvalue converted to value 725

While the specification for a compound literal meets the requirements needed to be an lvalue, wording elsewhere might be read to imply that the result is not an lvalue. This specification clarifies the behavior.

Other Languages

rvalue 736

Some languages consider, their equivalent of, compound literals to be just that, literals. For such languages the result is an rvalue.

---

footnote 81

81) Note that this differs from a cast expression. 1062

Commentary

A cast operator takes a single scalar value (if necessary any lvalue is converted to its value) as its operand and returns a value as its result.

Coding Guidelines

Developers are unlikely to write expressions, such as `(int){1}`, when `(int)1` had been intended (on standard US PC-compatible keyboards the pair of characters *({* and the pair *) }* appear on four different keys). Such usage may occur through the use of parameterized macros. However, at the time of this writing there is insufficient experience with use of this new language construct to know whether any guideline recommendation is worthwhile.

Example

The following all assign a value to `loc`. The first two assignments involve an lvalue to value conversion. In the second two assignments the operand being assigned is already a value.

```
1   extern int glob = 1;
2
3   void f(void)
4   {
5   int loc;
6
7   loc=glob;
8   loc=(int){1};
9
10  loc=2;
11  loc=(int)2;
12  }
```

1063 For example, a cast specifies a conversion to scalar types or **`void`** only, and the result of a cast expression is not an lvalue.

Commentary

These are restrictions on the types and operands of such an expression and one property of its result.

1134 cast
scalar or void type
1131 footnote 85

Example

```
1   &(int)x;   /* Constraint violation. */
2   &(int){x}; /* Address of an unnamed object containing the current value of x. */
```

1064 The value of the compound literal is that of an unnamed object initialized by the initializer list.

Commentary

The distinction between a compound literal acting as if the initializer list was its value, and an unnamed object (initialized with values from the initializer list) being its value, is only apparent when the address-of operator is applied to it. The creation of an unnamed object does not mean that locally allocated storage is a factor in this distinction. Implementations of languages where compound literals are defined to be literals sometimes use locally allocated temporary storage to hold their values. C implementations may find they can optimize away allocation of any actual unnamed storage.

Common Implementations

If a compound literal occurs in a context where its value is required (e.g., assignment) there are obvious opportunities for implementations to use the values of the initializer list directly. C99 is still too new to know whether most implementations will make use of this optimization.

Coding Guidelines

The distinction between the value of a compound literal being an unnamed object and being the values of the initializer list could be viewed as an unnecessary complication that is not worth educating a developer about. Until more experience has been gained with the kinds of mistakes developers make with compound literals, it is not possible to recommend any guidelines.

Example

```
#include <string.h>

struct TAG {
            int mem_1;
            float mem_2;
           };

struct TAG o_s1 = (struct TAG){1, 2.3};

void f(void)
{
memcpy(&o_s1, &(struct TAG){4, 5.6}, sizeof(struct TAG));
}
```

---

compound literal outside function body

If the compound literal occurs outside the body of a function, the object has static storage duration; 1065

Commentary

storage 448 duration object

This specification is consistent with how other object declarations, outside of function bodies, behave. The storage duration of a compound literal is based on the context in which it occurs, not whether its initializer list consists of constant expressions.

```
struct s_r {
           int mem;
           };

static struct s_r glob =              {4};
static struct s_r bolg =  (struct s_r){4}; /* Constraint violation. */
static struct s_r *p_g = &(struct s_r){4};

void f(void)
{
static struct s_r  loc =              {4};
static struct s_r  col =  (struct s_r){4}; /* Constraint violation. */
static struct s_r *p_l = &(struct s_r){4}; /* Constraint violation. */
}
```

Other Languages

The storage duration specified by other languages, which support some form of compound literal, varies. Some allow the developer to choose (e.g., Algol 68), others require them to be dynamically allocated (e.g., Ada), while in others (e.g., Fortran and Pascal) the issue is irrelevant because it is not possible to obtain their address.

---

compound literal inside function body

otherwise, it has automatic storage duration associated with the enclosing block. 1066

Commentary

A parallel can be drawn between an object definition that includes an initializer and a compound literal (that is the definition of an unnamed object). The lifetime of the associated objects starts when the block that

458 object lifetime from entry to exit of block
462 initialization performed every time declaration reached
1711 object initializer evaluated when
1026 function call recursive
1078 EXAMPLE compound literal single object

contains their definition is entered. However, the objects are not assigned their initial value, if any, until the declaration is encountered during program execution.

The unnamed object associated with a compound literal is initialized each time the statement that contains it is encountered during program execution. Previous invocations, which may have modified the value of the unnamed object, or nested invocations in a recursive call, do not affect the value of the newly created object. Storage for the unnamed object is created on block entry. Executing a statement containing a compound literal does not cause any new storage to be allocated. Recursive calls to a function containing a compound literal will cause different storage to be allocated, for the unnamed object, for each nested call.

```
1   struct foo {
2               struct foo *next;
3               int i;
4               };
5
6   void WG14_N759(void)
7   {
8   struct foo *p,
9               *q;
10  /*
11   * The following loop ...
12   */
13  p = NULL;
14  for (int j = 0; j < 10; j++)
15     {
16     q = &((struct foo){ .next = p, .i = j });
17     p = q;
18     }
19  /*
20   * ... is equivalent to the loop below.
21   */
22  p = NULL;
23  for (int j = 0; j < 10; j++)
24     {
25     struct foo T;
26
27     T.next = p;
28     T.i = j;
29     q = &T;
30     p = q;
31     }
32  }
```

Common Implementations

To what extent is it worth trying to optimize compound literals made up of a list of constant expressions; for instance, by detecting those that are never modified, or by placing them in a static region of storage that can be copied from or pointed at? The answer to these and many other optimization issues relating to compound literals will have to wait until translator vendors get a feel for how their customers use this new, to C, construct.

Coding Guidelines

Parallels can be drawn between the unnamed object associated with a compound literal and the temporaries created in C++. Experience has shown that C++ developers sometimes assume that the lifetime of a temporary is greater than it is required to be by that languages standard. Based on this experience it is to be expected that developers using C might make similar mistakes with the lifetime of the unnamed object associated with a compound literal. Only time will tell whether these mistakes will be sufficiently common, or serious, that the benefits of being able to apply the address-of operator to a compound literal (the operator that needs to be used to extend the range of statements over which an unnamed object can be accessed) are outweighed by the probably cost of faults.

object address assigned 1088.1

The guideline recommendation dealing with assigning the address of an object to a pointer object, whose lifetime is greater than that of the addressed object, is applicable here.

```
#include <stdlib.h>

extern int glob;
struct s_r {
           int mem;
           };

void f(void)
{
struct s_r *p_s_r;

if (glob == 0)
   {
   p_s_r = &((struct s_r){1});
   }
else
   {
   p_s_r = &((struct s_r){2});
   }
/* The value of p_s_r is indeterminate here. */

/*
 * The iteration-statements all enclose their associated bodies in
 * a block.  The effect of this block is to start and terminate
 * the lifetime of the contained compound literal.
 */
p_s_r=NULL;
while (glob < 10)
   {
   /*
    * In the following test the value of p_s_r is indeterminate
    * on the second and subsequent iterations of the loop.
    */
   if (p_s_r == NULL)
      ;
   p_s_r = &((struct s_r){1});
   }
}
```

All the semantic rules and constraints for initializer lists in 6.7.8 are applicable to compound literals.[82)] 1067

Commentary

They are the same except

- initializer lists don't create objects, they are simply a list of values with which to initialize an object; and
- the type is deduced from the object being initialized, not a type name.

Coding Guidelines

initialization syntax 1641

Many of the coding guideline issues discussed for initializers also apply to compound literals.

String literals, and compound literals with const-qualified types, need not designate distinct objects.[83)] 1068

string literal distinct object
compound literal distinct object

Commentary

A strictly conforming program can deduce if an implementation uses the same object for two string literals, or compound literals, by performing an equality comparison on their addresses (an infinite number of comparisons would be needed to deduce whether an implementation always used distinct objects). This permission for string literals is also specified elsewhere.

1076 EXAMPLE string literals shared
908 string literal distinct array

The only way a const-qualified object can be modified is by casting a pointer to it to a non-const-qualified pointer. Such usage results in undefined behavior. The undefined behavior, if the pointer was used to modify such an unnamed object that was not distinct, could also modify the values of other compound literal object values.

746 pointer converting qualified/unqualified

Other Languages

Most languages do not consider any kind of literal to be modifiable, so whether they share the same storage locations is not an issue.

Common Implementations

The extent to which developers will use compound literals having a const-qualified type, for which storage is allocated and whose values form a sharable subset with another compound literal, remains to be seen. Without such usage it is unlikely that implementors of optimizers will specifically look for savings in this area, although they may come about as a consequence of optimizations not specifically aimed at compound literals.

Example

In the following there is an opportunity to overlay the two unnamed objects containing zero values.

```
1   const int *p1 = (const int [99]){0};
2   const int *p2 = (const int [20]){0};
```

1069 EXAMPLE 1 The file scope definition

```
int *p = (int []){2, 4};
```

initializes **p** to point to the first element of an array of two ints, the first having the value two and the second, four. The expressions in this compound literal are required to be constant. The unnamed object has static storage duration.

Commentary

This usage, rather than the more obvious `int p[] = {2, 4};`, can arise because the initialization value is derived through macro replacement. The same macro replacement is used in noninitialization contexts.

1070 EXAMPLE 2 In contrast, in

```
void f(void)
{
        int *p;
        /* ... */
        p = (int [2]){*p};
        /* ... */
}
```

p is assigned the address of the first element of an array of two ints, the first having the value previously pointed to by **p** and the second, zero. The expressions in this compound literal need not be constant. The unnamed object has automatic storage duration.

Commentary

The assignment of values to the unnamed object occurs before the value of the right operand is assigned to p.

Example

The above example is not the same as declaring p to be an array.

```
1  void f(void)
2  {
3  int p[2]; /* Storage for p is created by its definition. */
4
5  /*
6   * Cannot assign new object to p, can only change existing values.
7   */
8  p[1]=0;
9  }
```

EXAMPLE 3 Initializers with designations can be combined with compound literals. Structure objects created using compound literals can be passed to functions without depending on member order: 1071

```
drawline((struct point){.x=1, .y=1},
         (struct point){.x=3, .y=4});
```

Or, if **drawline** instead expected pointers to **struct point**:

```
drawline(&(struct point){.x=1, .y=1},
         &(struct point){.x=3, .y=4});
```

Commentary

This usage removes the need to create a temporary in the calling function. The arguments are passed by value, like any other structure argument.

EXAMPLE 4 A read-only compound literal can be specified through constructions like: 1072

```
(const float []){1e0, 1e1, 1e2, 1e3, 1e4, 1e5, 1e6}
```

Commentary

An implementation may choose to place the contents of this compound literal in read-only memory, but it is not required to do so. The term *read-only* is something of a misnomer, since it is possible to cast its address to a non-const-qualified type and assign to the pointed-to object. (The behavior is undefined, but unless the values are held in a kind of storage that cannot be modified, they are likely to be modified.)

Other Languages

Some languages support a proper read-only qualifier.

Common Implementations

On some freestanding implementations this compound literal might be held in ROM.

---

footnote 82

82) For example, subobjects without explicit initializers are initialized to zero. 1073

Commentary

initializer 1682 fewer in list than members

This behavior reduces the volume of the visible source code when the object type includes large numbers of members or elements.

Coding Guidelines

initialization 1641 syntax

Some of the readability issues applicable to statements have different priorities than those for declarations. These are discussed elsewhere.

---

footnote 83

83) This allows implementations to share storage for string literals and constant compound literals with the same or overlapping representations. 1074

Commentary

The need to discuss an implementation's ability to share storage for string literals occurs because it is possible to detect such sharing in a conforming program (e.g., by comparing two pointers assigned the addresses of two distinct, in the visible source code, string literals). The C Committee choose to permit this implementation behavior. (There were existing implementations, when the C90 Standard was being drafted, that shared storage.)

1075 EXAMPLE 5 The following three expressions have different meanings:

```
"/tmp/fileXXXXXX"
(char []){"/tmp/fileXXXXXX"}
(const char []){"/tmp/fileXXXXXX"}
```

The first always has static storage duration and has type array of **char**, but need not be modifiable; the last two have automatic storage duration when they occur within the body of a function, and the first of these two is modifiable.

Commentary

In all three cases, a pointer to the start of storage is returned and the first 16 bytes of the storage allocated will have the same set of values. If all three expressions occurred in the same source file, the first and third could share the same storage even though their storage durations were different. Developers who see a potential storage saving in using a compound literal instead of a string literal (the storage for one only need be allocated during the lifetime of its enclosing block) also need to consider potential differences in the number of machine code instructions that will be generated. Overall, there may be no savings.

1076 EXAMPLE string literals shared

1076 EXAMPLE 6 Like string literals, const-qualified compound literals can be placed into read-only memory and can even be shared. For example,

EXAMPLE string literals shared

```
(const char []){"abc"} == "abc"
```

might yield 1 if the literals' storage is shared.

Commentary

In this example pointers to the first element of the compound literal and a string literal are being compared for equality. Permission to share the storage allocated for a compound literal only applies to those having a const-qualified type (there is no such restriction on string literals).

1068 compound literal distinct object
908 string literal distinct array

Coding Guidelines

Comparing string using an equality operator, rather than a call to the `strcmp` library function is a common beginner mistake. Training is the obvious solution.

Usage

In the visible source of the `.c` files 0.1% of string literals appeared as the operand of the equality operator (representing 0.3% of the occurrences of this operator).

1077 EXAMPLE 7 Since compound literals are unnamed, a single compound literal cannot specify a circularly linked object. For example, there is no way to write a self-referential compound literal that could be used as the function argument in place of the named object **endless_zeros** below:

```
struct int_list { int car; struct int_list *cdr; };
struct int_list endless_zeros = {0, &endless_zeros};
eval(endless_zeros);
```

Commentary

A modification using pointer types, and an additional assignment, creates a circularly linked list that uses the storage of the unnamed object:

```
struct int_list { int car; struct int_list *cdr; };
struct int_list *endless_zeros = &(struct int_list){0, 0};

endless_zeros->cdr=endless_zeros; /* Let's follow ourselves. */
```

The following statement would not have achieved the same result:

```
endless_zeros = &(struct int_list){0, endless_zeros};
```

because the second compound literal would occupy a distinct object, different from the first. The value of `endless_zeros` in the second compound literal would be pointing at the unnamed object allocated for the first compound literal.

Other Languages

Algol 68 supports the creation of circularly linked objects (see the Other Languages subsection in the following C sentence).

EXAMPLE compound literal single object

EXAMPLE 8 Each compound literal creates only a single object in a given scope: 1078

```
struct s { int i; };

int f (void)
{
        struct s *p = 0, *q;
        int j = 0;

again:
        q = p, p = &((struct s){ j++ });
        if (j < 2) goto again;

        return p == q && q->i == 1;
}
```

The function **f()** always returns the value 1.

Note that if an iteration statement were used instead of an explicit **goto** and a labeled statement, the lifetime of the unnamed object would be the body of the loop only, and on entry next time around **p** would have an indeterminate value, which would result in undefined behavior.

Commentary

Specifying that a single object is created helps prevent innocent-looking code consuming large amounts of storage (e.g., use of a compound literal in a loop).

Other Languages

In Algol 68 **LOC** creates storage for block scope objects. However, it generates new storage every time it is executed. The following allocates 1,000 objects on the stack.

```
MODE M = STRUCT (REF M next, INT i);
M p;
INT i := 0

again:
    p := LOC M := (p, i);
    i +:= 1;
    IF i < 1000 THEN
       GO TO again
    FI;
```

1079 **Forward references:** type names (6.7.6), initialization (6.7.8).

6.5.3 Unary operators

unary-expression syntax

1080

```
unary-expression:
                postfix-expression
                ++ unary-expression
                -- unary-expression
                unary-operator cast-expression
                sizeof unary-expression
                sizeof ( type-name )
unary-operator: one of
                &  *  +  -  ~  !
```

Commentary

Note that the operand of unary-operator is a *cast-expression*, not a *unary-expression*. A unary operator usually refers to an operator that takes a single argument. Technically all of the operators listed here, plus the postfix increment and decrement operators, could be considered as being unary operators.

1133 cast-expression syntax

Unary plus was adopted by the C89 Committee from several implementations, for symmetry with unary minus. Rationale

Other Languages

Some languages (i.e., Ada and Pascal) specify the unary operators to have lower precedence than the multiplicative operators; for instance, `-x/y` is equivalent to `-(x/y)` in Ada, but `(-x)/y` in C. Most languages call all operators that take a single-operand unary operators.

1143 multiplicative-expression syntax

Languages that support the unary `+` operator include Ada, Fortran, and Pascal. Some languages use the keyword **NOT** rather than `!`. In the case of Cobol this keyword can also appear to the left of an operator, indicating negation of the operator (i.e., **NOT** < meaning not less than).

Coding Guidelines

Coding guidelines need to be careful in their use of the term *unary operator*. Its meaning, as developers understand it, may be different from its actual definition in C. The operators in a *unary-expression* occur to the left of the operand. The only situation where a developer's incorrect assumption about precedence relationships might lead to a difference between predicted and actual behavior is when a postfix operator occurs immediately to the right of the *unary-expression*.

Dev 943.1

Except when *sizeof (type-name)* is immediately followed visually by a token having the lexical form of an additive operator, if a *unary-expression* is not immediately followed by a postfix operator it need not be parenthesized.

Although the expression `sizeof (int)-1` may not occur in the visible source code, it could easily occur as the result of macro replacement of the operand of the **sizeof** operator. This is one of the reasons behind the guideline recommendation specifying the parenthesizing of macro bodies (without parentheses the expression is equivalent to `(sizeof(int))-1`).

1931.2 macro definition expression

Example

```
1  struct s {
2            int x;
3            };
```

```
4   struct s *a;
5   int x;
6
7   void f(void)
8   {
9   x<-a->x;
10  x<--a->x;
11  x<- --a->x;
12  x<- - --a->x;
13
14  sizeof(long)-3; /* Could be mistaken for sizeof a cast-expression. */
15  (sizeof(long))-3;
16  sizeof((long)-3);
17  }
```

Usage

postfix-985 expression syntax

See the Usage section of *postfix-expression* for `++` and `--` digraph percentages.

Table 1080.1: Common token pairs involving **sizeof**, *unary-operator*, prefix `++`, or prefix `--` (as a percentage of all occurrences of each token). Based on the visible form of the `.c` files.

Token Sequence	% Occurrence of First Token	% Occurrence of Second Token	Token Sequence	% Occurrence of First Token	% Occurrence of Second Token
`!` defined	2.0	16.7	`!` `(`	14.5	0.5
`*v --v`	0.3	7.8	`-v` identifier	30.2	0.4

6.5.3.1 Prefix increment and decrement operators

Constraints

1081 The operand of the prefix increment or decrement operator shall have qualified or unqualified real or pointer type and shall be a modifiable lvalue.

postfix operator operand

Commentary

This constraint mirrors that for the postfix forms of these operators.

1081 postfix operator operand

C++

The use of an operand of type **bool** with the prefix ++ operator is deprecated (5.3.2p1); there is no corresponding entry in Annex D, but the proposed response to C++ DR #145 inserted one. In the case of the decrement operator:

> *The operand shall not be of type* ***bool****.* 5.3.2p1

A C source file containing an instance of the prefix -- operator applied to an operand having type **_Bool** is likely to result in a C++ translator issuing a diagnostic.

Coding Guidelines

Enumerated types are usually thought about in symbolic rather than arithmetic terms. The increment and decrement operators can also be given a symbolic interpretation. They are sometimes thought about in terms of moving on to the next symbolic name in a list. This *move to next* operation relies on the enumeration constants being represented by successive numeric values. While this usage is making use of representation information, there is often a need to step through a series of symbolic names (and C provides no other built-in mechanism), for instance, iterating over the named constants defined by an enumerated type.

822 symbolic name
517 enumeration set of named constants
1199 relational operators real operands

Dev 569.1 The operand of a prefix increment or decrement operator may have an enumerated type, provided the enumeration constants defined by that type have successive numeric values.

Semantics

prefix ++ incremented

The value of the operand of the prefix ++ operator is incremented. 1082

Commentary

postfix ++ result 1047

The ordering of this and the following C sentence is the reverse of that specified for the postfix ++ operator.

Common Implementations

The implementation of this operator is usually very straight-forward. A value is loaded into a register, incremented, and then stored back into the original object, leaving the result in the register. Some CISC processors contain instructions that increment the contents of storage directly. Processors that have a stack-based architecture either need to contain store instructions that leave the value on the stack, or be willing to pay the penalty of another load from storage.

Coding Guidelines

Translators have now progressed to the point where the optimizations many of them perform are much more sophisticated than those needed to detect the more verbose sequence of operations equivalent to the prefix ++ operator. The writers of optimizers study existing source code to find out what constructs occur frequently (they don't want to waste time and money implementing optimizations for constructs that rarely occur). However, in existing code it is rare to see an object being incremented (or decremented) without one of these operators being used. Consequently optimizers are unlikely to attempt to transform the C source `i=i+1` into `++i` (which they might have to do for say Pascal, which has no increment operators requiring optimizers to analyze an expression looking for operations that are effectively increment object). So the assertion that `++i` can be written as `i=i+1` and that it will be optimized by the translator is not guaranteed, even for a highly optimizing translator. However, this is rarely an important issue anyway; the difference in quality of generated machine code rarely has any impact on program performance.

From the coding guidelines perspective, uses of these operators can be grouped into three categories:

1. The only operator in an expression statement. In this context the result returned by the operation is ignored. The statement simply increments/decrements its operand. Use of the prefix, rather than the postfix, form does not follow the pattern seen at the start of most visible source code statement lines—an identifier followed by an operator (see Figure 940.2). A reader's scanning of the source looking for objects that are modified will be disrupted by the initial operator. For this reason, use of the postfix form is recommended.

   postfix operator constraint 1046

2. One of the operators in a full expression that contains other operators. It is possible to write the code so that a prefix operator does not occur in the same expression as other operators. The evaluation can be moved back before the containing expression (see the postfix operators for a fuller discussion of this point).

   full expression 1712

   postfix operator constraint 1046

   ```
   ...++i...
   ```

   becomes the equivalent form:

   ```
   i++;
   ...i...
   ```

   The total cognitive effort needed to comprehend the equivalent form may be less than the prefix form, and the peak effort is likely to be less (because the operations may have been split into smaller chunks in serial rather than nested form).

3. The third point is the same as for the postfix operators.

   postfix operator constraint 1046

Cg 1082.1

The prefix operators shall not appear in an expression statement.

1083 The result is the new value of the operand after incrementation.

prefix ++ result

Other Languages

Pascal contains the **succ** operator. This returns the successor value (i.e., it adds one to its operand), but it does not modify the value of an object appearing as its operand.

1084 The expression `++E` is equivalent to `(E+=1)`.

Commentary

The expression ++E need not be equivalent to E=E+1 (e.g., the expression E may contain a side effect).

C++

C++ lists an exception (5.3.2p1) for the case when E has type **bool**. This is needed because C++ does not define its boolean type in the same way as C. The behavior of this operator on operands is defined as a special case in C++. The final result is the same as in C.

476 _Bool large enough to store 0 and 1

1085 See the discussions of additive operators and compound assignment for information on constraints, types, side effects, and conversions and the effects of operations on pointers.

prefix operators see also

Commentary

The same references are given for the postfix operators.

1050 postfix operators see also

C++

[Note: see the discussions of addition (5.7) and assignment operators (5.17) for information on conversions.] 5.3.2p1

There is no mention that the conditions described in these clauses also apply to this operator.

1086 The prefix -- operator is analogous to the prefix ++ operator, except that the value of the operand is decremented.

Commentary

The same Commentary and Coding Guidelines' issues also apply. See the discussion elsewhere for cases where the affects are not analogous.

1082 prefix ++ incremented
1052 postfix -- analogous to ++

C++

The prefix **--** operator is not analogous to the prefix **++** operator in that its operand may not have type **bool**.

Other Languages

Pascal contains the **pred** reserved identifier. This returns the predecessor value, but does not modify the value of its operand.

Coding Guidelines

The guideline recommendation for the prefix **++** operator has been worded to apply to either operator.

1082.1 prefix in expression statement

1087 **Forward references:** additive operators (6.5.6), compound assignment (6.5.16.2).

6.5.3.2 Address and indirection operators

Constraints

1088 The operand of the unary **&** operator shall be either a function designator, the result of a **[]** or unary * operator, or an lvalue that designates an object that is not a bit-field and is not declared with the **register** storage-class specifier.

unary & operand constraints

Commentary

bit-field 1410 packed into

byte 53 addressable unit

register 1369 storage-class

Bit-fields are permitted (intended even) to occupy part of a storage unit. Requiring bit addressing could be a huge burden on implementations. Very few processors support bit addressing and C is based on the byte being the basic unit of addressability.

The **register** storage-class specifier is only a hint to the translator. Taking the address of an object could effectively prevent a translator from keeping its value in a register. A harmless consequence, but the C Committee decided to make it a constraint violation.

C90

The words:

> *. . . , the result of a* **[ ]** *or unary* * *operator,*

are new in C99 and were added to cover the following case:

```
int a[10];

for (int *p = &a[0]; p < &a[10]; p++)
    /* ... */
```

where C90 requires the operand to refer to an object. The expression `a+10` exists, but does not refer to an object. In C90 the expression `&a[10]` is undefined behavior, while C99 defines the behavior.

C++

Like C90 the C++ Standard does not say anything explicit about the result of a **[]** or unary * operator. The C++ Standard does not explicitly exclude objects declared with the **register** storage-class specifier appearing as operands of the unary **&** operator. In fact, there is wording suggesting that such a usage is permitted:

7.1.1p3 > *A* **register** *specifier has the same semantics as an* **auto** *specifier together with a hint to the implementation that the object so declared will be heavily used. [Note: the hint can be ignored and in most implementations it will be ignored if the address of the object is taken. —end note]*

Source developed using a C++ translator may contain occurrences of the unary **&** operator applied to an operand declared with the **register** storage-class specifier, which will cause a constraint violation if processed by a C translator.

```
void f(void)
{
register int a[10]; /* undefined behavior */
                    // well-formed

&a[1]  /* constraint violation */
       // well-formed
     ;
}
```

Other Languages

Many languages that support pointers have no address operator (e.g., Pascal and Java, which has references, not pointers). In these languages, pointers can only point at objects returned by the memory-allocation functions. The address-of operator was introduced in Ada 95 (it was not in available in Ada 83). Many languages do not allow the address of a function to be taken.

Coding Guidelines

In itself, use of the address-of operator is relatively harmless. The problems occur subsequently when the value returned is used to access storage. The following are three, coding guideline related, consequences of being able to take the address of an object:

- It provides another mechanism for accessing the individual bytes of an object representation (a pointer to an object can be cast to a pointer to character type, enabling the individual bytes of an object representation to be accessed). 761 pointer converted to pointer to character
- It is an alias for the object having that address.
- It provides a mechanism for accessing the storage allocated to an object after the lifetime of that object has terminated.

Assigning the address of an object potentially increases the scope over which that object can be accessed. When is it necessary to increase the scope of an object? What are the costs/benefits of referring to an object using its address rather than its name? (If a larger scope is needed, could an objects definition be moved to a scope where it is visible to all source code statements that need to refer to it?)

The parameter-passing mechanism in C is pass by value. What is often known as *pass by reference* is achieved, in C, by explicitly passing the address of an object. Different calls to a function having pass-by-reference arguments can involve different objects in different calls. Passing arguments, by reference, to functions is not a necessity; it is possible to pass information into and out of functions using file scope objects. 1004 function call preparing for

Assigning the address of an object creates an alias for that object. It then becomes possible to access the same object in more than one way. The use of aliases creates technical problems for translators (the behavior implied by the use of the **`restrict`** keyword was introduced into C99 to help get around this problem) and can require developers to use additional cognitive resources (they need to keep track of aliased objects). 1491 restrict intended use

A classification often implicitly made by developers is to categorize objects based on how they are accessed, the two categories being those accessed by the name they were declared with and those accessed via pointers. A consequence of using this classification is that developers overlook the possibility, within a sequence of statements, of a particular object being modified via both methods. When readers are aware of an object having two modes of reference (a name and a pointer dereference) is additional cognitive effort needed to comprehend the source? Your author knows of no research in on this subject. These coding guidelines discuss the aliasing issue purely from the oversight point of view (faults being introduced because of lack of information), because there is no known experimental evidence for any cognitive factors.

One way of reducing aliasing issues at the point of object access is to reduce the number of objects whose addresses are taken. Is it possible to specify a set of objects whose addresses should not be taken and what are the costs of having no alternatives for these cases? Is the cost worth the benefit? Restricting the operands of the address operator to be objects having block scope would limit the scope over which aliasing could occur. However, there are situations where the addresses of objects at file scope needs to be used, including:

- An argument to a function could be an object with block scope, or file scope; for instance, the `qsort` function might be called.
- In resource-constrained environments it may be decided not to use dynamic storage allocation. For instance, all of the required storage may be defined at file scope and pointers to objects within this storage used by the program.
- The return from a function call is sometimes a pointer to an object, holding information. It may simplify storage management if this is a pointer to an object at file scope.

The following guideline recommendation ensures that the storage allocated to an object is not accessed once the object's lifetime has terminated.

Cg 1088.1 The address of an object shall not be assigned to another object whose scope is greater than that of the object assigned.

Dev 1088.1 An object defined in block scope, having static storage duration, may have its address assigned to any other object.

function designator converted to type 732 array converted to pointer 729

A function designator can appear as the operand of the address-of operator. However, taking the address of a function is redundant. This issue is discussed elsewhere. Likewise for objects having an array type.

Example

In the following it is not possible to take the address of a or any of its elements.

```
1  register int a[3];
```

In fact this object is virtually useless (the identifier a can appear as the operand to the **sizeof** operator). If allocated memory is not permitted (we know the memory requirements of the following on program startup):

```
1  extern int *p;
2
3  void init(void)
4  {
5  static int p_obj[20];
6
7  p=&p_obj;
8  }
```

This provides pointers to objects, but hides those objects within a block scope. There is no pointer/identifier aliasing problem.

---

unary * operand has pointer type

The operand of the unary * operator shall have pointer type. 1089

Commentary

unary * result type 1098

Depending on the context in which it occurs, there may be restrictions on the pointed-to type (because of the type of the result).

C++

5.3.1p1 *The unary * operator performs indirection: the expression to which it is applied shall be a pointer to an object type, or a pointer to a function type . . .*

C++ does not permit the unary * operator to be applied to an operand having a pointer to **void** type.

```
1  void *g_ptr;
2
3  void f(void)
4  {
5  &*g_ptr; /* DR #012 */
6           // DR #232
7  }
```

Other Languages

In some languages indirection is a postfix operator; for instance, Pascal uses the token ^ as a postfix operator.

Semantics

1090 The unary & operator yields the address of its operand.

unary & operator

Commentary

For operands with static storage duration, the value of the address operator may be a constant (objects having an array type also need to be indexed with a constant expression). There is no requirement that the address of an object be the same between different executions of the same program image (for objects with static storage duration) or different executions of the same function (for objects with automatic storage duration).

1341 address constant

All external function references are resolved during translation phase 8. Any identifier denoting a function definition will have been resolved.

139 translation phase 8

The C99 Standard refers to this as the *address-of* operator.

1014 footnote 79

C90

This sentence is new in C99 and summarizes what the unary **&** operator does.

C++

Like C90, the C++ Standard specifies a pointer to its operand (5.3.1p1). But later on (5.3.1p2) goes on to say: "In particular, the address of an object of type "*cv* T" is "pointer to *cv* T," with the same cv-qualifiers."

Other Languages

Many languages do not contain an address-of operator. Fortran 95 has an address assignment operator, **=>**. The left operand is assigned the address of the right operand.

Common Implementations

Early versions of K&R C treated p=&x as being equivalent to p&=x.[723]

In the case of constant addresses the value used in the program image is often calculated at link-time. For objects with automatic storage duration, their address is usually calculated by adding a known, at translation time, value (the offset of an object within its local storage area) to the value of the frame pointer for that function invocation. Addresses of elements, or members, of objects can be calculated using the base address of the object plus the offset of the corresponding subobject.

Having an object appear as the operand of the address-of operator causes many implementations to play safe and not attempt to perform some optimizations on that object. For instance, without sophisticated pointer analysis, it is not possible to know which object a pointer dereference will access. (Implementations often assume all objects that have had their address taken are possible candidates, others might use information on the pointed-to type to attempt to reduce the set of possible accessed objects.) This often results in no attempt being made to keep the values of such objects in registers.

Implementations' representation of addresses is discussed elsewhere.

540 pointer type describes a

1091 If the operand has type "*type*", the result has type "pointer to *type*".

Commentary

Although developers often refer to the address returned by the address-of operator, C does not have an *address* type.

1092 If the operand is the result of a unary * operator, neither that operator nor the & operator is evaluated and the result is as if both were omitted, except that the constraints on the operators still apply and the result is not an lvalue.

&*

Commentary

The only effect of the operator pair &* is to remove any lvalueness from the underlying operand. The combination *& returns an lvalue if its operand is an lvalue. This specification is consistent with the behavior of the last operator applied controlling lvalue-ness. This case was added in C99 to cover a number of existing coding idioms; for instance:

1114 footnote 84

1115 *&

```
#include <stddef.h>

void DR_076(void)
{
int *n = NULL;
int *p;

/*
 * The following case is most likely to occur when the
 * expression *n is a macro argument, or body of a macro.
 */
p = &*n;
/* ... */
}
```

C90

The responses to DR #012, DR #076, and DR #106 specified that the above constructs were constraint violations. However, no C90 implementations known to your author diagnosed occurrences of these constructs.

C++

This behavior is not specified in C++. Given that either operator could be overloaded by the developer to have a different meaning, such a specification would be out of place.

At the time of this writing a response to C++ DR #232 is being drafted (a note from the Oct 2003 WG21 meeting says: "We agreed that the approach in the standard seems okay: `p = 0; *p;` is not inherently an error. An lvalue-to-rvalue conversion would give it undefined behavior.").

```
void DR_232(void)
{
int *loc = 0;

if (&*loc == 0) /* no dereference of a null pointer, defined behavior */
                // probably not a dereference of a null pointer.
   ;

&*loc = 0; /* not an lvalue in C */
           // how should an implementation interpret the phrase must not (5.3.1p1)?
}
```

Common Implementations

Some C90 implementations did not optimize the operator pair &* into a no-op. In these implementations the behavior of the unary * operator was not altered by the subsequent address-of operator. C99 implementations are required to optimize away the operator pair &*.

Similarly, if the operand is the result of a `[]` operator, neither the `&` operator nor the unary * that is implied by the `[]` is evaluated and the result is as if the `&` operator were removed and the `[]` operator were changed to a `+` operator. 1093

Commentary

This case was added in C99 to cover a number of coding idioms; for instance:

```
void DR_076(void)
{
int a[10];
int *p;

```

```
6  /*
7   * It is possible to point one past the end of an object.
8   * For instance, we might want to loop over an object, using
9   * this one past the end value.  Given the equivalence that
10  * applies to the subscript operator the operand of & in the
11  * following case is the result of a unary * operator.
12  */
13 p = &a[10];
14
15 for (p = &a[0]; p < &a[10]; p++)
16    /* ... */ ;
17 }
```

C90

This requirement was not explicitly specified in the C90 Standard. It was the subject of a DR #076 that was closed by adding this wording to the C99 Standard.

C++

This behavior is not specified in C++. Given that either operator could be overloaded by the developer to have a different meaning, such a specification would be out of place. The response to C++ DR #232 may specify the behavior for this case.

Common Implementations

This requirement describes how all known C90 implementations behave.

Coding Guidelines

The expression `&a[index]`, in the visible source code, could imply

- a lack of knowledge of C semantics (why wasn't `a+index` written?),
- that the developer is trying to make the intent explicit, and
- that the developer is adhering to a coding standard that recommends against the use of pointer arithmetic— the authors of such standards often view `(a+index)` as pointer arithmetic, but `a[index]` as an array index (the equivalence between these two forms being lost on them).

989 array subscript identical to

1094 Otherwise, the result is a pointer to the object or function designated by its operand.

Commentary

There is no difference between the use of objects having a pointer type and using the address-of operator. For instance, the result of the address-of operator could be assigned to an object having the appropriate pointer type, and that object used interchangeably with the value assigned to it.

Common Implementations

In most implementations a pointer refers to the actual address of an object or function.

540 pointer type describes a

1095 The unary * operator denotes indirection.

unary * indirection

Commentary

The terms *indirection* and *dereference* are both commonly used by developers.

C++

*The unary * operator performs indirection.*

Other Languages

Some languages (e.g., Pascal and Ada) use the postfix operator `^`. Other languages— Algol 68 and Fortran 95— implicitly perform the indirection operation. In this case, an occurrence of operand, having a pointer type, is dereferenced to return the value of the pointed-to object.

Coding Guidelines

Some coding guideline documents place a maximum limit on the number of simultaneous indirection operators that can be successively applied. The rationale being that deeply nested indirections can be difficult to comprehend. Is there any substance to this claim?

sequential nesting * / sequential 1000 nesting ()

Expressions, such as `***p`, are similar to nested function calls in that they have to be comprehended in a right-to-left order. The issue of nested constructions in natural language is discussed in that earlier C sentence. At the time of this writing there is insufficient experimental evidence to enable a meaningful cost/benefit analysis to be performed and these coding guidelines say nothing more about this issue.

If sequences of unary * operators are needed in an expression, it is because an algorithm's data structures make the usage necessary. In practice, long sequences of indirections using the unary * operator are rare. Like the function call case, it may be possible to provide a visual form that provides a higher-level interpretation and hides the implementation's details of the successive indirections.

member 1031 selection

An explicit unary * operator is not the only way of specifying an indirection. Both the array subscript, `[]`, and member selection, `->`, binary operators imply an indirection. Developers rarely use the form `(*s).m` (`(&s)->m`), the form `s->m` (`s.m`) being much more obvious and natural. While the expression `s1->m1->m2->m3` is technically equivalent to `(*(*(*s1).m1).m2).m3`, it is comprehended in a left-to-right order.

Usage

SPEC 0 benchmarks

A study by Mock, Das, Chambers, and Eggers[949] looked at how many different objects the same pointer dereference referred to during program execution (10 programs from the SPEC95 and SPEC2000 benchmarks were used). They found that in 90% to 100% of cases (average 98%) the set of objects pointed at, by a particular pointer dereference, contained one item. They also performed a static analysis of the source using a variety of algorithms for deducing points-to sets. On average (geometric mean) the static points to sets were 3.3 larger than the dynamic points to sets.

If the operand points to a function, the result is a function designator; 1096

Commentary

The operand could be an object, with some pointer to function type, or it could be an identifier denoting a function that has been implicitly converted to a pointer to function type. This result is equivalent to the original function designator. Depending on the context in which it occurs this function designator may be converted to a pointer to function type.

function 731 designator

function 732 designator converted to type

C++

The C++ Standard also specifies (5.3.1p1) that this result is an lvalue. This difference is only significant for reference types, which are not supported by C.

Other Languages

Those languages that support some form of pointers to functions usually only provide a mechanism for, indirect, calls to the designated value. Operators for obtaining the function designator independent of a call are rarely provided. Some languages (e.g., Algol 88, Lisp) provide a mechanism for defining anonymous functions in an expression context, which can be assigned to objects and subsequently called.

Common Implementations

For most implementations the result is an address of a storage location. Whether there is a function definition (translated machine code) at that address is not usually relevant until an attempt is made to call the designated function (using the result).

Coding Guidelines

Because of the implicit conversions a translator is required to perform, the unary * operator is not required to cause the designated function to be called. There are a number of situations that can cause such usage to appear in source code: the token sequence may be in automatically generated source code, or the sequence may occur in developer-written source via arguments passed to macros, or developers may apply it to objects having a pointer to function type because they are unaware of the implicit conversions that need to be performed.

Example

```
1  extern void f(void);
2  extern void (*p_f)(void);
3
4  void g(void)
5  {
6  f();
7  (*f)();
8  (*******f)();
9  (*p_f)();
10 }
```

1097 if it points to an object, the result is an lvalue designating the object.

Commentary

The indirection operator produces a result that allows the pointed-to object to be treated like an anonymous object. The result can appear in the same places that an identifier (defined to be an object of the same type) can appear. The resulting lvalue might not be a modifiable lvalue. There may already be an identifier that refers to the same object. If two or more different access paths to an object exist, it is said to be *aliased*.

724 modifiable lvalue
971 object aliased

Common Implementations

Some processors (usually CISC) have instructions that treat their operand as an indirect reference. For instance, an indirect load instruction obtains its value from the storage location pointed to by the storage location that is the operand of the instruction.

1098 If the operand has type "pointer to *type*", the result has type "*type*".

unary * result type

Commentary

The indirection operator removes one level of pointer from the operand's type. The operand is required to have pointer type. In many contexts the result type of a pointer to function type will be implicitly converted back to a pointer type.

1089 unary * operand has pointer type
732 function designator converted to type

1099 If an invalid value has been assigned to the pointer, the behavior of the unary * operator is undefined.[84)]

Commentary

The standard does not provide an all-encompassing definition of what an *invalid value* is. The footnote gives some examples. An invalid value has to be created before it can be assigned and this may involve a conversion operation. Those pointer conversions for which the standard defines the behavior do not create

1114 footnote 84
743 pointer to void converted to/from

invalid values. So the original creation of the invalid value, prior to assignment, must also involves undefined behavior.

object 461 initial value indeterminate

If no value has been assigned to an object, it has an indeterminate value.

array subscript 989 identical to

The equivalence between the array access operator and the indirection operator means that the behavior of what is commonly known as an *out of bounds array access* is specified here.

C++

The C++ Standard does not explicitly state the behavior for this situation.

Common Implementations

For most implementations the undefined behavior is decided by the behavior of the processor executing the program. The root cause of applying the indirection operator to an invalid valid is often a fault in a program and implementations that perform runtime checks sometimes issue a diagnostic when such an event occurs. (Some vendors have concluded that their customers would not accept the high performance penalty incurred in performing this check, and they don't include it in their implementation.) The result can often be manipulated independently of whether there is an object at that storage location, although some processors do perform a few checks.

pointer 454 cause undefined behavior

Techniques for detecting the dereferencing of invalid pointer values usually incur a significant runtime overhead[65, 681, 690, 1032, 1288] (programs often execute at least a factor of 10 times slower). A recent implementation developed by Dhurjati and Adve[351] reported performance overheads in the range 12% to 69%.

Coding Guidelines

guidelines 0 not faults

This usage corresponds to a fault in the program and these coding guidelines are not intended to recommend against the use of constructs that are obviously faults.

Forward references: storage-class specifiers (6.7.1), structure and union specifiers (6.7.2.1). 1100

6.5.3.3 Unary arithmetic operators

Constraints

The operand of the unary + or - operator shall have arithmetic type; 1101

Commentary

The unary - operator is sometimes passed as a parameter in a macro invocation. In those cases where negation of an operand is not required (in the final macro replacement), the unary + operator can be passed as an argument (empty macro arguments cause problems for some preprocessors). The symmetry of having two operators can also simplify the automatic generation of source code. While it would have been possible to permit the unary + operator to have an operand of any type (since it has no effect other than performing the integer promotions on its operand), it is very unlikely that this operator would ever appear in a context that the unary - operator would not also appear in.

C++

The C++ Standard permits the operand of the unary + operator to have pointer type (5.3.1p6).

Coding Guidelines

While applying the unary minus operator to an operand having an unsigned integer type is seen in some algorithms (it can be a more efficient method of subtracting the value from the corresponding `U*_MAX` macro, in **`<limits.h>`**, and adding one), this usage is generally an oversight by a developer.

Rev 1101.1 The promoted operand of the unary - operator shall not be an unsigned type.

1102 of the ~ operator, integer type;

Commentary

There are algorithms (e.g., in graphics applications) that require the bits in an integer value to be complemented, and processors invariably contain an instruction for performing this operation. Complementing the bits in a floating-point value is a very rarely required operation and processors do not contain such an instruction. This constraint reflects this common usage.

Other Languages

While many languages do not contain an equivalent of the ~ operator, their implementations sometimes include it as an extension.

Coding Guidelines

Some coding guideline documents only recommend against the use of operands having a signed type. The argument is that the representation of unsigned types is defined by the standard, while signed types might have one of several representations. In practice, signed types almost universally have the same representation—two's complement. However, the possibility of variability of integer representation across processors is not the only important issue here. The ~ operator treats its operand as a sequence of bits, not a numeric value. As such it may be making use of representation information and the guideline recommendation dealing with this issue would be applicable.

612 two's complement
569.1 representation information using

1103 of the ! operator, scalar type.

! operand type

Commentary

The logical negation operator is defined in terms of the equality operator, whose behavior in turn is only defined for scalar types.

1113 ! equivalent to
1213 equality operators constraints

C++

The C++ Standard does not specify any requirements on the type of the operand of the ! operator.

> *The operand of the logical negation operator* **!** *is implicitly converted to* **bool** *(clause 4);* 5.3.1p8

But the behavior is only defined if operands of scalar type are converted to **bool**:

> *An rvalue of arithmetic, enumeration, pointer, or pointer to member type can be converted to an rvalue of type* **bool**. 4.12p1

Other Languages

Some languages require the operand to have a boolean type.

Coding Guidelines

The following are two possible ways of thinking about this operator are:

1. As a shorthand form of the != operator in a conditional expression. That is, in the same way the two forms `if (x)` and `if (x == 0)` are equivalent, the two forms `if (!x)` and `if (x != 0)` are equivalent.
2. As a logical negation operator that reverses the state of a boolean value (it can take as its operand a value in either of the possible boolean representation models and map it to the model that uses the 0/1 for its boolean representation).

476 boolean role

A double negative is very often interpreted as a positive statement in English (e.g., "It is not unknown for double negatives to occur in C source"). The same semantics that apply in C. However, in some languages

(e.g., Spanish) a double negative is interpreted as making the statement more negative (this usage does occur in casual English speech, e.g., "you haven't seen nothing yet", but it is rare and frowned on socially[121]).

The token `!` is commonly called the *not* operator. This term is a common English word whose use in a sentence is similar to its use in a C expression. Through English language usage the word *not*, or an equivalent form, can appear as part of an identifier spelling (e.g., `not_finished`, `no_signal`, or `unfinished`). The use of such identifiers in an expression can create a double negative (e.g., `!not_finished` or `not_finished != 1`).

English 792 negation

A simple expression containing a double negation is likely to require significantly more cognitive resources to comprehend than a one that does not. Changing the semantic associations of an identifier from (those implied by) `not_finished` to `finished` would require that occurrences of `not_finished` be changed to `!finished` (plus associated changes to any appearances of the identifier as the operand of the `!` or the equality operators).

Calculating the difference in cognitive cost/benefit between using an identifier spelling that represents a negated form and one that does not requires information on a number of factors. For instance, whether any double negative forms actually appear in the source, the extent to which the *not* spelling form provides a good fit to the application domain, and any cognitive cost differences between the alternative forms `not_finished` and `!finished`. Given the uncertainty in the cost/benefit analysis no guideline recommendation is given here.

Table 1103.1: Occurrence of the unary `!` operator in various contexts (as a percentage of all occurrences of this operator and the percentage of all occurrences of the given context that contains this operator). Based on the visible form of the `.c` files.

Context	% of `!`	% of Contexts
`if` control-expression	91.0	17.4
`while` control-expression	2.3	8.2
`for` control-expression	0.3	0.7
`switch` control-expression	0.0	0.0
other contexts	6.4	—

Semantics

The result of the unary + operator is the value of its (promoted) operand. 1104

Commentary

Also, the result of the unary **+** is not an lvalue.

Other Languages

Many languages do not include a unary **+** operator.

Common Implementations

Early versions of K&R C treated `p=+2` as being equivalent to `p+=2`.[723]

Coding Guidelines

One use of the unary **+** operator is to remove the lvalue-ness of an object appearing as an argument in a macro invocation. This usage guarantees that the object passed as an argument cannot be modified or have its address taken.

Use of the unary **+** operator is very rare in developer-written source. If it appears immediately after the **=** operator in existing code, the possible early K&R interpretation might be applicable. The usage is now sufficiently rare that a discussion on whether to do nothing, replace every occurrence by the sequence **+=**, introduce a separating white-space character, parenthesize the value being assigned, or do something else is not considered worthwhile.

Example

```
/*
 * Sum up to three values.  Depending on the arguments
 * passed + is either a unary or binary operator.
 */
#define ADD3(a, b, c)    (a + b + c + 0)

        ADD3(1, 2, 3) => (1 + 2 + 3 + 0)
        ADD3(1, 2,  ) => (1 + 2 +   + 0)
        ADD3(1,  , 3) => (1 +   + 3 + 0)
        ADD3(1,  ,  ) => (1 +   +   + 0)
        ADD3( ,  ,  ) => (  +   +   + 0)
```

1105 The integer promotions are performed on the operand, and the result has the promoted type.

Commentary

The two contexts in which the integer promotions would not be performed, unless the unary + operator is applied, are the right operand of a simple assignment and the operand of the **`sizeof`** operator.

1303 simple assignment
1119 sizeof result of

1106 The result of the unary - operator is the negative of its (promoted) operand.

Commentary

The expression `-x` is not always equivalent to `0-x`; for instance, if `x` has the value `0.0`, the results will be `-0.0` and `0.0`, respectively.

Common Implementations

Most processors include a single instruction that performs the negation operation. On many RISC processors this instruction is implemented by the assembler using an alias of the subtract instruction (for integer operands only). On such processors there is usually a register hardwired to contain the value zero (the IBM/Motorola PowerPC[969] does not); subtracting the operand from this register has the required effect. For IEC 60559 floating-point representations, the negation operator simply changes the value of the sign bit.

Coding Guidelines

If the operand has an unsigned type, the result will always be a positive or zero value. This issue is discussed elsewhere.

1101.1 unary minus unsigned operand

Example

The expression `-1` is the unary `-` operator applied to the integer constant `1`.

1107 The integer promotions are performed on the operand, and the result has the promoted type.

Commentary

Because unary operators have a single operand, it is not necessary to perform the usual arithmetic conversions (the integer promotions are performed on the operands of the unary operators for the same reason).

706 usual arithmetic conversions
675 integer promotions

Coding Guidelines

The integer promotions may convert an unsigned type to a signed type. However, this can only happen if the signed type can represent all of the values of the unsigned type. This is reflected in the guideline recommendation for unsigned types.

715 signed integer represent all unsigned integer values
1101.1 unary minus unsigned operand

1108 The result of the ~ operator is the bitwise complement of its (promoted) operand (that is, each bit in the result is set if and only if the corresponding bit in the converted operand is not set).

bitwise complement result is

Commentary

bitwise not, logical negation 1111 result is

The term *bitwise not* is sometimes used to denote this operator (it is sometimes also referred to by the character used to represent it, tilde). Because its use is much less frequent than logical negation, this term is rarely shortened.

Common Implementations

Most processors have an instruction that performs this operation. An alternative implementation is to exclusive-or the operand with an all-bits-one value (containing the same number of bits as the promoted type). The Unisys A Series[1390] uses signed magnitude representation. If the operand has an unsigned type, the sign bit in the object representation (which is treated as a padding bit) is not affected by the bitwise complement operator. If the operand has a signed type, the sign bit does take part in the bitwise complement operation.

Example

```
1  V &= ~BITS; /* Clear the bits in V that are set in BITS. */
```

The integer promotions are performed on the operand, and the result has the promoted type. 1109

Commentary

Performing the integer promotions can increase the number of representation bits used in the value that the complement operator has to operate on.

Coding Guidelines

The impact of the integer promotions on the value of the result is sometimes overlooked by developers. During initial development these oversights are usually quickly corrected (the results differ substantially from the expected range of values and often have a significant impact on program output). Porting existing code to a processor whose **`int`** size differs from the original processor on which the code executed can cause latent differences in behavior to appear. For instance, if `sizeof(int)==sizeof(short)` on the original processor, then any integer promotions on operands having type **`short`** would not increase the number of bits in the value representation and a program may have an implicit dependency on this behavior occurring. Moving to a processor where `sizeof(int) > sizeof(short)` may require modifications to explicitly enforce this dependency. The issues involved in guideline recommendations that only deliver a benefit when a program is ported to a processor whose integer widths are different from the original processor are discussed elsewhere.

coding guidelines 0 the benefit

Example

```
1  unsigned char uc = 2;
2  signed char sc = -1;
3
4  void f(void)
5  {
6  /*
7   * Using two's complement notation the value 2 is represented
8   * in the uc object as the bit pattern 00000010
9   * If int is represented using 16 bits, this value is promoted
10  * to the representation     0000000000000010
11  * after being complemented  1111111111111101 is the result
12  */
13            ~uc             ;
14 /*
15  * Using two's complement notation the value -1 is represented
16  * in the sc object as the bit pattern 11111110
17  * If int is represented using 16 bits, this value is promoted
```

```
18    * to the representation     1111111111111110
19    * after being complemented  0000000000000010 is the result
20    */
21              ~sc             ;
22    }
```

1110 If the promoted type is an unsigned type, the expression **~E** is equivalent to the maximum value representable in that type minus **E**.

Commentary

This is the standard pointing out an equivalence that holds for the binary representation of integer values.

C++

The C++ Standard does not point out this equivalence.

Coding Guidelines

The issues surrounding the use of bitwise operations to perform equivalent arithmetic operations is discussed elsewhere.

945 bitwise operators

1111 The result of the logical negation operator **!** is 0 if the value of its operand compares unequal to 0, 1 if the value of its operand compares equal to 0.

logical negation result is

Commentary

The term *not* (or *logical not*) is often used to denote this operator. The much less frequently used operator, bitwise complement, takes the longer name.

logical not
1108 bitwise complement result is

C++

its value is **true** *if the converted operand is* **false** *and* **false** *otherwise.* 5.3.1p8

This difference is only visible to the developer in one case. In all other situations the behavior is the same false and true will be converted to 0 and 1 as-needed.

1112 logical negation result type

Other Languages

Languages that support a boolean data type usually specify **true** and **false** return values for these operators.

Common Implementations

The implementation of this operator often depends on the context in which it occurs. The machine code generated can be very different if the result value is used to decide the control flow (e.g., it is the final operation in the evaluation of a controlling expression) than if the result value is the operand of further operators. In the control flow case an actual value of 0 or 1 is not usually required. On many processors loading a value from storage into a register will set various bits in a conditional flags register (these flag bit settings usually specify some relationship between the value loaded and zero— e.g., equal to, less than, etc.). A processor's conditional branch instructions use the current settings of combinations of these bits to decide whether to take the branch or not. When the result is used as an operand in further operations, a 0 or 1 value is needed; the generated machine code is often more complex. A common solution is the following pseudo machine code sequence (which leaves the result in REG_1):

1744 if statement operand compare against 0

```
1   load REG_1, 0
2   load REG_2, Operand
3   Branch_over_next_instr_if_last_load_not_zero
4   load REG_1, 1
```

The instruction Branch_over_next_instr_if_last_load_not_zero may be a single instruction, or several instructions.

Coding Guidelines

While the result is specified in numeric terms, most occurrences of this operator are as the top-level operator in a controlling expression (see Usage below). These contexts are usually considered in boolean rather than numeric terms.

boolean role 476

---

logical negation result type

The result has type **int**. 1112

Commentary

The C90 Standard did not include a boolean data type and C99 maintains compatibility with this existing definition.

C++

5.3.1p8 *The type of the result is* ***bool****.*

The difference in result type will result in a difference of behavior if the result is the immediate operand of the **sizeof** operator. Such usage is rare.

Other Languages

In languages that support a boolean type the result of logical operators usually has a boolean type.

Coding Guidelines

The possible treatment of the result of logical, and other operators as having a boolean type, is discussed elsewhere.

boolean role 476

! equivalent to

The expression **!E** is equivalent to **(0==E)**. 1113

Commentary

null pointer 748 constant

In the case of pointers the 0 is equivalent to the null pointer constant. In the case of E having a floating-point type, the constant 0 will be converted to 0.0. The standard is being idiosyncratic in expressing this equivalence (the form (E==0) is more frequent, by a factor of 28, in existing code).

C++

There is no explicit statement of equivalence given in the C++ Standard.

Common Implementations

logical 1111 negation result is

Both forms occur sufficiently frequently, in existing code, that translator implementors are likely to check for the context in which they occur in order to generate the appropriate machine code.

Coding Guidelines

visually compact code 0 efficiency belief punctuator 912 syntax

Both forms are semantically identical, and it is very likely that identical machine code will be generated for both of them. (The sometimes-heard rationale of visual complexity of an expression being equated to inefficiency of program execution is discussed elsewhere.) Because of existing usage (the percentage occurrence of both operators in the visible source is approximately comparable) developers are going to have to learn to efficiently comprehend expressions containing both operators. Given this equivalence and existing practice, is there any benefit to be gained by a guideline recommending one form over the other? Both have their disadvantages:

- The **!** character is not frequently encountered in formal education, and it may be easy to miss in a visual scan of source (no empirical studies using the **!** character are known to your author).

controlling 1740 expression if statement

- The equality operator, **==**, is sometimes mistyped as an assignment operator, **=**.

Perhaps the most significant distinguishing feature of these operators is the conceptual usage associated with their operand. If this operand is primarily thought about in boolean terms, the conceptually closest operator is `!`. If the operand is thought of as being arithmetic, the conceptually closest operator is `==`. 476 boolean role

A number of studies have investigated the impact of negation in reasoning tasks. In natural languages negation comes in a variety of linguistic forms (e.g., "no boys go to class", "few boys go to class", "some boys go to class") and while the results of these studies[696] of human performance using these forms may be of interest to some researchers, they don't have an obvious mapping to C language usage (apart from the obvious one that negating a sentence involves an additional operator, the negation, which itself needs cognitive resources to process).

Usage

The visible form of the `.c` files contain 95,024 instances of the operator `!` (see Table 912.2 for information on punctuation frequencies) and 27,008 instances of the token sequence `== 0` (plus 309 instances of the form `== 0x0`). Integer constants appearing as the operand of a binary operator occur 28 times more often as the right operand than as the left operand.

1114 84) Thus, `&*E` is equivalent to `E` (even if `E` is a null pointer), and `&(E1[E2])` to `((E1)+(E2))`. footnote 84

Commentary

This footnote sentence should really have been referenced from a different paragraph, where these equivalences are discussed. 1092 &*

C90

This equivalence was not supported in C90, as discussed in the response to DR #012, #076, and #106.

C++

At the moment the C++ Standard specifies no such equivalence, explicitly or implicitly. However, this situation may be changed by the response to DR #232.

1115 It is always true that if `E` is a function designator or an lvalue that is a valid operand of the unary `&` operator, `*&E` is a function designator or an lvalue equal to `E`. *&

Commentary

This statement can be deduced from the specifications of the two operators concerned.

1116 If `*P` is an lvalue and `T` is the name of an object pointer type, `*(T)P` is an lvalue that has a type compatible with that to which `T` points.

Commentary

The result of the cast operator is not an lvalue. However, if the operand is a pointer, the pointed-to object does not lose its lvalue-ness. This sentence simply points out the type of the result of the operations and its lvalue-ness; it does not give any additional semantics to the cast or dereference. 1131 footnote 85

C++

The C++ Standard makes no such observation.

1117 Among the invalid values for dereferencing a pointer by the unary `*` operator are a null pointer, an address inappropriately aligned for the type of object pointed to, and the address of an object after the end of its lifetime.

Commentary

This list contains some examples of invalid values that may appear directly in the source; it is not exhaustive (another example is dereferencing a pointer-to function). The invalid values may also be the result of an operation that has undefined behavior. For instance, using pointer arithmetic to create an address that does

not correspond to any physical memory location supported by a particular computing system. (In virtual memory systems this case would correspond to an unmapped address.)

C90

The wording in the C90 Standard only dealt with the address of objects having automatic storage duration.

C++

The C++ Standard does not call out a list of possible invalid values that might be dereferenced.

Other Languages

Most other languages do not get involved in specifying such low-level details, although their implementations invariably regard the above values as being invalid.

Common Implementations

A host's response to an attempt to use an invalid pointer value will usually depend on the characteristics of the processor executing the program image. In some cases an exception which can be caught by the program, may be signaled. The extent to which a signal handler can recover from the exception will depend on the application logic and the type of invalid valid dereference.

On many implementations the `offsetof` macro expands to an expression that dereferences the null pointer.

Coding Guidelines

coding guidelines background to 0

One of the ways these guideline recommendations attempt to achieve their aim is to attempt to prevent invalid values from being created in the first place.

6.5.3.4 The `sizeof` operator

Constraints

---

sizeof constraints

The **`sizeof`** operator shall not be applied to an expression that has function type or an incomplete type, to the parenthesized name of such a type, or to an expression that designates a bit-field member. 1118

Commentary

In the C90 Standard the result of the **`sizeof`** operator was a constant known at translation time. While there are some applications where being able to find out the size of a function would be useful (one specification might be the number of bytes in its generated machine code), this information is not of general utility. The C90 constraint was kept.

If the **`sizeof`** operator accepted a bit-field as an operand, it would have to return a value measured in bits for all its operands.

sizeof result of 1119

C++

The C++ Standard contains a requirement that does not exist in C.

5.3.3p5 *Types shall not be defined in a **`sizeof`** expression.*

A C source file that defines a type within a **`sizeof`** expression is likely to cause a C++ translator to issue a diagnostic. Defining a type within a **`sizeof`** expression is rarely seen in C source.

```
1  int glob = sizeof(enum {E1, E2}); /* does not affect the conformance status of the program */
2                                    // ill-formed
```

Other Languages

A few other languages provide an explicit mechanism (e.g., an operator or a keyword) for obtaining the number of bytes occupied by an object. Such a mechanism is also a common extension in implementations of languages that do not specify one. Other languages obtain the size implicitly in those contexts where it is needed (i.e., the operand in a call to **new** memory allocation function in Pascal).

Table 1118.1: Occurrence of the **sizeof** operator having particular operand types (as a percentage of all occurrences of this operator). Based on the translated form of this book's benchmark programs.

Type	%	Type	%
struct	48.2	**unsigned short**	2.7
[ ]	12.2	**struct ***	2.6
int	11.6	**char**	2.0
other-types	4.7	**unsigned char**	1.5
long	3.8	**char ***	1.5
unsigned int	3.6	**signed int**	1.2
unsigned long	3.4	**union**	1.1

Semantics

1119 The **sizeof** operator yields the size (in bytes) of its operand, which may be an expression or the parenthesized name of a type.

sizeof result of

Commentary

The operand referred to is the execution-time value of the operand. In the case of string literals, escape sequences will have been converted to a single or multibyte character. In these cases the value returned by the **sizeof** operator does not correspond to the number of characters visible in the source code. Most of the uses of the result of this operator work at the byte, not the bit, level; for instance, the argument of a memory-allocation function, which operates in units of bytes. Having to divide the result by CHAR_BIT, for most uses, would not be worth the benefit of being able to accept bit-field members.

133 translation phase 5

Other Languages

The **SIZE** attribute in Ada returns the number of bits allocated to hold the object, or type. The **BIT_SIZE** intrinsic in Fortran 90 returns the number of bits in its integer argument; the **SIZE** intrinsic returns the number of elements in an array.

Common Implementations

A few vendors have extended the **sizeof** operator. For instance, Diab Data[353] supports a second argument to the parenthesized form of the **sizeof** operator. The value of this argument changes the information returned (e.g., if the value of the second argument is 1 the alignment of the type is returned, if it is 2 a unique value denoting the actual type is returned).

Coding Guidelines

The size of an object, or type, is representation information and the guideline recommendation dealing with the use of representation information might be thought to be applicable. However, in some contexts many uses of the **sizeof** operator are symbolic. The contexts in which the size of an operand is often used include the following:

569.1 representation information

822 symbolic name using

- A call to a storage allocation function requires the number of bytes to allocate.
- When copying the representation of an object, either to another object or to a binary file, the number of bytes to be copied is required.
- When an object is being overlaid over the same storage as another object (using a union or pointer to object type), the sizes in the two types need to agree.

- When calculating the range of values representable by the operand (based on the number of bits it contains).

In some of the uses in these contexts the result of the **sizeof** operator is treated as a symbolic value— the size of its operand, with no interest in its numeric properties. While in others the result is manipulated as an arithmetic value; it is an intermediate value used in the calculation of the final value. However, a strong case can be made for claiming that certain kinds of arithmetic operations are essentially symbolic in nature:

- Multiplication of the result (e.g, to calculate the size of an array of objects)
- Division of the result (e.g., to calculate how many objects will fit in a given amount of storage)
- Subtracting from the result (e.g., to calculate the offset of the character that is third from the end of a string literal.
- Adding to the result (e.g., calculating the size of an array needed to hold several strings)

Dev 569.1 The **sizeof** operator may be used provided the only operators applied to its result (and the result of these operations) are divide and multiple.

Dev 569.1 The **sizeof** operator whose operand has an array type may be used provided the only operators applied to its result (and the result of these operations) are divide, multiply, addition, and subtraction.

For simplicity the deviation wording permits some unintended uses of representation information. For instance, the deviations permit both of the expressions `sizeof(array_of_int)-5` and `sizeof(array_of_char)-5`. There is a difference between the two in that in the former case the developer is either making use of representation information or forgot to write `sizeof(array_of_int)-5*sizeof(int)` (these guideline recommendations are not intended to recommend against constructs that are faults). Character types are special in that `sizeof(char)` is required to be 1, so it is accepted practice to omit the multiplication for these types.

guidelines 0 not faults
sizeof char 1124 defined to be 1

The size is determined from the type of the operand. 1120

Commentary

If an object appears as the operand, its declared type is used, not its effective type. The operand is also a special case in that some implicit conversions do not occur in this context.

For floating-types, any extra precision maintained by an implementation is not included in the number of bytes returned. For instance, `sizeof(a_double * b_double)` always returns the size of the type specified by the C semantics, not the size of the representation used by the implementation when multiplying two objects of type **double**.

lvalue 725 converted to value
array 729 converted to pointer
function 732 designator converted to type
FLT_EVAL_METHOD 354

C++

5.3.3p1 *The **sizeof** operator yields the number of bytes in the object representation of its operand.*

Coding Guidelines

Developers sometimes write code that uses an operand's size to deduce the range of values it can represent (applies to integer types only). Information on the range of values representable in a type is provided by the contents of the header **<limits.h>**. However, when writing a macro having an argument that can be one of several types, there is no mechanism for deducing the type actually passed. It is not possible to use any of

the macros provided by the header **<limits.h>**. The **sizeof** operator provides a solution that works on the majority of processors.

A size determined from the type of the operand need not provide an accurate indication of the range of values representable in that operand type (it provides an upper bound on the range of values that can be stored in an object of that type). A type may contain padding bytes, which will be included in its size. In the case of floating-point types, it is also possible that an expression is evaluated to a greater precision than implied by its type. Using the **sizeof** operator for this purpose is covered by the guideline recommendation dealing with the use of representation information.

354 FLT_EVAL_METH
569.1 representation information using

1121 The result is an integer.

Commentary

To be exact, the result has an integer type, `size_t`.

C90

In C90 the result was always an integer constant. The C99 contexts in which the result is not an integer constant all involve constructs that are new in C99.

C++

Like C90, the C++ Standard specifies that the result is a constant. The cases where the result is not a constant require the use of types that are not supported by C++.

1122 If the type of the operand is a variable length array type, the operand is evaluated;

sizeof operand evaluated

Commentary

The number of elements in the variable length array is not known until its index expression is evaluated. This evaluation may cause side effects. The requirement specified in this C sentence is weakened by a later sentence in the standard. It is possible that the operand may only be partially evaluated.

1584 sizeof VLA unspecified evaluation

C90

Support for variable length array types is new in C99.

C++

Variable length array types are new in C99 and are not available in C++.

Coding Guidelines

The issue of side effects in VLA's is discussed elsewhere.

1584 sizeof VLA unspecified evaluation

Example

```
1  extern int glob;
2
3  void f(void)
4  {
5  int loc = sizeof(int [glob++]); /* glob is incremented. */
6
7  /*
8   * To obtain the size of the type ++glob need not be evaluated in
9   * the first case, but must be evaluated in the second.
10  */
11 loc=sizeof((int *)[++glob]);
12 loc=sizeof( int * [++glob]);
13 }
```

1123 otherwise, the operand is not evaluated and the result is an integer constant.

sizeof operand not evaluated

Commentary

A full expression having a **sizeof** operator as its top-level operator, with such an operand, can occur anywhere that an integer constant can occur. The size is obtained from the type of the operand. This information is available during translation. (There is no need to generate any machine code to evaluate the operand, and this requirement prohibits such generation.) Although the operand is not evaluated, any operators that appear in it will still cause the integer promotions and usual arithmetic conversions to be performed.

integer promotions 675
usual arithmetic conversions 706

Coding Guidelines

Some coding guideline documents recommend that the operand of the **sizeof** operator should not contain any side effects. In practice such usage is very rarely seen and no such guideline recommendation is given here.

Example

```
1  extern int i;
2  extern unsigned char uc;
3
4  void f(void)
5  {
6  int loc_i = sizeof(i++);    /* i is not incremented. */
7  int loc_uc = sizeof(uc);    /* sizeof an unsigned char. */
8  int loc_i_uc = sizeof(+uc); /* Operand promoted first. */
9  }
```

---

sizeof char defined to be 1

When applied to an operand that has type **char**, **unsigned char**, or **signed char**, (or a qualified version thereof) the result is 1. 1124

Commentary

The number of bits in the representation of a character type is irrelevant. By definition the number of bytes in a character type is one.

byte 53
addressable unit

Coding Guidelines

Developers sometimes associate a byte as always containing eight bits. On hosts where the character type is 16 bits, this can lead to the incorrect assumption that applying **sizeof** to a character type will return the value 2. These issues are discussed elsewhere.

CHAR_BIT 307
macro

When applied to an operand that has array type, the result is the total number of bytes in the array.[85)] 1125

Commentary

In this case an array is not converted to a pointer to its first element.

array 729
converted to pointer

When applied to an operand that has structure or union type, the result is the total number of bytes in such an object, including internal and trailing padding. 1126

Commentary

All of the bytes in the object representation need to be included because of the kinds of use to which the result of the **sizeof** operator is put (e.g., allocating storage and copying objects). Trailing padding needs to be taken into account because more than one object of that type may be allocated or copied (e.g., an array of types having a given size, or a structure containing a member having a flexible array type). The standard requires that there be no leading padding.

structure 1428
trailing padding
structure 1424
unnamed padding

1127 The value of the result is implementation-defined, and its type (an unsigned integer type) is **size_t**, defined in **<stddef.h>** (and other headers). sizeof result type

Commentary

The implementation-defined value will be less than or equal to the value of the SIZE_MAX macro. There is no requirement that SIZE_MAX == PTRDIFF_MAX. When the operand of **sizeof** contains more bytes than can be represented in the type size_t (e.g., char x[SIZE_MAX/2][SIZE_MAX/2];). The response to DR #266 stated:

The committee has deliberated and decided that more than one interpretation is reasonable. DR #266

There is no requirement on implementations to provide a definition of the type size_t that is capable of representing the number of bytes in any object that the implementation is capable of allocating storage for. It is the implementation's responsibility to ensure that the type it uses for size_t internally is the same as the typedef definition of size_t in the supplied header, **<stddef.h>**. If these types differ, the implementation is not conforming.

A developer can define a typedef whose name is size_t (subject to the constraints covering declarations of identifiers). Such a declaration does not affect the type used by a translator as its result type for the **sizeof** operator.

C++

. . . ; the result of ***sizeof*** *applied to any other fundamental type (3.9.1) is implementation-defined.* 5.3.3p1

The C++ Standard does not explicitly specify any behavior when the operand of **sizeof** has a derived type. A C++ implementation need not document how the result of the **sizeof** operator applied to a derived type is calculated.

Coding Guidelines

Use of the **sizeof** operator can sometimes produce results that surprise developers. The root cause of the surprising behavior is usually that the developer forgot that the result of the **sizeof** has an unsigned type (which causes the type of the other operand, of a binary operator, to be converted to an unsigned type). Developers forgetting about the unsignedness of the result of a **sizeof** is not something that can be addressed by a guideline recommendation.

1128 EXAMPLE 1 A principal use of the **sizeof** operator is in communication with routines such as storage allocators and I/O systems. A storage-allocation function might accept a size (in bytes) of an object to allocate and return a pointer to **void**. For example:

```
extern void *alloc(size_t);
double *dp = alloc(sizeof *dp);
```

The implementation of the **alloc** function should ensure that its return value is aligned suitably for conversion to a pointer to **double**.

Commentary

Measurements of existing source (see Table 1080.1) shows that this usage represents at most 14% of all uses of the **sizeof** operator.

1129 EXAMPLE 2 Another use of the **sizeof** operator is to compute the number of elements in an array:

```
sizeof array / sizeof array[0]
```

Commentary

The declaration of an object having an array type may not contain an explicit value for the size, but obtain it from the number of elements in an associated initializer.

Other Languages

Some languages provide built-in support for obtaining the bounds or the number of elements in an array. For instance, Fortran has the intrinsic functions **LBOUND** and **UBOUND**; Ada specifies the attributes **first** and **last** to return the lower and upper bounds of array, respectively.

EXAMPLE 3 In this example, the size of a variable length array is computed and returned from a function: 1130

```
#include <stddef.h>

size_t fsize3(int n)
{
        char b[n+3];       // variable length array
        return sizeof b;   // execution time sizeof
}

int main()
{
        size_t size;
        size = fsize3(10); // fsize3 returns 13
        return 0;
}
```

Commentary

In this example the result of the **sizeof** operator is not known at translation time.

C90

This example, and support for variable length arrays, is new in C99.

---

footnote 85

85) When applied to a parameter declared to have array or function type, the **sizeof** operator yields the size of the adjusted (pointer) type (see 6.9.1). 1131

Commentary

array type 1598 adjust to pointer to array 729 converted to pointer

The more specific reference is 6.7.5.3. The parameter type is converted before the **sizeof** operator operates on it. There is no array type for the operand exception.

C++

This observation is not made in the C++ Standard.

Other Languages

Converting an array parameter to a pointer type is unique to C (and C++).

Coding Guidelines

qualified 1571 array of

Traditionally, the reason for declaring a parameter to have an array type is to create an association in the developer's mind and provide hints to static analysis tools. (Functionality added in C99 provides a mechanism for specifying additional semantics with this usage.) In most contexts it does not matter whether readers of the code treat the parameter as having an array or pointer type. However, in the context of an operand to the **sizeof** operator, there is an important difference in behavior.

Example

In the following the array `b` will be declared to have an upper bound of `sizeof(int *)`, not the number of bytes in the array `a`.

```
1  void f(int a[3])
2  {
```

```
3  unsigned char b[sizeof(a)];
4  }
```

1132 **Forward references:** common definitions <stddef.h> (7.17), declarations (6.7), structure and union specifiers (6.7.2.1), type names (6.7.6), array declarators (6.7.5.2).

6.5.4 Cast operators

cast-expression syntax

1133

cast-expression:
unary-expression
(*type-name* **)** *cast-expression*

Commentary

A *cast-expression* is also a unary operator. Given that the evaluation of a sequence of unary operators always occurs in a right-to-left order, the lower precedence of the cast operator is not significant.

C++

The C++ Standard uses the terminal name *type-id*, not *type-name*.

Other Languages

Some languages parenthesize the *cast-expression* and leave the *type-name* unparenthesized.

Usage

Measurements by Stiff, Chandra, Ball, Kunchithapadam, and Reps[1301] of 1.36 MLOC (SPEC95 version of gcc, binutils, production code from a Lucent Technologies product and a few other programs) showed a total of 23,947 casts involving 2,020 unique types. Of these 15,704 involved scalar types (not involving a structure, union, or function pointer) and 447 function pointer types. Of the remaining casts 7,796 (1,276 unique types) involved conversions between pointers to **void/char** and pointers to structure (in either direction) and 1,053 (209 unique types) conversions between pointers to structs.

Constraints

1134 Unless the type name specifies a void type, the type name shall specify qualified or unqualified scalar type and the operand shall have scalar type.

cast scalar or void type

Commentary

Casting to the **void** type is a method of explicitly showing that the value of the operand is discarded. Casting a value having a structure or union type has no obvious meaning. (Would corresponding member names be assigned to each other? What would happen to those members that did not correspond to a member in the other type?)

C++

There is no such restriction in C++ (which permits the type name to be a class type). However, the C++ Standard contains a requirement that does not exist in C.

Types shall not be defined in casts. 5.4p3

A C source file that defines a type within a cast is likely to cause a C++ translator to issue a diagnostic (this usage is rare).

```
1  extern int glob;
2
```

```
3  void f(void)
4  {
5  switch ((enum {E1, E2, E3})glob) /* does not affect the conformance status of the program */
6                                   // ill-formed
7     {
8     case E1: glob+=3;
9              break;
10    /* ... */
11    }
12 }
```

Other Languages

Some languages require the cast to have an arithmetic type. Algol 68 permits a cast to any type for which an assignment would be permitted, and nothing else (e.g., if `T var; var := value` is permitted, then `value` can be cast to type T).

Common Implementations

gcc supports the casting of scalar types to union types. The scalar type must have the same type as one of the members of the union type. The cast is treated as being equivalent to assigning to the member having that type. This extension removes the need to know the name of the union member.

```
1  union T {
2           int mem_1;
3           double mem_2;
4          } u;
5  int x;
6  double y;
7
8  void f(void)
9  {
10 u = (union T)x;       /* gcc: equivalent to u.mem_1 = x */
11 u = (__typeof__(u))y; /* gcc: equivalent to u.mem_2 = y */
12 }
```

Coding Guidelines

In this discussion a suffixed literal will be treated as an explicit cast of a literal value, while an unsuffixed literal is not treated as such. An explicit cast is usually interpreted as showing that the developer intended the conversion to take place. It is taken as a statement of intent. It is often assumed, by readers of the source, that an explicit cast specifies the final type of the operand. An explicit cast followed by an implicit one is suspicious; it suggests that either the original developer did not fully understand what was occurring or that subsequent changes have modified the intended behavior.

Cg 1134.1 The result of a cast operation shall not be implicitly converted to another type.

Dev 1134.1 If the result of a macro substitution has the form of an expression, that expression may be implicitly converted to another type.

Example

```
1  #include "stuff.h"
2
3  #define MAX_THINGS 333333u
4  #define T_VAL ((int)x)
```

```
5
6   extern SOME_INTEGER_TYPE x;
7
8   void f(void)
9   {
10  long num_1_things = MAX_THINGS;
11  long num_2_things = (long)MAX_THINGS;
12  short num_3_things = (short)MAX_THINGS;
13
14  long count_1_things = (long)44444u;
15  short count_2_things = (short)44444u;
16
17  long things_1_val = x;
18  long things_2_val = (long)x;
19  long things_3_val = (long)(int)x;
20  long things_4_val = (long)T_VAL;
21  }
```

Usage

Usage information on implicit conversions is given elsewhere (see Table 653.1).

Table 1134.1: Occurrence of the cast operator having particular operand types (as a percentage of all occurrences of this operator). Based on the translated form of this book's benchmark programs.

To Type	From Type	%	To Type	From Type	%
(other-types)	other-types	40.1	(char *)	const char *	1.6
(void *)	_ int	18.9	(union *)	void *	1.5
(struct *)	struct *	11.2	(void)	long	1.3
(struct *)	_ int	4.2	(unsigned long)	unsigned long	1.3
(char *)	char *	4.0	(int)	int	1.3
(char *)	struct *	3.9	(unsigned int)	int	1.2
(struct *)	void *	2.8	(enum)	int:8 24	1.2
(unsigned char)	int	1.7	(char)	_ int	1.2
(struct *)	char *	1.7	(unsigned long)	ptr-to *	1.0

1135 Conversions that involve pointers, other than where permitted by the constraints of 6.5.16.1, shall be specified by means of an explicit cast.

pointer conversion constraints

Commentary

The special cases listed in 6.5.16.1 allow some values that are assigned to have their types implicitly converted to that of the object being assigned to. There are also contexts (e.g., the conditional operator) where implicit conversions occur.

1296 simple assignment constraints
1266 conditional operator second and third operands

C90

This wording appeared in the Semantics clause in the C90 Standard; it was moved to constraints in C99. This is not a difference if it is redundant.

C++

The C++ Standard words its specification in terms of assignment:

> *An expression* `e` *can be implicitly converted to a type* `T` *if and only if the declaration "*`T t=e;`*" is well-formed, for some invented temporary variable* `t` *(8.5).*

4p3

Semantics

Preceding an expression by a parenthesized type name converts the value of the expression to the named type. 1136

Commentary

simple assignment constraints 1296
default argument promotions 1009
pointer conversion constraints 1135
_Bool converted to 680

Most of the implicit conversions that occur in C cause types to be widened. In the case of assignment and passing arguments narrowing may occur. Explicit casts are required to support conversions involving pointers. The use of the phrase *named type* is misleading in that the type converted to may be anonymous. For most pairs of types, but not all, the cast operator is commutative (assuming the operand is within the defined range of the types).

Although C has a relatively large number of integer types (compared to the single one supported in most languages), the language has been designed so that explicit casts are rarely required for these constructs. For instance, an explicit cast is required to convert an array index having a floating type or to convert an argument having type **long** to **int** when using old style function declarations. Typedef names are synonyms and do not require the use of explicit casts seen in more strongly typed languages.

typedef 1633 is synonym

Common Implementations

The most common implementation of pointer and widening integer conversions is to treat the existing value bits as having the new type (in many cases values having integer type will already be represented in a processor's register using the full number of bits).

In the case of conversions to narrower integer types, the generated machine code may depend on what operation performed on the result of the cast. In the case of assignment the appropriate least-significant bits of the unconverted operand are usually stored. For other operators implementations often zero out the nonsignificant bits (performing a bitwise-AND operation is often faster than a remainder operation) and for signed types sign extend the result.

The representation difference between integer and floating-point types is so great that many processors contain instructions that perform the conversion. In other cases internal calls to library functions have to be generated by the translator.

Coding Guidelines

Casts are sometimes used as a means of reducing a value so that it falls within a particular range of values (i.e., effectively performing a modulo operation). This usage may be driven by the desire not to use two other possible operators: (1) bitwise operators, because of the self-evident use of representation information; and (2) the remainder operator, because it is viewed as having poor performance. A cast operator used for this purpose is making use of representation information; the range of values that happen to be supported by the cast type on the implementation used. This usage is a violation of the guideline recommendation dealing with the use of representation information.

% operator 1149 result

representation information using object 569.1 480.1 int type only

Following the guideline recommendation specifying the use of a single integer type removes the need to consider many of the conversion issues that can otherwise arise with these types.

In some contexts an explicit conversion is required, while in other contexts a translator will perform an implicit conversion. Are there any benefits to using an explicit cast operator in these other contexts? An explicit cast can be thought about in several ways:

operand 653 convert automatically

- An indicator of awareness on the part of the codes author. The assumption is often made by subsequent readers of the source that an explicit cast shows that a conversion was expected/intended. Static analysis tools tend to treat implicit conversions with some suspicion.
- A change of interpretation of a numeric value (e.g., signed/unsigned or integer/floating-point conversions).
- A method of removing excess accuracy in floating-point operations.
- A method of changing the conversions that would have occurred as a result of the usual arithmetic conversions.

FLT_EVAL_METHOD 354

usual arithmetic conversions 706

- A method of explicitly indicating that a change in role, or symbolic name status, of an object is intended.

1352 object role
822 symbolic name

The cost/benefit issues and possible guideline recommendations are discussed elsewhere.

653 operand convert automatically

1137 This construction is called a *cast*.[86)]

Commentary

This defines the term *cast*. Developers often call this construction an *explicit cast*, while an implicit conversion performed by a translator is often called an *implicit cast*.

C++

The C++ Standard uses the phrase *cast notation*. There are other ways of expressing a type conversion in C++ (functional notation, or a type conversion operator). The word *cast* could be said to apply in common usage to any of these forms (when technically it refers to none of them).

Other Languages

The terms *cast* or *coercion* are often used in programming language definitions.

Coding Guidelines

The term *cast* is often used by developers to refer to the implicit conversions performed by an implementation. This is incorrect use of terminology, but there is very little to be gained in attempting to change existing, common usage developer terminology.

1138 A cast that specifies no conversion has no effect on the type or value of an expression.[87)]

Commentary

The standard does not define what is meant by *no conversion*; only one kind of cast can have no effect on the semantic type (i.e., a cast that has the same type as the expression it operates on). If an implementation uses the same representation for two types, any cast between those two types will have no effect on the value. A cast to **`void`** specifies no conversion in the sense that the value is discarded. As footnote 87 points out, it is possible to cast an operand to the type it already has and change its value.

1142 footnote 87

The footnote was moved to normative text by the response to DR #318.

C++

The C++ Standard explicitly permits an expression to be cast to its own type (5.2.11p1), but does not list any exceptions for such an operation.

Common Implementations

The special case of a cast that specifies no conversion is likely to be subsumed into an implementation's general handling of machine code generation for cast operations.

Coding Guidelines

Technically, a cast that specifies no conversion is a redundant operation. A cast that has no effect can occur for a number of reasons:

190 redundant code

- When typedef names are used; for instance, converting a value having type `TYPE_A` to `TYPE_B`, when both typedef names are defined to have the type **`int`**.
- When an object is defined to have different types in different arms of a **`#if`** preprocessing directive. Casts of such an object may be redundant when one arm is selected, but not the other.
- When an argument to a macro invocation is cast to its declared type in the body of the macro.
- When an invocation of a macro is cast to the type of the expanded macro body.
- Developer incompetence, or changes to existing code, such that uses no longer fit in the above categories.

Some redundant casts may unnecessarily increase the cost of comprehending source code. (Their existence in source code will require effort to process; a redundant cast may generate additional effort because it is surprising and the reader may invest additional effort investigating it.) However, in practice many redundant casts exist for a good reason. But, providing a definition for an *unnecessary* redundant cast is likely to be a complex task. A guideline recommending against some form of redundant casts does not appear to be worthwhile.

While a cast operation may not specify any conversion based on the requirements contained in the C Standard, it may specify a conceptual conversion based on the representation of the application domain (i.e., the types of the cast and its operand are specified using different typedef names which happen to use the same underlying type). Checking that the rules behind these conceptual conversions are followed requires support from a static analysis tool (at the translator level these conversions appear to be redundant code).

redundant code 190

Example

```
1  typedef int TYPE_A;
2  typedef int TYPE_B;
3
4  extern signed int i_1;
5  extern TYPE_A t_1;
6
7  #include "stuff.h"
8
9  void f(void)
10 {
11 int loc_1 = i_1;
12 int loc_2 = (int)i_1;
13 int loc_3 = (TYPE_B)i_1;
14 int loc_4 = t_1;
15 int loc_5 = COMPLEX_EXPR;
16 int loc_6 = (int)COMPLEX_EXPR;
17 int loc_7 = (int)loc_1;
18
19 TYPE_B toc_1 = t_1;
20 TYPE_B toc_2 = (int)t_1;
21 TYPE_B toc_3 = (TYPE_B)t_1;
22 TYPE_B toc_4 = i_1;
23 TYPE_B toc_5 = COMPLEX_EXPR;
24 TYPE_B toc_6 = (TYPE_B)COMPLEX_EXPR;
25 TYPE_B toc_7 = (TYPE_B)toc_1;
26 }
```

Forward references: equality operators (6.5.9), function declarators (including prototypes) (6.7.5.3), simple assignment (6.5.16.1), type names (6.7.6). 1139

footnote 86

86) A cast does not yield an lvalue. 1140

Commentary

The idea behind the cast operator is to convert values, not the types of objects. A cast of a value having a point type may not be an lvalue, but the result can be dereferenced to yield an lvalue.

```
1  extern int *p_i;
2
3  void f(void)
4  {
5  (int)*p_i = 3;   /* Constraint violation, left operand not an lvalue.      */
```

```
6   *(int *)p_i = 3; /* Does not affect the conformance status of the program. */
7   }
```

C++

The result is an lvalue if T is a reference type, otherwise the result is an rvalue. 5.4p1

Reference types are not available in C, so this specification is not a difference in behavior for a conforming C program.

Common Implementations

Some implementations (e.g., `gcc`) allow casts to yield an lvalue.

```
1   int loc;
2
3   (char)loc = 0x02; /* Set one of the bytes of an object to 0x02. */
```

1141 Thus, a cast to a qualified type has the same effect as a cast to the unqualified version of the type.

Commentary

Type qualifiers affect how translators treat objects, not values. The standard specifies some requirements on pointers to unqualified/qualified versions of types.

1478 qualifier meaningful for lvalues
559 pointer to qualified/unqualified types

C++

Casts that involve qualified types can be a lot more complex in C++ (5.2.11). There is a specific C++ cast notation for dealing with this form of type conversion, `const_cast<T>` (where T is some type).

[Note: some conversions which involve only changes in cv-qualification cannot be done using ***`const_cast`****. For instance, conversions between pointers to functions are not covered because such conversions lead to values whose use causes undefined behavior.* 5.2.11p12

The other forms of conversions involve types not available in C.

Coding Guidelines

Casting to a qualified type can occur through the use of typedef names. Explicitly specifying a type qualifier in the visible source is sufficiently rare that it does not warrant a guideline (while it may not affect the behavior of a translator, the developer's beliefs about such a cast are uncertain).

---

footnote 87

1142 ~~87)~~ If the value of the expression is represented with greater precision or range than required by the type named by the cast (6.3.1.8), then the cast specifies a conversion even if the type of the expression is the same as the named type.

Commentary

This footnote clarifies that the permission to perform operations with greater precision (values having floating-point types may be represented to greater precision than is implied by the type of the expression) does not apply to the cast operator. The issues surrounding this usage are discussed elsewhere.

695 float promoted to double or long double
354 FLT_EVAL_ME

The footnote was moved to normative text by the response to DR #318.

C++

The C++ Standard is silent on this subject.

Common Implementations

The representation used during the evaluation of operands having floating-point type is usually dictated by the architecture of the processor. Processors that operate on a single representation often have instructions for converting to other representations (which can be used to implement the cast operation). An alternative implementation technique, in those cases where no conversion instruction is available, is for the implementation to specify all floating-point types as having the same representation.

6.5.5 Multiplicative operators

multiplicative-expression syntax

```
multiplicative-expression:
                cast-expression
                multiplicative-expression * cast-expression
                multiplicative-expression / cast-expression
                multiplicative-expression % cast-expression
```

Commentary

The use of the term *multiplicative* is based on the most commonly occurring of the three operators.

Table 338.2 lists various results from operating on infinities and NaNs; annex F (of the C Standard) discusses some of the expression optimizing transformations these results may prohibit.

C++

In C++ there are two operators (pointer-to-member operators, `.*` and `->*`) that form an additional precedence level between *cast-expression* and *multiplicative-expression*. The nonterminal name for such expressions is *pm-expression*, which appears in the syntax for *multiplicative-expression*.

Other Languages

Many languages designed before C did not support a remainder operator. Pascal uses **rem** to denote this operator, while Ada uses both **rem** and **mod** (corresponding to the two interpretation of its behavior).

Common Implementations

Multiplicative operators often occur in the bodies of loops with one of their operands being a loop counter. It is sometimes possible to transform the loop, by making use of a regular pattern of loop increments; multiplicative operations can be replaced by additive operations,[277] while replacing division, remainder, or modulo operations requires the introduction of a nested loop.[1223]

Coding Guidelines

expression 943.1 shall be parenthesized

No deviation is listed in the parenthesizing guideline recommendation for the remainder operator because developers are very unlikely to have received any significant practice in its usage (compared to the other two operators, which will have been encountered frequently during their schooling).

Unlike multiplication, people do not usually learn division tables at school. The published studies of multiplicative operators have not been as broad and detailed as those for the additive operators. Many of those that have been performed have investigated mental multiplication, with a few studies of mental division (those that have been performed involved operands that gave an exact integer result, unlike division operations in source code which may not be exact), and your author could find none investigating the remainder operation.

- A study by Parkman[1056] showed subjects a series of simple multiplication problems of the form $p \times q = n$ and asked them to respond as quickly as possible as to whether the value n was correct (both p and q were single-digit values). The time taken for subjects to respond was measured. The results followed the pattern found in an earlier study involving addition; that is, it was possible to fit the results to a number of straight lines (i.e., $RT = ax + b$). In one case x was determined by the value $\min(p, q)$, in the other by $p * q$.

additive-expression syntax 1153

- A study by LeFevre, Bisanz, Daley, Buffone, Greenham, and Sadesky[825] gave subjects single-digit multiplication problems to solve and then asked them what procedure they had used to solve the problems. In 80% of trials subjects reported retrieving the answer from memory; other common solution techniques included: 6.4% deriving it (e.g., $6\times7 \Rightarrow 6\times6+1$), 4.5% number series (e.g., $3\times5 \Rightarrow 5, 10, 15$), and 3.8% repeated addition (e.g., $2\times4 \Rightarrow 2+2$).
- A study by Campbell[194] measured the time taken for subjects to multiply numbers between two and nine, and to divide a number (that gave an exact result) by a number between two and nine. The results showed a number of performance parallels (i.e., plots of their response times and error rates, shown in Figure 1143.1, had a similar shape) between the two operations, although division was more difficult. These parallels suggest that similar internal processes are used to perform both operations.
- A study by LeFevre and Morris[826] supported the idea that multiplication and division are stored in separate mental representations and that sometimes the solution to difficult division problems was recast as a multiplication problem (e.g., $56/8$ as $8\times? = 56$).

Adults (who spent five to six years as children learning their times tables) can recall answers to single digit multiplication questions in under a second, with an error rate of 7.6%.[195] The types of errors made can be put into the following categories[543] (see Table 1143.1):

- *Operand errors.* One of the digits in an operand being multiplied is replaced by another digit. For example, $8\times8 = 40$ is an operand error because it shares an operand, 8, with $5\times8 = 40$.
- *Close operand errors.* This is a subclass of operand errors, with the replaced digit being within ±2 of the actual digit (e.g., $5\times4 = 24$). This behavior is referred to as the *operand distance effect*.
- *Frequent product errors.* The result of the multiplication is given as one of the numbers 12, 16, 18, 24 or 36. These five numbers frequently occur as the result of multiplying operands between 2 and 9.
- *Table errors.* Here the result is a value that is an answer to multiplying two unrelated digits, than those actually given (e.g., $4\times5 = 12$).
- *Operation errors.* Here the multiplication operation is replaced by an additional operation (e.g., $4\times5 = 9$).
- *Non-table errors.* Here the result is a value that is not an answer to multiplying any two single digits; for instance, $4\times3 = 13$, where 13 is not the product of any pair of integers.

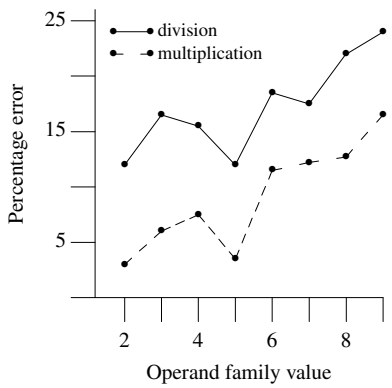

Figure 1143.1: Mean percentage of errors in simple multiplication (e.g., 3×7) and division (e.g., $81/9$) problems as a function of the operand value (see paper for a discussion of the effect of the relative position of the minimum/maximum operand values). Adapted from Campbell.[194]

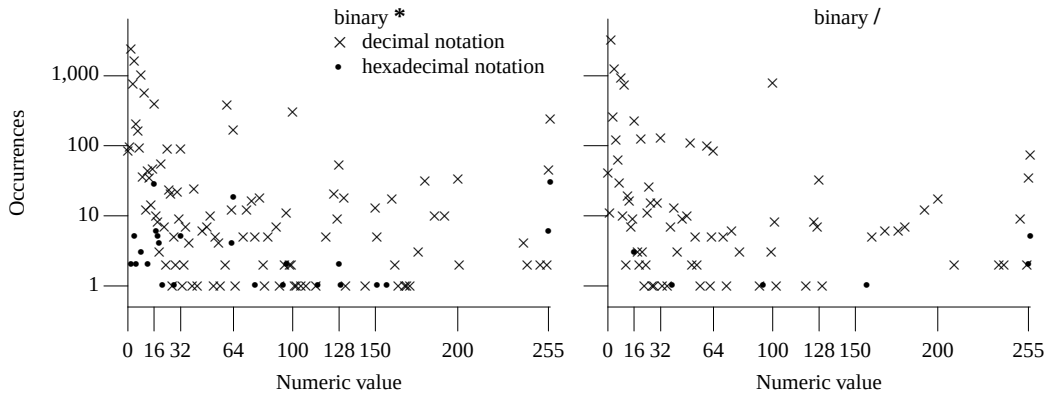

Figure 1143.2: Number of *integer-constant*s having a given value appearing as the right operand of the multiplicative operators. Based on the visible form of the `.c` files.

Table 1143.1: Percentage breakdown of errors in answers to multiplication problems. Figures are mean values for 60 adults tested on 2×2 to 9×9 from Campbell and Graham,[195] and 42 adults tested on 0×0 to 9×9 from Harley.[543] For the Campbell and Graham data, the operand error and operation error percentages are an approximation due to incomplete data.

	Campbell and Graham	Harley
Operand errors	79.1	86.2
Close operand errors	76.8	76.74
Frequent product errors	24.2	23.26
Table errors	13.5	13.8
Operation error	1.7	13.72
Error frequency	7.65	6.3

For a discussion of multiplication of operands containing more than one digit see Dallaway.[310]

Example

See annex G.5.1 EXAMPLE 1 and EXAMPLE 2 for an implementation of complex multiple and divide functions.

Table 1143.2: Common token pairs involving multiplicative operators (as a percentage of all occurrences of each token). Based on the visible form of the `.c` files. Note: a consequence of the method used to perform the counts is that occurrences of the sequence *identifier* `*` are over estimated (e.g., occurrences of a typedef name followed by a `*` are included in the counts).

Token Sequence	% Occurrence of First Token	% Occurrence of Second Token	Token Sequence	% Occurrence of First Token	% Occurrence of Second Token
identifier `*`	3.4	92.1	`/ sizeof`	9.0	3.6
identifier `%`	0.0	57.7	`*` identifier	76.5	2.8
identifier `/`	0.1	54.3	`* )`	14.4	2.0

Constraints

multiplicative operand type

Each of the operands shall have arithmetic type. 1144

Commentary

These operators have no common usage for anything other than arithmetic types.

Coding Guidelines

Enumerated types are often thought about in symbolic, not arithmetic, terms. The use of operands having an enumerated type is discussed elsewhere.

822 symbolic name
517 enumeration set of named constants

A boolean value may be thought about in terms of a zero/nonzero representation. In this case a multiplication operation involving an operand representing a boolean value will return a boolean (in the zero/nonzero sense) result. In this case multiplication is effectively a logical-OR operation. Can a parallel be drawn between such usage and using bitwise operations to perform arithmetic operations (with the aim of using similar rationales to make guideline recommendations)? Although this might be an interesting question, given the relative rareness of the usage these coding guidelines do not discuss the issue further.

476 boolean role

Table 1144.1: Occurrence of multiplicative operators having particular operand types (as a percentage of all occurrences of each operator; an _ prefix indicates a literal operand). Based on the translated form of this book's benchmark programs.

Left Operand	Operator	Right Operand	%	Left Operand	Operator	Right Operand	%
int	%	_int	40.6	_unsigned long	*	_int	2.8
int	/	_int	25.6	int	/	float	2.7
other-types	*	other-types	18.1	long	/	_int	2.5

unsigned long	%	_int	3.1				

1145 The operands of the % operator shall have integer type.

Commentary

The modulus operator could have been defined to include arithmetic types. However, processors rarely include instructions for performing this operation using floating-point operands.

Semantics

1146 The usual arithmetic conversions are performed on the operands.

Commentary

These conversions may result in the integer promotions being performed.

710 arithmetic conversions integer promotions

Common Implementations

All three operators are sufficiently expensive to implement[1263] (both in terms of transistors needed by the hardware and time taken to execute the instruction) that some processors contain instructions where one or more operands has a type narrower than **int**. A translator can make use of such instructions, invoking the as-if rule, when the operands have the appropriate bit width; for instance, multiplying two 8-bit operands to yield a 16-bit result.

A number of processors do not support integer multiply and/or divide instructions in hardware (e.g., early high-performance processors CDC 6x00 and 7x00, Cray; most low-cost processors; RISC processors seeking to simply their design— HP PA-RISC 1.0, 1.1, 2.0,[571] HP–was DEC– Alpha;[1247] Sun SPARC, pre-version 8[1450]).

A recently proposed hardware acceleration technique[239] is to store the results of previous multiplication and division operations in a cache, reusing rather than recalculating the result whenever possible. (Dynamic profiling has found that a high percentage of these operations share the same operands as previous operations.)

---

binary * result

The result of the binary * operator is the product of the operands. 1147

Commentary

array 992 n-dimensional reference pointer 1167 arithmetic addition result

Source code can contain implicit multiplications as well as explicit ones; for instance, array indexing. If imaginary types are supported, the expression `Infinity*I` is simply a way of obtaining an infinite imaginary value.

Common Implementations

Multiplication is sufficiently common and generally executes sufficiently slowly that implementations often put a lot of effort into alternative implementation strategies. A common special case is multiplying by a known (at translation time) constant.[885, 1443]

A multiply instruction can be expressed as a combination of one or more add, subtract, or left shift (by any amount) instructions. For instance, multiplying by 9 is equivalent to shifting a value left 3 bits and adding in the original value, the later probably executing in a few machine cycles. A general expression giving the minimum number of add/subtract/shift instructions required for any constant is not known, but the following are some upper bounds:

- multiplication by an n-bit constant can always be performed using at most n instructions,[1443]
- if the constant n contains many 0-bits, an algorithm that generates $4g(n) + 2s(n) - 1 - \theta$ instructions, where $g(n)$ is the number of groups of two or more consecutive 1-bits in the constant n, $s(n)$ is the number of single 1-bits, and θ is 1 if n ends in a 1-bit and 0 otherwise, may produce a shorter sequence,
- if a fused shift–add instruction is available (e.g., HP PA-RISC[571]) six or less of these instructions are required to multiply by any constant between 0 and 10,000.[885]

multiply always truncate IEC 60559 29 correctly 64 rounded result

Approximately half of the hardware needed to perform a IEEE compliant floating-point multiply is only there to guarantee a correctly rounded result. Significant savings in power consumption and execution delays can be achieved by not providing this guarantee[1205] and a number of vendors[350, 626, 971] support multiplication instructions that do not guarantee this behavior (e.g., they always truncate).

Usage

Measurements by Citron, Feitelson, and Rudolph[239] found that in a high percentage of cases the operands of multiplication operations repeat themselves (59% for integer operands and 43% for floating-point). Measurements were based on maintaining previous results in a 32-entry, 4-way associative, cache.

---

binary / result

The result of the / operator is the quotient from the division of the first operand by the second; 1148

Commentary

The identity $1/\infty \Rightarrow 0$ is consistent with the possibility that the infinity was the result of a division by zero.

Common Implementations

Because of its iterative nature, a divide operation is expensive in terms of the number of transistors required to implement it (in hardware) and its execution time. Divide instructions are often the slowest operation (involving integer operands) on a processor (it can take up to 60 cycles on the HP–was DEC– Alpha 21064 and 46 cycles on the Intel Pentium). Internally it is often implemented as a sequence of steps, computing the quotient digit by digit using some recursive formula; combinatorial implementations replicate the hardware that performs the division step (up to n times, where n is the number of bits in the significand). Because it is an infrequently used operation processor designers often trade significant amounts of chip resources (transistors) against performance (greater performance requires greater numbers of transistors). Many low-cost processors do not contain a divide instruction. For different reasons most of the early versions of the commercial RISC processors did not include a divide instruction. What was provided were one or more simpler instructions that could be used to create a sequence of code capable of performing a division operation. The length of the sequence is usually proportional to the number of bits in the narrowest operand.

Dynamic profiling information of hydro2d (from the SPEC92)[189] found that 64% of the executed divide instructions had either a 0 for its numerator or a 1 for its denominator. Using value profiling techniques, they were able to reduce the execution time of hydro2d by 15%, running on a HP–was DEC– Alpha 21064 processor; and were able to reduce the number of cycles executed by an Intel Pentium running some games' programs by an estimated 5%.

940 value profiling

An alternative to performing a divide is to take the reciprocal and multiply. This technique was used by Cray for floating-point operands in the hardware implementation of some of their processors.[299] The Diab Data compiler[353] `-Xieee754-pedantic` option enables developers to specify that the convert divide-to-multiple optimization should not be attempted. At least one processor vendor has proposed this optimization for integer operations.[23]

A common optimization is to replace division by a constant divisor that is a power of 2 by the appropriate right shift, when the numerator value is known to be positive. A less well known optimization[1443] enables any division by a constant to be replaced by a multiply. The basic idea is to multiply by a kind of reciprocal of the divisor (this reciprocal value, on a 32-bit processor, has a value close to $2^{32}/d$) and to extract the most significant 32 bits of the product.

Magenheimer, Peters, Pettis, and Zuras[885] describe an algorithm for obtaining sequences of shifts and adds that are equivalent to division by a constant.

Coding Guidelines

Many developers are aware of the relatively poor performance of the divide operator and sometimes transform the expression to use another operator. The issue of a right-shift operator being used to divide by a power of two is discussed elsewhere, as is the issue of using a bitwise operator to perform an arithmetic operation. A divide by a floating constant might be rewritten as a multiply by its reciprocal `x/5.0` becoming `x*0.2`. However, such a transformation does not yield numerically equivalent expressions unless the constants have an exact representation (in the floating-point representation used by the implementation executing the program).

1194 right-shift result
945 bitwise operators

Testing code containing a division operator can require checking a number of special cases. It is possible for the left operand to be incorrect and still obtain the correct answer most of the time. For instance, if `(x+1)/101` had been written instead of `(x+2)/101`, the result would be correct for 99% of the values of `x`. A white-box testing strategy would use test cases that provide left operand values just less than and just greater than the value of the right operand, however, testing is not within the scope of these coding guidelines.

Usage

Measurements by Oberman[1024] found that in a high percentage of cases division operations on floating-point operands repeat themselves (i.e., the same numerator and denominator values). The measurements were done using the SPECfp92 and NAS (Fortran-based) benchmarks.[82] Simulations using an infinite division operand cache found a hit rate (i.e., cache lookup could return the result of the division) of 69.8%, while a cache containing 128 entries had a hit rate of 60.9%. A more detailed analysis by Citron, Feitelson, and

0 SPEC benchmarks

Rudolph[239] found a great deal of variability over different applications, with multimedia applications having hit rates of 50% (using a 32 entry, 4-way associative cache).

% operator result

the result of the % operator is the remainder. 1149

Commentary

The character % is one of the few characters not already used as an operator in other programming languages that appears on most keyboards. It also is also visually similar to the character used to represent the divide operator token.

Common Implementations

In some processors the division instruction also calculates the remainder, putting it in a separate register. While a few processors have instructions that only perform the remainder operation, many more do not support this operation in hardware.

binary / 1148 result

The reciprocal-multiply algorithm listed as a possible replacement for division by a constant can also be used to calculate the remainder when the right operand is constant.

Coding Guidelines

binary / 1148 result

Like the divide operator, the performance of the remainder operator is generally poor and there are a number of well-known special cases that can be optimized. For instance, when the first operand has an unsigned type and the value of the second operand is a power of two, a bitwise-AND operation can zero out the top bits. Replacing an arithmetic operator by equivalent bitwise operations is discussed elsewhere.

bitwise operators 945

The result of this operator, when the left operand is positive, will range from zero to one less than the value of the right operand. Sometimes a value that varies between one and the value of the right operand is required. This can lead to off-by-one mistakes like those commonly seen in array subscripting.

---

divide by zero
remainder by zero

In both operations, if the value of the second operand is zero, the behavior is undefined. 1150

Commentary

The usual mathematical convention (for divide) is to say that the result is infinity. The C integer types do not support a representation for infinity; however, the IEC 60559 representation does. The IEC 60559 Standard defines three possible results, depending on the value of the left operand: $+\infty$, $-\infty$, and NaN.

IEC 60559 29

The behavior can also depend on the setting of the FENV_ACCESS pragma.

Other Languages

Some languages regard a second operand of zero for this operator as being more serious than undefined behavior (e.g., Ada requires an exception to be raised).

Common Implementations

Many processors raise an exception if the second operand is zero and has an integer type. This exception may be catchable within a program via a signal handler.

Coding Guidelines

Having a zero value for the second operand rarely makes any sense, algorithmically. It is unusual for a developer to intend it to occur. These coding guidelines are not intended to recommend against the use of constructs that are obviously faults.

guidelines 0 not faults

When integers are divided, the result of the / operator is the algebraic quotient with any fractional part discarded.[88] 1151

Commentary

C99 reflects almost universal processor behavior (as does the Fortran Standard). This definition truncates toward zero and the expression (-(a/b) == (-a)/b) && (-(a/b) == a/(-b)) is always true. It also means that the absolute value of the result does not depend on the signs of the operands; for example:

```
+10 / +3 == +3      +10 % +3 == +1      -10 / +3 == -3      -10 % +3 == -1

+10 / -3 == -3      +10 % -3 == +1      -10 / -3 == +3      -10 % -3 == -1
```

C90

When integers are divided and the division is inexact, if both operands are positive the result of the / operator is the largest integer less than the algebraic quotient and the result of the % operator is positive. If either operand is negative, whether the result of the / operator is the largest integer less than or equal to the algebraic quotient or the smallest integer greater than or equal to the algebraic quotient is implementation-defined, as is the sign of the result of the % operator.

If either operand is negative, the behavior may differ between C90 and C99, depending on the implementation-defined behavior of the C90 implementation.

```
1  #include <stdio.h>
2
3  int main(void)
4  {
5  int x = -1,
6      y = +3;
7
8  if ((x%y > 0) ||
9     ((x+y)%y == x%y))
10    printf("This is a C90 translator behaving differently than C99\n");
11 }
```

Quoting from the C9X Revision Proposal, WG14/N613, that proposed this change:

The origin of this practice seems to have been a desire to map C's division directly to the "natural" behavior of the target instruction set, whatever it may be, without requiring extra code overhead that might be necessary to check for special cases and enforce a particular behavior. However, the argument that Fortran programmers are unpleasantly surprised by this aspect of C and that there would be negligible impact on code efficiency was accepted by WG14, who agreed to require Fortran-like behavior in C99. WG14/N613

C++

If both operands are nonnegative then the remainder is nonnegative; if not, the sign of the remainder is implementation-defined[74)]. 5.6p4

Footnote 74 describes what it calls *the preferred algorithm* and points out that this algorithm follows the rules by the Fortran Standard and that C99 is also moving in that direction (work on C99 had not been completed by the time the C++ Standard was published).

The C++ Standard does not list any options for the implementation-defined behavior. The most likely behaviors are those described by the C90 Standard (see C90/C99 difference above).

Other Languages

Ada supports two remainder operators (**rem** and **mod**) corresponding to the two interpretations of the remainder operator (round toward or away from zero when one of the operands is negative).

Common Implementations

All C90 implementations known to your author follow the C99 semantics.

Coding Guidelines

While experience shows that developers do experience difficulties in comprehending code where one or more of the operands of the / operator has a negative value, there are no obvious guideline recommendations.

Example

```
1  int residua_modulo(int x, int y) /* Assumes y != 0 */
2  {
3  if (x >= 0)
4     return x%y;
5  else
6     return x%y + ((y > 0) ? +y : -y);
7  }
```

If the quotient **a/b** is representable, the expression **(a/b)*b + a%b** shall equal **a**. 1152

Commentary

This requirement was in C90 and only needed to be this complex because there were two possibilities for the result of the division operator in C90.

6.5.6 Additive operators

---

additive-expression syntax additive operators 1153

additive-expression:
multiplicative-expression
additive-expression + *multiplicative-expression*
additive-expression - *multiplicative-expression*

Commentary

The use of the term *additive* is based on the most commonly occurring of the two operators.

The probability that the sum of two floating-point numbers, randomly chosen from a logarithmic distribution, overflows is given by[415] (the probability of the subtraction underflowing has a sightly more complicated form, however it differs by at most 1 part in 10^{-9} of the probability given by this formula):

$$\frac{\pi^2}{6(\ln(\Omega/\omega))^2} \tag{1153.1}$$

where Ω and ω are the largest and smallest representable values respectively.

EXAMPLE 381 IEC 60559 floating-point

In the case of a representation meeting the minimum requirements of IEC 60559 the overflow probabilities are 7×10^{-7} for single-precision and 4×10^{-11} for double-precision. In practice application constraints may significantly limit the likely range of operand values (see Table 334.1), resulting in a much lower probability of overflow.

Table 338.2 lists various results from operating on infinities and NaNs; annex F (of the C Standard) discusses some of the expression optimizing transformations these results may prohibit.

Other Languages

These operators have the same precedence in nearly all languages. Their precedence relative to the multiplicative operators is also common to nearly all languages and with common mathematical usage.

Coding Guidelines

A study by Parkman and Groen[1057] showed subjects a series of simple addition problems of the form $p + q = n$ and asked them to respond as quickly as possible as to whether the value n was correct (both p and q were single-digit values). The time taken for subjects to respond was measured. It was possible to fit the results to a number of straight lines (i.e., $RT = ax + b$). In one case x was determined by the value $\min(p, q)$ in the other by $p + q$. That is, the response time increased as the minimum of the two operands increased, and as the sum of the operands increased. In both cases the difference in response time between when n was correct and when it was not correct (i.e., the value of b) was approximately 75 ms greater for incorrect. The difference in response time over the range of operand values was approximately 175 ms.

0 rule-base mistakes

VanLehn studied the subtraction mistakes made by school-children. The results showed a large number of different kinds of mistakes, with no one mistake being significantly more common than the rest (unlike the situation for multiplication).

1147 binary * result

The so-called *problem size* effect describes the commonly found subject performance difference between solving arithmetic problems involving large numbers and small numbers (e.g., subjects are slower to solve $9 + 7$ than $2 + 3$). A study by Zbrodoff[1502] suggested that this effect may be partly a consequence of the fact that people have to solve arithmetic problems involving small numbers more frequently than larger numbers (i.e., it is a learning effect); interference from answers to other problems was also a factor.

Table 1153.1: Common token pairs involving additive operators (as a percentage of all occurrences of each token). Based on the visible form of the `.c` files.

Constraints

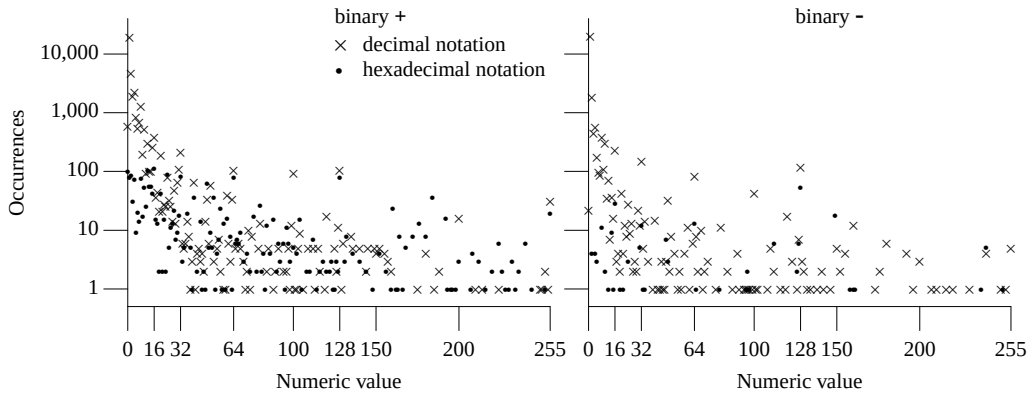

Figure 1153.1: Number of *integer-constant*s having a given value appearing as the right operand of additive operators. Based on the visible form of the `.c` files.

addition operand types

For addition, either both operands shall have arithmetic type, or one operand shall be a pointer to an object type and the other shall have integer type. 1154

Commentary

null pointer 748 constant

Both operands in the expression 0+0 have to be interpreted as having an arithmetic type. Although 0 can be interpreted as the null pointer constant, treating it as such would violate this constraint (because it is not a pointer to object type).

C++

The C++ Standard specifies that the null pointer constant has an integer type that evaluates to zero (4.10p1). In C the `NULL` macro might expand to an expression having a pointer type. The expression `NULL+0` is always a null pointer constant in C++, but it may violate this constraint in C. This difference will only affect C source developed using a C++ translator and subsequently translated with a C translator that defines the `NULL` macro to have a pointer type (occurrences of such an expression are also likely to be very rare).

Other Languages

Many languages do not support pointer arithmetic (i.e., adding integer values to pointer values). Some languages use the `+` operator to indicate string concatenation.

Coding Guidelines

array sub-989 script identical to

When some coding guideline documents prohibit the use of pointer arithmetic, further investigation often reveals that the authors only intended to prohibit the operands of an arithmetic operation having a pointer type. As discussed elsewhere, it is not possible to prevent the use of pointer arithmetic by such a simple-minded interpretation of C semantics.

symbolic 822 name enumeration 517 set of named constants postfix 1081 operator operand multiplicative 1144 operand type

Enumerated types are often thought about in symbolic, not arithmetic terms. The use of operands having an enumerated type is discussed elsewhere. The rationale for the deviation given for some operators does not apply to the addition operator.

The possibility of arithmetic operations on operands having a boolean role is even less likely than for the multiplication operators.

Table 1154.1: Occurrence of additive operators having particular operand types (as a percentage of all occurrences of each operator; an _ prefix indicates a literal operand). Based on the translated form of this book's benchmark programs.

Left Operand	Operator	Right Operand	%	Left Operand	Operator	Right Operand	%

(Incrementing is equivalent to adding 1.) 1155

Commentary

This specifies how the term *incrementing* is to be interpreted in the context of the additive operators.

Coding Guidelines

A common beginner programming mistake is to believe that incrementing an object used for input will cause the next value to be input.

1156 For subtraction, one of the following shall hold:

Commentary

Unlike addition, subtraction is not a symmetrical operator, and it is simpler to specify the different cases via bullet points.

1157 88) This is often called "truncation toward zero". footnote 88

Commentary

Either the term *truncation toward zero* or *rounded toward zero* is commonly used by developers to describe this behavior.

C90

This term was not defined in the C90 Standard because it was not necessarily the behavior, for this operator, performed by an implementation.

C++

Footnote 74 uses the term *rounded toward zero*.

Other Languages

This term is widely used in many languages.

1158 — both operands have arithmetic type;

Commentary

This includes the complex types.

Other Languages

Support for operands of this type is universal to programming languages.

Coding Guidelines

These are the operand types that developers use daily in their nonprogramming lives. The discussion on operands having enumerated types or being treated as boolean, is applicable here.

521 arithmetic type
1154 addition operand types

1159 — both operands are pointers to qualified or unqualified versions of compatible object types; or subtraction pointer operands

Commentary

The additive operators are not defined for operands having pointer to function types. The expression 0−0 is covered by the discussion on operand types for addition.

1154 addition operand types

Although the behavior is undefined unless the two pointers point into the same object, one of the operands may be a parameter having a qualified type. Hence the permission for the two operands to differ in the qualification of the pointed-to type. Differences in the qualification of pointed-to types is guaranteed not to affect the equality status of two pointer values.

1173 pointer subtraction point at same object
746 pointer converting qualified/unqualified

C++

5.7p2

— both operands are pointers to cv-qualified or cv-unqualified versions of the same completely defined object type; or

Requiring the same type means that a C++ translator is likely to issue a diagnostic if an attempt is made to subtract a pointer to an enumerated type from its compatible integer type (or vice versa). The behavior is undefined in C if the pointers don't point at the same object.

```
#include <stddef.h>

enum e_tag {E1, E2, E3}; /* Assume compatible type is int. */
union {
      enum e_tag m_1[5];
      int m_2[10];
      } glob;

extern enum e_tag *p_e;
extern int *p_i;

void f(void)
{
ptrdiff_t loc = p_i-p_e; /* does not affect the conformance status of the program */
                         // ill-formed
}
```

addition 1154 operand types The expression `NULL-0` is covered by the discussion on operand types for addition.

Other Languages

Support for subtracting two values having pointer types is unique to C (and C++).

Table 1159.1: Occurrence of operands of the subtraction operator having a pointer type (as a percentage of all occurrences of this operator with operands having a pointer type). Based on the translated form of this book's benchmark programs.

Left Operand	Operator	Right Operand	%	Left Operand	Operator	Right Operand	%
char *	-	**char** *	48.9	**void** *	-	**void** *	1.4

`char *`	+	`unsigned int`	1.9	`char *`	+	`unsigned short`	1.0
`struct *`	+	`int`	1.8	other-types	-	other-types	0.0

1161 (Decrementing is equivalent to subtracting 1.)

Commentary

This specifies how the term *decrementing* is to be interpreted in the context of the additive operators.

Semantics

1162 If both operands have arithmetic type, the usual arithmetic conversions are performed on them.

additive operators semantics

Commentary

There is no requirement to perform the usual arithmetic conversions if only one of the operands has arithmetic type. The only possible other operand type is a pointer and the result has its type. Performing the usual arithmetic conversions may result in the integer promotions being performed.

706 usual arithmetic conversions

710 arithmetic conversions integer promotions

Common Implementations

Most processors use the same instructions for performing arithmetic involving pointer types as they use for arithmetic types. An operand having an arithmetic type is likely to undergo the same conversions, irrespective of the type of the other operand (and the same optimizations are likely to be applicable).

Coding Guidelines

There is a common incorrect assumption that if the operands of the additive operators have the same type, the operation will be performed using that type. This issue is discussed elsewhere. If the guideline recommendation specifying the use of a single integer type is followed these conversions will have no effect.

653 operand convert automatically

480.1 object int type only

1163 The result of the binary + operator is the sum of the operands.

Commentary

It is quite common for a series of values to be added together to create a total. When the operands have a floating type, each addition operation introduces an error. Are some algorithms better than others at minimizing the error in the final result? The following analysis is based on Robertazzi and Schwartz.[1171] This analysis assumes that the relative error for each addition operation will be independent of the others (i.e., have a zero mean) with a variance (mean square error) of σ^2. Let N represent the number of values being added, which are assumed to be positive. These values can have a number of distributions. In a uniform distribution they are approximately evenly distributed between the minimum and maximum values; while in an exponential distribution they are distributed closer to the maximum value.

A series of values can be added to form a sum in a number of different ways. It is known[1466] that the minimum error in the result occurs if the values are added in order of increasing magnitude. In practice most programs loop over the elements of an array, summing them (i.e., the ordering of the magnitude of the values is random). The mean square error for various simple methods of summing a list of values is shown in columns 2 to 6 of Table 1163.1.

Table 1163.1: Mean square error in the result of summing, using five different algorithms, N values having a uniform or exponential distribution; where μ is the mean of the N values and σ^2 is the mean square error that occurs when two numbers are added.

Distribution	Increasing Order	Random Order	Decreasing Order	Insertion	Adjacency
Uniform $(0, 2\mu)$	$0.2\mu^2N^3\sigma^2$	$0.33\mu^2N^3\sigma^2$	$0.53\mu^2N^3\sigma^2$	$2.6\mu^2N^2\sigma^2$	$2.7\mu^2N^2\sigma^2$
Exponential (μ)	$0.13\mu^2N^3\sigma^2$	$0.33\mu^2N^3\sigma^2$	$0.63\mu^2N^3\sigma^2$	$2.63\mu^2N^2\sigma^2$	$4.0\mu^2N^2\sigma^2$

The simple algorithms maintain a single intermediate sum, to which all values are added in turn. Using the observation that the error in addition is minimized if values of similar magnitude are used,[888] more accurate algorithms are possible. An insertion adder takes the result of the first addition and inserts it into the remaining list of vales to be added. The next two lowest values are added and their result inserted into the remaining list, and so on until a single value, the final result, remains. The adjacency algorithm orders the values by magnitude and then pairs them off. The smallest value paired with the next smallest and so on, up to the largest value. Each pair is added to form a new list of values and the process repeated. Eventually a single value, the final result, remains. The error analysis for these two algorithms shows (last two columns of Table 1163.1) a marked improvement. The difference between these sets of results is that the latter varies as the square of the number of values being added, while the former varies as the cube of the number of values.

These formula can be expressed in terms of information content by defining the signal-to-noise ratio as the square of the final sum divided by the mean square error of this sum, then for the simple ordering algorithm the ratio decreases linearly with N. For the insertion and adjacency addition algorithms, it is independent of N. Another way to decrease the error in the simple ordering algorithms is to increase the number of bits in the significand of the result. Performance can be improved to that of the insertion or adjacency algorithm by using $\log_2(sqrt(N))$ additional bits.

As an example, after adding 4,096 values, the mean square error in the result is approximately 1×10^{-2} using the simple ordering algorithms, and approximately 3×10^{-5} for the insertion and adjacency algorithms.

When negative, as well as positive, values are being summed, there are advantages to working from the largest to the smallest. For an analysis of the performance of seven different algorithms, see Mizukami.[948]

Demmel and Hida

The preceding analysis provides a formula for the average error, what about the maximum error? Demmel and Hida[344] analyzed the maximum error in summing a sorted list of values. They proved an upper bound on the error (slightly greater than 1.5 ULPs) provided the condition $N \leq M$ was met, where N is the number of values in the list and $M = 1 + floor(2^{F-f}/(1-2^{-f}))$, f is the precision of the values being added, and F is the precision of the temporary used to hold the running total. They also showed that if $N \geq M + 2$, the relative error could be greater than one (i.e., no relative accuracy).

ULP 346
precision 335
floating-point

Using IEC 60559 representation for single- and double-precision values: if 65,537, single-precision values are summed, storing the running total in a temporary having double-precision; the maximum error will only be slightly greater than 1.5 ULPs. If the temporary has single-precision, then three additions are sufficient for the error to be significantly greater than this.

Other Languages

Some languages also use the binary **+** operator to indicate string concatenation (not just literals, but values of objects).

Common Implementations

Error analysis on the Cray

Some Cray processors do not implement IEC 60559 arithmetic. On the Cray the error analysis formula

for addition and subtraction differs from that discussed elsewhere. Provided $fl(a \pm b)$ does not overflow or underflow, then: 346 error analysis

$$fl(a \pm b) = ((1 + \epsilon_1) \times a) \pm ((1 + \epsilon_2) \times b) \tag{1163.1}$$

In particular, this means that if a and b are nearly equal, so $a - b$ is much smaller than either a or b (known as *extreme cancellation*), then the relative error may be quite large. For instance, when subtracting $1 - x$, where x is the next smaller floating-point number than 1, the answer is twice as large on a Cray C90, and 0 when it should be nonzero on a Cray 2. This happens because when x's significand is shifted to line its binary point up with 1's binary point, prior to actually subtracting the significands, any bits shifted past the least significant bit of 1 are simply thrown away (differently on a Cray C90 and Cray 2) rather than participating in the subtraction. On IEC 60559 machines, there is a so-called guard digit (actually 3 of them) to store any bits shifted this way, so they can participate in the subtraction.

Usage

A study by Sweeney[1323] dynamically analyzed the floating-point operands of the addition operator. In 26% of cases the values of the two operands were within a factor of 2 of each other, in 13% of cases within a factor of 4, and in 84% of cases within a factor of 1,024.

1164 The result of the binary - operator is the difference resulting from the subtraction of the second operand from the first. subtraction result of

Commentary

If the floating-point operands of a subtraction operator differ from each other by less than a factor of 2, and the result is correctly rounded, then the result is exact[500] (mathematically, $x/2 < y < 2x \Rightarrow x \ominus y = x - y$). 64 correctly rounded result

Common Implementations

Some implementations of this operator complement the value of the right operand and perform an addition. For IEC 60559 arithmetic the expression 0-0 yields -0 when the rounding direction is toward -∞. Cuyt and Verdonk[306] describe the very different results obtained, using two different processors with various combinations of floating-point types, when evaluating an expression that involves subtracting operands having very similar values.

Example

```
1  #include <stdio.h>
2
3  extern float ef1, ef2;
4
5  void f(void)
6  {
7  if (((ef1 - ef2) == 0.0) &&
8      (ef1 != ef2))
9     printf("ef1 and ef2 have very small values\n");
10 }
```

1165 For the purposes of these operators, a pointer to an object that is not an element of an array behaves the same as a pointer to the first element of an array of length one with the type of the object as its element type. additive operators pointer to object

Commentary

Pointer types specify the type they point at; nothing is assumed about how many objects of that type may be contiguous in storage at the pointed-to location. Common developer terminology is to refer to each of these *elements* as an *object*. The same sentence appears elsewhere in the standard.

1203 relational operators pointer to object
1232 equality operators pointer to object

Other Languages

More strongly typed languages require that pointer declarations fully specify the type of object pointed at. A pointer to **int** is assumed to point at a single instance of that type. A pointer to an object having an array type requires a pointer to that array type. Needless to say these strongly typed languages do not support the use of pointer arithmetic.

Common Implementations

Implementations that do not treat storage as a linear array of some type are very rare. The Java virtual machine is one such. Here the intent is driven by security issues; programs should not be able to access protected data or to gain complete control of the processor. All data is typed and references (Java does not have pointers as such) to allocated storage must access it using the type with which it was originally allocated.

Coding Guidelines

Having a pointer to an object behaves the same as if it pointed to the first element of an array; it is part of the C model of pointer handling. It fits in with behavior specified in other parts of the standard, and modifying this single behavior creates a disjoint pointer model (not a more strongly typed model).

---

pointer arithmetic type

When an expression that has integer type is added to or subtracted from a pointer, the result has the type of the pointer operand. 1166

Commentary

The additive operation returns a modified pointer value. This pointer value denotes a location having the pointer's pointed-to type.

---

pointer arithmetic addition result

If the pointer operand points to an element of an array object, and the array is large enough, the result points to an element offset from the original element such that the difference of the subscripts of the resulting and original array elements equals the integer expression. 1167

Commentary

This specification allows pointers to be treated, by developers, like array indexes. This would not be possible if adding/subtracting integer values to/from pointer values operated at the byte level (unless the operand had pointer to character type).

Common Implementations

byte 54 address unique

pointer 1174 arithmetic subtraction result binary * 1147 result

Because every byte of an object has a unique address, adding one to a pointer to **int**, for instance, requires adding `(1*sizeof(int))` to the actual pointer value. Adding, or subtracting, `x` to a pointer to `type` requires that the pointer value be offset by `(x*sizeof(type))`. Subtracting two pointers involves a division operation. Scalar type sizes are often a power of two and optimization techniques, described elsewhere, can be applied. Structure types, may require an actual divide.

In other words, if the expression **P** points to the *i*-th element of an array object, the expressions **(P)+N** (equivalently, **N+(P)**) and **(P)-N** (where **N** has the value *n*) point to, respectively, the *i+n*-th and *i-n*-th elements of the array object, provided they exist. 1168

Commentary

array sub-script identical to 989

Adding to a pointer value can be compared to adding to an array index variable. The storage, or array, is not accessed, until the dereference operator is applied to it.

---

pointer one past end of object

Moreover, if the expression **P** points to the last element of an array object, the expression **(P)+1** points one past the last element of the array object, and if the expression **Q** points one past the last element of an array object, the expression **(Q)-1** points to the last element of the array object. 1169

Commentary

The concept of *one past the last object* has a special meaning in C. When array objects are indexed in a loop (for the purposes of this discussion the array index may be an object having pointer type rather than the form `a[i]`), it is common practice to start at the lowest index and work up. This often means that after the last iteration of the loop to the array the index has a value that is one greater than the number of elements it contains (however, the array object is never indexed with this value). This common practice makes one past the end of the array object special, rather than the one before the start of the array object (which has no special rules associated with it).

This specification requires that a pointer be able to point one past the end of an object, but it does not permit storage to be accessed using such a value. There is an implied requirement that all pointers to one past the end of the same object compare equal.

The response to DR #221 pointed out that:

Simply put, 10 == 9+1. Based on the "as-if" rule, there is no semantic distinction among any of the following: DR #221

```
v+9+1
(v+9)+1
v+(9+1)
v+10
```

This means that there are many ways of creating a pointer to *one past the last element*, other than adding one to a pointer-to the last element.

1170 If both the pointer operand and the result point to elements of the same array object, or one past the last element of the array object, the evaluation shall not produce an overflow; pointer arithmetic defined if same object

Commentary

This is a requirement on the implementation. *Overflow* is not a term usually associated with pointer values. Here it is used in the same sense as that used for arithmetic values (i.e., denoting a value that is outside of the accepted bounds).

Common Implementations

The standard does not impose any representation requirements on the value of "one past the last element of an array object". There is a practical problem on host processors that use a segmented memory architecture. If an object occupies an entire segment, there is a unique location for the one past the end pointer, to point. *One past the end* could be represented by adding one to the current pointer value (which for a multiple byte element type would not be a pointer to the next element). 590 pointer segmented architecture

Example

```
1  int a[10];
2

```

pointer arithmetic undefined

otherwise, the behavior is undefined. 1171

Commentary

Any pointer arithmetic that takes a pointer outside of the pointed-to object (apart from the one past exception) is undefined behavior. There is no requirement that the pointer be dereferenced; creating it within a subexpression is sufficient.

Common Implementations

pointer 590 segmented architecture Motorola 39 56000

Most implementations treat storage as a contiguous sequence of bytes. Incrementing a pointer simply causes it to point at different locations. On a segmented architecture the value usually wraps from either end of the segment to point at the other end. Some processors[6] support circular buffers by using modulo arithmetic for operations on pointer values.

Some implementations perform checks on the results of pointer arithmetic operations during program execution.[681,690] (Most implementations that perform pointer checking only perform checks on accesses to storage.)

Coding Guidelines

Expressions whose intermediate results fall outside the defined bounds that can be pointed out (such as the `(a+20)-19` example above), but whose final result is within those bounds, do occur in practice. In practice, the behavior of the majority of processors results in the expected final value of the expression being returned. Given the behavior of existing processors and the difficulty of enforcing any guideline recommendation (the operands are rarely translation-time constants, meaning the check could only be made during program execution), no recommendation is made here.

one past the end accessing

If the result points one past the last element of the array object, it shall not be used as the operand of a unary * operator that is evaluated. 1172

Commentary

&* 1092

Accessing storage via such a result has undefined behavior. The special case of `&*p` is discussed elsewhere.

C++

This requirement is not explicitly specified in the C++ Standard.

Common Implementations

This is one of the checks that has to be performed by runtime checking tools that claim to do pointer checking.[65,548,681,690,1032,1288] The granularity of checking actually performed varies between these tools. Some tools try to minimize the runtime overhead by only performing a small number of checks (e.g., does the pointer point within the stack or within the storage area currently occupied by allocated storage). A few tools check that storage is allocated for objects at the referenced location. Even fewer tools detect a dereference of a *one past the last object* pointer value.

Coding Guidelines

guidelines 0 not faults

Developers rarely intend to reference storage via such a pointer value. These coding guidelines are not intended to recommend against the use of constructs that are obviously faults.

pointer subtraction point at same object

When two pointers are subtracted, both shall point to elements of the same array object, or one past the last element of the array object; 1173

Commentary

structure members 1206 later compare later

The standard does not contain any requirements on the relative positions, in storage, of different objects. (Although there is a relational requirement for the members of structure types.) Subtracting two pointers that do not point at elements of the same object (or one past the last element) is undefined behavior. This requirement renders `P-Q` undefined behavior when both operands have a value that is equal to the null pointer constant.

C90

The C90 Standard did not include the wording "or one past the last element of the array object;". However, all implementations known to your author handled this case according to the C99 specification. Therefore, it is not listed as a difference.

Common Implementations

Processors do not usually contain special arithmetic instructions for operands having pointer types. The same instruction used for subtracting two integer values is usually used for subtracting two pointer values. This means that checking pointer operands, to ensure that they both point to elements of the same object, incurs a significant runtime time-performance overhead. Only a few of the tools that perform some kind of runtime pointer checking perform this check.[65, 681, 690, 1288] The behavior of most implementations is to treat all storage as a single array object of the appropriate type. Whether the two pointers refer to declared objects does not usually affect behavior.

Coding Guidelines

Developers sometimes do intend to subtract pointers to different array objects and such usage makes use of information on the layout of objects in storage, which is discussed elsewhere.

1354 storage layout

Example

```
#include <stddef.h>

extern void zero_storage(char *, size_t);

void f(void)
{
char start;
/* ... */
char end;

if (&start < &end)
   zero_storage(&start, &end-&start);
else
   zero_storage(&end, &start-&end);
}
```

1174 the result is the difference of the subscripts of the two array elements.

pointer arithmetic subtraction result

Commentary

This specification matches the behavior for adding/subtracting integer values to/from pointer values. The calculated difference could be added to the value of the right operand to yield the value of the left operand.

1167 pointer arithmetic addition result

Common Implementations

Because every byte of an object has a unique address, subtracting two pointers to **`int`**, for instance, requires dividing the result of the subtraction by `sizeof(int)`. Subtracting two pointers to type requires that the subtracted value be divided by `sizeof(type)`.

54 byte address unique

The size of scalar types is often a power of two and an obvious optimization technique is to map the divide to a shift instruction. However, even if the size of the element type is not a power of two, a divide may not need to be performed. A special case of the technique that allows a divide to be replaced by a multiply instruction applies when it is known that the division is exact (i.e., zero remainder).[1443] For instance, on a 32 bit processor, division by 7 can be mapped to multiplication by 0xB6DB6DB7 and extracting the least significant 32 bits of the result.

1148 binary / result

Note: this technique produces widely inaccurate results if the numerator is not exactly divisible, which can occur if the value of one of the pointers involved in the original subtraction has been modified so that it no longer points to the start of an element.

Example

In the following the first `printf` should yield 10 for both differences. The second `printf` should yield the value `sizeof(int)*10`.

```
#include <stdio.h>

void f(void)
{
char a1[20], *p11 = a1, *p12 = a1+10;
int  a2[20], *p21 = a2, *p22 = a2+10;

printf("a1 pointer difference=%d, a2 pointer difference=%d\n",
                                          (p12 - p11), (p22 - p21));
printf("char * cast a2 pointer difference=%d\n",
                                         ((char *)p22 - (char *)p21));
}
```

---

pointer subtract result type

The size of the result is implementation-defined, and its type (a signed integer type) is **`ptrdiff_t`** defined in the **`<stddef.h>`** header. 1175

Commentary

Here the word *size* is referring to the numeric value of the result. The implementation-defined value will be greater than or equal to the value of the `PTRDIFF_MIN` macro and less than or equal to the value of the `PTRDIFF_MAX` macro. There is no requirement that `SIZE_MAX == PTRDIFF_MAX` or that `ptrdiff_t` be able to represent a difference in pointers into an array object containing the maximum number of bytes representable in the type `size_t`.

sizeof 1127 result type

It is the implementation's responsibility to ensure that the type it uses for `ptrdiff_t` internally is the same as the typedef definition of `ptrdiff_t` in the supplied header, **`<stddef.h>`**. A developer can define a typedef whose name is `ptrdiff_t` (provided the name is unique in its scope). Such a declaration does not affect the type used by a translator as the result type for the subtraction operator when both operands have a pointer type.

Other Languages

Most languages have a single integer type, if they support pointer subtraction, there is often little choice for the result type.

Coding Guidelines

While the type `ptrdiff_t` may cause a change in type of subsequent operations within the containing full expression, the effect is not likely to be significant.

sizeof 1127 result type

If the result is not representable in an object of that type, the behavior is undefined. 1176

Commentary

Most processors have an unsigned address space, represented using the same number of bits as the width of the largest integer type supported in hardware. (Operations on values having pointer and integer types are usually performed using the same instructions.) Given that `ptrdiff_t` is a signed type, an implementation only needs to support the creation of an object occupying more than half the total addressable storage before nonrepresentable results can be obtained. (The object need contain only a single element since a pointer to one past the last element can be the second operand.)

width 626 integer type

C90

As with any other arithmetic overflow, if the result does not fit in the space provided, the behavior is undefined.

Common Implementations

For the majority of processors that use the same instructions for integer and pointer operands the behavior for nonrepresentable results is likely to be the same in both cases. The IBM AS/400 hardware uses a 16-byte pointer. The ILE C documentation[617] is silent on the issue of this result not being representable.

Coding Guidelines

Programs creating objects that are sufficiently large for this undefined behavior to be a potential issue are sufficiently rare that these coding guidelines say nothing about the issue.

1177 In other words, if the expressions `P` and `Q` point to, respectively, the *i*-th and *j*-th elements of an array object, the expression `(P)-(Q)` has the value *i-j* provided the value fits in an object of type `ptrdiff_t`.

Commentary

This sentence specifies the behavior described in the previous C sentences in more mathematical terms.

1178 Moreover, if the expression `P` points either to an element of an array object or one past the last element of an array object, and the expression `Q` points to the last element of the same array object, the expression `((Q)+1)-(P)` has the same value as `((Q)-(P))+1` and as `-((P)-((Q)+1))`, and has the value zero if the expression `P` points one past the last element of the array object, even though the expression `(Q)+1` does not point to an element of the array object.[89)]

Commentary

The equivalence between these expressions requires that pointer subtraction produce the same result when one or more of the operands point within the same array object or one past the last element of the same array object.

1179 EXAMPLE Pointer arithmetic is well defined with pointers to variable length array types.

```
{
        int n = 4, m = 3;
        int a[n][m];
        int (*p)[m] = a;          // p == &a[0]
        p += 1;                   // p == &a[1]
        (*p)[2] = 99;             // a[1][2] == 99
        n = p - a;                // n == 1
}
```

If array `a` in the above example were declared to be an array of known constant size, and pointer `p` were declared to be a pointer to an array of the same known constant size (pointing to `a`), the results would be the same.

Commentary

The machine code generated by a translator to perform the pointer arithmetic needs to know the size of the type pointed-to, which in this example will not be a constant value that is known at translation time. 548 known constant size

C90

This example, and support for variable length arrays, is new in C99.

Common Implementations

When the pointed-to type is a variable length array, its size is not known at translation time. A variable size on the second or subsequent subscript prevents optimization of any of the implicit multiplication operations needed when performing pointer arithmetic.

pointer 1167 arithmetic addition result

At the time of this writing your author is not aware of any C based pointer-checking tools that support checking on pointers to variably sized arrays.

Forward references: array declarators (6.7.5.2), common definitions `<stddef.h>` (7.17). 1180

6.5.7 Bitwise shift operators

shift-expression syntax

1181

```
shift-expression:
                additive-expression
                shift-expression << additive-expression
                shift-expression >> additive-expression
```

Commentary

Bit shift instructions are ubiquitous in processor instruction sets. These operators allow writers of C source to access them directly. Many processors also contain bit rotate instructions; however, the definition of these instructions varies (in some cases the rotate includes a bit in the status flags register), and they are not commonly called for in algorithms.

Other Languages

Most languages do not get involved in providing such low level operations, just because such instructions are available on most processors. Java also defines the `>>>` operator.

Table 1181.1: Common token pairs involving the shift operators (as a percentage of all occurrences of each token). Based on the visible form of the `.c` files.

Token Sequence	% Occurrence of First Token	% Occurrence of Second Token	Token Sequence	% Occurrence of First Token	% Occurrence of Second Token
identifier >>	0.1	63.9	] <<	0.5	5.3

integer-constant <<	0.5	36.1	>> *integer-constant*	79.8	0.7
) >>	0.2	28.0	<< identifier	28.4	0.1
) <<	0.2	20.3	<< (	8.1	0.1
] >>	0.4	6.2	>> identifier	15.9	0.0

Constraints

Each of the operands shall have integer type. 1182

Commentary

This constraint reflects the fact that processors rarely contain instructions for shifting non-integer types (e.g., floating-point types), which in turn reflects the fact that there is no commonly defined semantics for shifting other types.

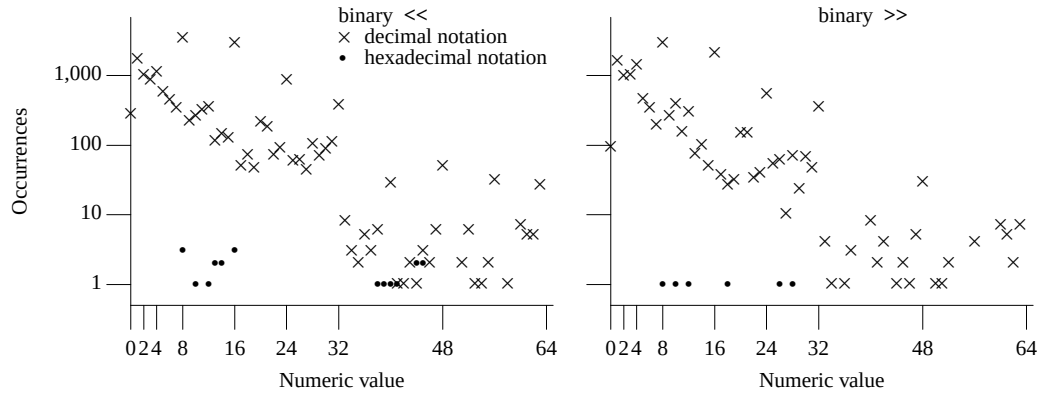

Figure 1181.1: Number of *integer-constant*s having a given value appearing as the right operand of the shift operators. Based on the visible form of the `.c` files.

Table 1182.1: Occurrence of shift operators having particular operand types (as a percentage of all occurrences of each operator; an _ prefix indicates a literal operand). Based on the translated form of this book's benchmark programs.

Semantics

1183 The integer promotions are performed on each of the operands.

shift operator integer promotions

Commentary

This is the only implicit conversion performed on the operands.

Common Implementations

The shift instructions on some processors can operate on operands of various widths, provided both widths are the same (e.g., those on the Intel x86 processor family can operate on either 8, 16, or 32 bit operands). However, the result returned by these instructions usually has the same width as the operand. For instance, shifting an operand having type **unsigned char** and value 0xf0 left by two bits returns 0xc0 rather than 0x3c0. If the next operation is an assignment to an object having the same type as the operand type, an optimizer might choose to make use of one of these narrower-width instructions; otherwise, the width corresponding to the promoted type has to be used. The width of the left operand will be the same as the object assigned to when the compound assignment form of these operators is used.

1288 assignment-expression syntax

Coding Guidelines

The type of the left operand needs to be taken into account when thinking about the result of a shift operation. However, some developers have a mental model that does not include the integer promotions. The effect of the integer promotions on an object having type **`signed char`** or **`short`** (when `sizeof(short)!= sizeof(int)`), and a negative value, is to increase the number nonzero bits in the value representation. The issue of right-shifting negative values is discussed elsewhere. Using shift operators to perform arithmetic operations is making use of representation information; this is covered by a guideline recommendation. In this case unsigned types need to be used and a deviation is provided to cover this situation.

right-shift 1196
negative value representation 569.1
representation information using object 480.1
int type only

The type of the result is that of the promoted left operand. 1184

Commentary

The usual arithmetic conversions are not performed on the operands. The right operand does not affect the type of the left operand.

Common Implementations

In some prestandard implementations the usual arithmetic conversions were performed on both operands, which meant the result type might not have been that of the promoted left operand.

Example

```
1  extern unsigned long glob;
2
3  void f(void)
4  {
5  unsigned int loc;
6
7  /*
8   * The result of the << operation is int (bits may be shifted off the
9   * end, which might not occur if loc were promoted to unsigned long),
10  * which is then promoted to type unsigned long.
11  */
12 loc = glob % (loc << glob);
13 }
```

If the value of the right operand is negative or is greater than or equal to the width of the promoted left operand, the behavior is undefined. 1185

Commentary

This specification takes into account the variation in behavior of processor shift instructions when asked to shift by a negative amount. For instance, some processors require the shift amount to be loaded into a special register, which is only capable of holding a limited range of values. Loading a value greater than the width of the operand into one of these registers may result in a shift amount of zero, while loading a negative value may result in the largest shift amount.

Other Languages

Java ensures that the value of the right operand is always in range by specifying that the equivalent of a bitwise-AND is performed on it (the number of bits extracted depending on the type of the left operand). Algol is unusual in that it defines shifting by a negative amount as reversing the direction of the shift operator (e.g., `x << -2` shifts x right by 2).

Common Implementations

The behavior may be decided by the translator or by the characteristics of the processor that executes the machine code generated to perform the operation. For instance, many translators will fold `(1 << 32)` to 0,

while generating machine code to evaluate `(y << 32)`. The Intel Pentium[627] `SAL` instruction (generated by both `gcc` and Microsoft C++ to evaluate left-shifts) only uses the bottom five bits of the shift amount (leading to `y` being shifted by zero bits in the example below).

```
1  #include <stdio.h>
2
3  int y = 1;
4
5  int main(void)
6  {
7  if ((1 << 32) != (y << 32))
8     printf("1 != %d\n", y);
9  }
```

Coding Guidelines

Developers sometimes incorrectly assume that a very large shift value will generate a result of all bits zero or all bits one (i.e., when right-shifting negative values is implemented arithmetically). Shifting by a negative amount has no common meaning associated with it (such usage is invariably a fault and nothing is served by having a guideline recommending against faults).

0 guidelines not faults

1186 89) Another way to approach pointer arithmetic is first to convert the pointer(s) to character pointer(s): In this scheme the integer expression added to or subtracted from the converted pointer is first multiplied by the size of the object originally pointed to, and the resulting pointer is converted back to the original type.

footnote 89

Commentary

This describes common implementation practice.

1187 For pointer subtraction, the result of the difference between the character pointers is similarly divided by the size of the object originally pointed to.

Commentary

This describes common implementation practice.

1188 When viewed in this way, an implementation need only provide one extra byte (which may overlap another object in the program) just after the end of the object in order to satisfy the "one past the last element" requirements.

Commentary

A *one past the last element* value needs to point at something. Because an implementation is not required to support the dereferencing of any pointers to this location, it need only consist of a single byte.

1172 one past the end accessing

Common Implementations

Most implementations do not allocate storage for this *one past the last element* location. In many cases such an address is the first byte of the next object defined in the source. Using the address of another object as the value of the *one past the last element* location makes it difficult for execution-time verification of pointer usage. Such a checking implementation would either have to leave some extra storage at the end of every object or use an alternative representation. The Model Implementation C Checker[681] uses a special region of storage to represent this concept. It contains information on which object is being pointed one past of, and the execution-time system knows that all pointers to this area of storage are pointing one past the end of some object.

1189 The result of **`E1 << E2`** is **`E1`** left-shifted **`E2`** bit positions;

Commentary

A left-shift moves bits from less significant positions to more significant positions within the representation. Once bits are shifted passed the most significant bit, they cease to be part of the value representation. Unlike the arithmetic operators, it is accepted that bits may be *lost* during a shift operation.

Common Implementations

Many processors contain instructions for shifting by a constant amount (the value is embedded in the instruction). Others require that the amount to shift by be loaded into a register. Some offer both forms (e.g., Intel x86). Some processors implement this instruction such that it performs the complete shift in one cycle (a barrel shifter). Other processors may take a cycle-per-bit position shifted.

Coding Guidelines

representation information using 569.1

Left-shifting is commonly known to be equivalent, in a binary representation, to multiplying a positive value by a power of two. The issue of replacing arithmetic operations by bitwise operations is covered by the guideline recommendation dealing with the use of representation information.

---

vacated bits are filled with zeros. 1190

Commentary

The vacated bits occur in the least significant bit, as the operand is shifted left.

---

left-shift of positive value

If **E1** has an unsigned type, the value of the result is $\mathbf{E1} \times 2^{\mathbf{E2}}$, reduced modulo one more than the maximum value representable in the result type. 1191

Commentary

value representation 595

This is one of the consequences of requiring that all bits in the value representation participate in forming a value. There are no more bits visible to a shift operator shift than are visible from an arithmetic operator.

Common Implementations

This C sentence is a mathematical description of the behavior. In practice processor implementations have circuitry that shifts bits rather than multiplying them.

If **E1** has a signed type and nonnegative value, and $\mathbf{E1} \times 2^{\mathbf{E2}}$ is representable in the result type, then that is the resulting value; 1192

Commentary

positive signed integer type 495
subrange of equivalent unsigned type

A positive value, having a signed type, has the same representation as the corresponding unsigned type.

C90

This specification of behavior is new in C99; however, it is the behavior that all known C90 implementations exhibit.

C++

Like the C90 Standard, the C++ Standard says nothing about this case.

Other Languages

Java defines this to be the behavior of the left-shift operator for all values (including negative ones) of E1.

---

left-shift undefined

otherwise, the behavior is undefined. 1193

Commentary

sign bit 610
representation

A negative value incorporates a sign bit. There is no consistent behavior across all processors and, given the desire to efficiently implement the C Standard on a wide range of processors, the Committee was not able to agree on a behavior.

C90

This undefined behavior was not explicitly specified in the C90 Standard.

C++

Like the C90 Standard, the C++ Standard says nothing about this case.

Common Implementations

In practice the defined behaviors are invariably one of the following:

- sign bit is treated just like the other bits (e.g., it is shifted).
- sign bit is ignored and it remains unchanged by the shift instruction (e.g., the Unisys A Series[1390]).
- sign bit is *sticky* (i.e., as soon as a 1 is shifted through it, its value stays set at 1).

Coding Guidelines

These guidelines recommend the use of a single integer type, which is signed. This undefined behavior, for signed types, means that developers wanting to portably manipulate a scalar type as a sequence of bits are going to have to declare an object to have an unsigned type.

480.1 object int type only

Dev 480.1 An object whose value is always treated as a sequence of bits, rather than an arithmetic value, may be declared to have an unsigned type.

1194 The result of `E1 >> E2` is `E1` right-shifted `E2` bit positions.

right-shift result

Commentary

A right-shift moves bits from most significant positions to less significant positions within the representation. Once bits are shifted passed the least significant bit, they cease to be part of the value representation. Unlike the arithmetic operators, it is accepted that bits may be *lost* during a shift operation. On processors that use either one's complement or sign and magnitude representation for the integer types, the right-shift operator is always equivalent to a divide by the appropriate power of 2. Steele[1286] gives examples of how often right-shift and division by powers of 2 are incorrectly treated as being equivalent when integer types are represented using two's complement.

Coding Guidelines

Shifting right is commonly known to be equivalent, in a binary representation, to dividing a positive value by powers of 2. The issue of replacing arithmetic operations by bitwise operations is covered by the guideline recommendation dealing with the use of representation information.

569.1 representation information using

1195 If `E1` has an unsigned type or if `E1` has a signed type and a nonnegative value, the value of the result is the integral part of the quotient of $E1 / 2^{E2}$.

Commentary

The issues are the same as for left-shift.

1191 left-shift of positive value

Common Implementations

This C sentence is a mathematical description of the behavior. In practice processor implementations have circuitry that shifts bits rather than dividing them.

1196 If `E1` has a signed type and a negative value, the resulting value is implementation-defined.

right-shift negative value

Commentary

Two different forms of right-shift instruction are invariably implemented by processors. One form treats the sign bit like the other value bits and vacated bits are filled with zeros (sometimes known as a logical right-shift). The other form fills vacated bits with the value of the sign bit (sometimes known as an arithmetic right-shift). Recognizing that it is possible for implementations to predict the behavior in this case, the C Committee specified the behavior as implementation-defined.

Other Languages

Java defines the `>>` operator to use sign extension and the `>>>` operator to use zero extension.

Common Implementations

Many processors have instructions that perform either form of right-shift. In such cases the decision on which to generate is made by the translator. Vendors often provide an option to select between arithmetic and logical right-shift.

Coding Guidelines

object int type only 480.1

This issue is addressed by a deviation.

6.5.8 Relational operators

relational operators syntax

```
relational-expression:
                shift-expression
                relational-expression <  shift-expression
                relational-expression >  shift-expression
                relational-expression <= shift-expression
                relational-expression >= shift-expression
```

Commentary

The term *comparison operators* is commonly used by developers to refer to the relational operators. These operators are often combined to specify intervals. (C does not support SQL's **`between`** operator, or the Cobol form `(x > 0 and < 10)`, which is equivalent to `(x > 0 and x < 10)`.)

Other Languages

Nearly every other computer language uses these tokens for these operators. Fortran uses the tokens **`.LT.`**, **`.GT.`**, **`.LE.`**, and **`.GE.`** to represent the above operators. Cobol supports these operators as well as the equivalent keywords **`LESS THAN`**, **`LESS THAN OR EQUAL`**, **`GREATER THAN`**, and **`GREATER THAN OR EQUAL`**.

Some languages (e.g., Ada and Fortran) specify that the relational and equality operators have the same precedence level.

Common Implementations

relational operators unordered

Some implementations support the unordered relational operators **`!<`**, **`!<=`**, **`!>=`**, and **`!>`**. The NCEG also included **`!<>`** for unordered or equal; **`!<>=`** for unordered; **`<>=`** for less, equal, or greater; and defines **`!=`** to mean unordered, less or greater; which enables the 26 distinct comparison predicates defined by IEC 60559 to be used. These operators were included in the Technical Report produced by the NCEG FP/IEEE Subcommittee. The expressions `(a !op b)` and `!(a op b)` have the same logical value. Without any language or library support, `a !> b` could be implemented as: `(a != a) || (b != b) || (a <= b)`.

Coding Guidelines

distance effect numeric difference

A study by Moyer and Landauer[975] found that the time taken for subjects to decide which of two single-digit values was the largest was inversely proportional to the numeric difference in their values (known as a *distance effect*).

How do people compare multi-digit integer constants? For instance, do they compare them digit by digit (i.e., a serial comparison), or do they form two complete values before comparing their magnitudes (the

so-called *holistic* model)? The following two studies show that the answer depends on how the comparisons are made:

- A study by Dehaene, Dupoux, and Mehler[340] told subjects that numbers distributed around the value 55 would appear on a screen and asked them to indicate whether the number that appeared was larger or smaller than 55 (other numbers— e.g., 65— were also used as the center point). The time taken for subjects to respond was measured. The results were generally consistent with subjects using the holistic model (exceptions occurred for values ending in zero, where subjects may have noticed that a single-digit comparison was sufficient, and when the value being compared against contained two identical digits). The response times also showed a distance effect.
- A study by Zhang and Wang[1508] told subjects that they would see two numbers, both containing two digits, on a screen and asked them to indicate whether the number that appeared on the left or the right was the largest. The time taken for subjects to respond was measured. When the largest value was less than 65, the results were generally consistent with subjects using a modified serial comparison of the digits (modified to take account of Stroop-like interference between the unit and ten's digit). When the largest value was greater than 65, a serial comparison gave a slightly better fit to the results than the modified serial comparison model.

1641 stroop effect

Other studies have found that people do not treat all relational comparisons in the same way. A so-called *symbolic distance effect* exists. This is a general effect that occurs when people compare numbers or other symbols having some measure that varies along some continuum.

symbolic distance effect

For instance, a study by Moyer and Bayer[974] gave four made-up names to four circles of different diameters. One set of four circles (the small range set) had diameters 11, 13, 15, and 17 mm, while a second set (the large range set) had diameters 11, 15, 19, and 23 mm. On the first day one group of subjects learned the association between the four made-up names and their associated circle in the small range set, while another group of subjects learned the word associations for the large range set. On the second day subjects were tested. They were shown pairs of the made-up names and had to indicate which name represented the larger circle. Their response times and error rates were measured. In both cases, response rate was faster, and error rate lower, when comparing circles whose diameters differed by larger amounts. However, performance was better at all diameter differences for subjects who had memorized an association to the circles in the large range set; they responded more quickly and accurately than subjects using the small range set. The results showed a distance effect that was inversely proportional to the difference of the area of the circles being compared.

A symbolic distance effect (which is inversely proportional to the *distance* between the quantities being compared) has also been found for comparisons involving a variety of objects that differ in some way.

Freksa[453] adapted Allen's temporal algebra[15] to take account of physical constraints on perception, enabling *cognitively plausible* inferences on intervals to be performed.[748]

Table 1197.1: Common token pairs involving relational operators (as a percentage of all occurrences of each token). Based on the visible form of the `.c` files.

Token Sequence	% Occurrence of First Token	% Occurrence of Second Token	Token Sequence	% Occurrence of First Token	% Occurrence of Second Token
identifier <	0.7	87.9	>= *character-constant*	3.6	1.5
identifier >=	0.2	85.9	< *integer-constant*	40.0	1.3
identifier >	0.3	85.0	> *integer-constant*	53.2	0.9
identifier <=	0.1	84.8	>= *integer-constant*	41.2	0.4
) <=	0.1	10.4	< identifier	53.9	0.4

`switch` control-expression	0.0 (0.0)	0.0 (0.0)	0.0 (0.0)	0.0 (0.0)

Constraints

relational operators constraints

One of the following shall hold:

Commentary

This list does not include pointer to function types.

Other Languages

Some languages support string values as operands to the relational operators. The comparison is usually made by comparing the corresponding characters in each string, using the designated operator.

1199 — both operands have real type;

relational operators
real operands

Commentary

Relational operators applied to complex types have no commonly accepted definition (unlike equality) and the standard does not support this usage.

1214 equality operators
arithmetic operands

Rationale

Some mathematical practice would be supported by defining the relational operators for complex operands so that `z1` *op* `z2` would be true if and only if both `creal(z1)` *op* `creal(z2)` and `cimag(z1) == cimag(z2)`. Believing such use to be uncommon, the C99 Committee voted against including this specification.

C90

both operands have arithmetic type;

The change in terminology in C99 was necessitated by the introduction of complex types.

Coding Guidelines

As discussed elsewhere, it is sometimes necessary to step through the members of an enumeration type. This suggests the use of looping constructs, which in turn implies using a member of the enumerated type in the loop termination condition.

1081 postfix operator
operand

Dev 569.1

Both operands of a relational operator may have an enumeration type or be an enumeration constant, provided it is the same enumerated type or a member of the same enumerated type.

Example

```
1  enum color {first_color, red=first_color, orange, yellow, green, blue,
2              indigo, violet, last_color};
3
4  void f(void)
5  {
6  for (enum color index=first_color; index < last_color; index++)
7     ;
8  }
```

Table 1199.1: Occurrence of relational operators having particular operand types (as a percentage of all occurrences of each operator; an _ prefix indicates a literal operand). Based on the translated form of this book's benchmark programs.

relational operators pointer operands

— both operands are pointers to qualified or unqualified versions of compatible object types; or 1200

Commentary

subtraction 1159 pointer operands

The rationale for supporting pointers to qualified or unqualified type is the same as for pointer subtraction. Differences in the qualification of pointed-to types is guaranteed not to affect the equality status of two pointer values.

pointer 746 converting qualified/unqualified

C++

5.9p2

Pointers to objects or functions of the same type (after pointer conversions) can be compared, with a result defined as follows:

The pointer conversions (4.4) handles differences in type qualification. But the underlying basic types have to be the same in C++. C only requires that the types be compatible. When one of the pointed-to types is an enumerated type and the other pointed-to type is the compatible integer type, C permits such operands to occur in the same relational-expression; C++ does not (see pointer subtraction for an example).

subtraction 1159 pointer operands

Other Languages

Few languages support relational comparisons on objects having pointer types.

Table 1200.1: Occurrence of relational operators having particular operand pointer types (as a percentage of all occurrences of each operator with operands having a pointer type). Based on the translated form of this book's benchmark programs.

Left Operand	Op	Right Operand	%	Left Operand	Op	Right Operand	%
char *	>	**char ***	67.5	**const char ***	>	**const char ***	4.0

1201 — both operands are pointers to qualified or unqualified versions of compatible incomplete types.

relational operators pointer to incomplete type

Commentary

Because the operands are pointers to compatible types, a relational operator only needs to compare the pointer values (i.e., information on the pointed-to type is not needed to perform the comparison).

C++

C++ classifies incomplete object types that can be completed as object types, so the discussion in the previous C sentence is also applicable here. 475 object types

Other Languages

Those languages that do not support pointer arithmetic invariably do not support the operands of the relational operators having pointer type.

Example

```
1  extern int a[];
2
3  void f(void *p)
4  {
5  if (a+1 > p)   /* Constraint violation. */
6     ;
7  if (a+1 > a+2) /* Does not affect the conformance status of the program. */
8     ;
9  }
```

Semantics

relational operators
usual arithmetic conversions
arithmetic 710 conversions
integer promotions

If both of the operands have arithmetic type, the usual arithmetic conversions are performed. 1202

Commentary

This may also cause the integer promotions to be performed.

Common Implementations

The *comparison* (the term *relational* is not usually used by developers) instructions on some processors can operate on operands of various widths, provided both widths are the same (e.g., those on the Intel x86 processor family can operate on 8-, 16-, or 32-bit operands). If both operands have the same type before the usual arithmetic conversions, an implementation may choose to make use of such instructions.

Coding Guidelines

The relational operators produce some of the most unexpected results from developers' point of view. The root cause of the unexpected behavior is invariably a difference in the sign of the types after the integer promotions of the operands. Following the guideline recommendation specifying the use of a single integer type reduces the possibility of this unexpected behavior occurring. However, the use of typedef names from the standard header, or third-party libraries (or even the use of some operators), can cause of a mixture of signed types to appear as operands.

object 480.1 int type only

Cg 1202.1

The types of the two operands in a *relational-expression*, after the integer promotions are performed on each of them, shall both be either signed or both unsigned.

Example

```
#include <stdio.h>

extern int glob;

void f(void)
{
if (glob > sizeof(glob))
   {
   if (glob < (int)sizeof(glob))
      print("glob has a negative value\n");
   else
      print("glob has a positive value\n");
   }
else if (glob != 0)
   print("glob has at most 66.66....% chance of being negative\n");
}
```

relational operators pointer to object

For the purposes of these operators, a pointer to an object that is not an element of an array behaves the same as a pointer to the first element of an array of length one with the type of the object as its element type. 1203

Commentary

additive 1165 operators pointer to object

The same sentence appears elsewhere in the standard and the issues are discussed there.

C++

This wording appears in 5.7p4, Additive operators, but does not appear in 5.9, Relational operators. This would seem to be an oversight on the part of the C++ committee, as existing implementations act as if the requirement was present in the C++ Standard.

1204 When two pointers are compared, the result depends on the relative locations in the address space of the objects pointed to.

Commentary

Here the term *address space* refers to the object within which the two pointers point. It is not being used in the common usage sense of the address space of the program, which refers to all the storage locations available to an executing program. The standard does not define the absolute location of any object or subobject. However, in some cases it does define their locations relative to other subobjects (and the relational operators are about relative positions).

1206 structure members later compare later

C++

The C++ Standard does not make this observation.

Common Implementations

In most implementations all objects have a location relative to all other objects in the storage used by a program. Processors rarely perform any checks on the values of pointers. Pointers to different storage locations (which may or may not currently be used to hold an object) return a result based on these relative positions in that storage.

Coding Guidelines

Having provided a mechanism to index subcomponents of an object, relational operations on the values of indexing expressions is the same whether the types involved are integers or pointers.

1205 If two pointers to object or incomplete types both point to the same object, or both point one past the last element of the same array object, they compare equal.

Commentary

Relational comparison of pointer values has a meaningful interpretation in C because of the language's support for arithmetic on pointer values. A more detailed specification of pointer equality is given elsewhere in the standard.

1233 pointers compare equal

Some expressions, having pointer type, can be paired as operands of a relational operator but not as operands of the subtraction operator; for instance, given the declarations:

```
struct S {
           int    mem_1;
           double mem_2[5];
           int    mem_3;
           double mem_4[5];
         } x,
           y[10];
```

then the following pairs of expressions may appear together as operands of the relational operators, but not as operands of the subtraction operator:

```
        x   .mem_1    op   x   .mem_3
        y[1].mem_1    op   y[3].mem_3
        y[1].mem_1    op   y[3].mem_3
        x   .mem_2[1] op   x   .mem_4[1]
```

C++

This requirement can be deduced from:

5.9p2

— *If two pointers* `p` *and* `q` *of the same type point to the same object or function, or both point one past the end of the same array, or are both null, then* `p<=q` *and* `p>=q` *both yield* **`true`** *and* `p<q` *and* `p>q` *both yield* **`false`**.

structure members later compare later
array elements later compare later

If the objects pointed to are members of the same aggregate object, pointers to structure members declared later compare greater than pointers to members declared earlier in the structure, and pointers to array elements with larger subscript values compare greater than pointers to elements of the same array with lower subscript values. 1206

Commentary

member 1422 address increasing

The standard does not specify a representation for pointer types, but rather some of the properties they must have. The relative addresses of members of the same structure type are specified elsewhere. This wording specifies that increasing the value of an address causes it to compare greater than the original address, provided both addresses refer to the same structure object. This requirement is not sufficient to calculate the address of subsequent members of a structure type. For instance, the expression `&x.m1+sizeof(x.m1)` does not take into account any padding that may occur after the member `m1`. There is existing source code that uses pointer arithmetic to access the members of a structure object. However, the more widespread usage is interpreting the same object using different types. This requirement and the creation of the `offsetof` macro codifies existing practice.

There are two possible ordering of array elements in storage. Established practice, prior to the design of C, was for increasing index values to refer to elements ever further away from the first. This C sentence specifies this implementation behavior.

structure 1424 unnamed padding

Nothing is said about the result of comparing pointers to any padding bytes. Neither is anything said about the behavior of relational operators when their operands point to different objects.

C++

This requirement also applies in C++ (5.9p2). If the declaration of two pointed-to members are separated by an access-specifier label (a construct not available in C), the result of the comparison is unspecified.

Other Languages

The implementation details of array types in Java is sufficiently opaque that storage for each element could be allocated on a different processor, or in contiguous storage locations on one processor.

Coding Guidelines

pointer 1167 arithmetic addition result

Common existing practice, for C developers, is to use the less than rather than the not equal operator as a loop termination condition (see Table 1763.1). Pointer arithmetic is based on accessing the elements of an array, not its bytes. Looping through an array object using pointer arithmetic and relational operators has a fully defined behavior.

Example

```
1  struct T {
2            int first;
3            /* Some member declarations. */
4            int middle;
5            /* More member declarations. */
6           } glob;
7
8  void f(void)
9  {
10 int *p_loc = &glob.first;
11
12 /*
```

```
13    * Set all members before middle to zero.
14    */
15   while (p_loc < &glob.middle)
16      {
17      *p_loc=0;
18      p_loc++;
19      }
20   }
```

1207 All pointers to members of the same union object compare equal.

pointer to union members compare equal

Commentary

This behavior can also be deduced from pointers to the members of the same union type also pointing at the union object and pointers to the same object comparing equal.

1427 union members start same address
1233 pointers compare equal

1208 If the expression `P` points to an element of an array object and the expression `Q` points to the last element of the same array object, the pointer expression `Q+1` compares greater than `P`.

Commentary

This special case deals with pointers that do not point at the same object (but have an association with the same object).

C90

The C90 Standard contains the additional words, after those above:

> *even though Q+1 does not point to an element of the array object.*

Common Implementations

On segmented architectures incrementing a pointer past the end of a segment causes the address to wrap around to the beginning of that segment (usually address zero). If an array is allocated within such a segment, either the implementation must ensure that there is room after the array for there to be a one past the end address, or it uses some other implementation technique to handle this case (e.g., if the segment used is part of a pointer's representation, a special *one past the end* segment value might be assigned).

590 pointer segmented architecture

1209 In all other cases, the behavior is undefined.

relational pointer comparison undefined if not same object

Commentary

The C relational operator model enables pointers to objects to be treated in the same way as indexes into array objects. Relational comparisons between indexes into two different array objects (that are not both subobjects of a larger object) rarely have any meaning and the standard does not define such support for pointers. Some applications do need to make use of information on the relative locations of different objects in storage. However, this usage was not considered to be of sufficient general utility for the Committee to specify a model defining the behavior.

C90

If the objects pointed to are not members of the same aggregate or union object, the result is undefined with the following exception.

C++

5.9p2

— *Other pointer comparisons are unspecified.*

Source developed using a C++ translator may contain pointer comparisons that would cause undefined behavior if processed by a C translator.

Common Implementations

Most implementations perform no checks prior to any operation on values having pointer type. Most processors use the same instructions for performing relational comparisons involving pointer types as they use for arithmetic types. For processors that use a segmented memory architecture, a pointer value is often represented using two components, a segment number and an offset within that segment. A consequence of this representation is that there are many benefits in allocating storage for objects such that it fits within a single segment (i.e., storage for an object does not span a segment boundary). One benefit is an optimization involving the generated machine code for some of the relational operators, which only needs to check the segment offset component. This can lead to the situation where `p >= q` is false but `p > q` is true, when `p` and `q` point to different objects.

pointer 590 segmented architecture

Coding Guidelines

Developers sometimes do intend to perform relational operations on pointers to different objects (e.g., to perform garbage collection). Such usage makes use of information on the layout of objects in storage, this issue is discussed elsewhere.

storage 1354 layout

---

relational operators result value

Each of the operators < (less than), > (greater than), <= (less than or equal to), and >= (greater than or equal to) shall yield 1 if the specified relation is true and 0 if it is false.[90)] 1210

Commentary

The four comparisons (<, <=, >=, >) raise the invalid exception if either operand is a NaN (and returns 0). Some implementations support what are known as *unordered* relational operators. The floating-point comparison macros (`isgreater`, `isgreaterequal`, `isless`, `islessequal`, `islessgreater`, and `isunordered`), new in C99, can be used in those cases where NaNs may occur. They are similar to the existing relational operators, but do not raise invalid for NaN operands.

relational 1197 operators unordered

C++

5.9p1 *The operators* < *(less than),* > *(greater than),* <= *(less than or equal to), and* >= *(greater than or equal to) all yield* **`false`** *or* **`true`**.

This difference is only visible to the developer in one case, the result type. In all other situations the behavior is the same; false and true will be converted to 0 and 1 as-needed.

relational 1211 operators result type

Other Languages

Languages that support a boolean data type usually specify **`true`** and **`false`** return values for these operators.

Common Implementations

The constant 0 is commonly seen as an operand to these operators. The principles used for this case generally apply to all other combinations of operand (see the logical negation operator for details). When one of the operands is not the constant 0, a comparison has to be performed. Most processors require the two operands to be in registers. (A few processors[968] support instructions that compare the contents of storage, but the available addressing modes are usually severely limited.) The comparison of the contents of the two specified registers is reflected in the settings of the bits in the condition flags register. RISC processors do not contain instructions for comparing integer values, the subtract instruction is used to set condition flags (e.g., `x > y` becoming `x-y > 0`). Most processors contain compare instructions that include a small constant as part of their encoding. This removes the need to load a value into a register.

logical 1111 negation result is

Relational operators are often used to control the number of iterations performed by a loop. The implementation issues involved in this usage are discussed elsewhere.

iteration 1763 statement syntax

Coding Guidelines

While the result is specified in numeric terms, most occurrences of this operator are as the top-level operator in a controlling expression (see Table 1197.3). These contexts are usually treated as involving a boolean role, 476 boolean role rather than a numeric value.

1211 The result has type **int**.

relational operators result type

Commentary

The first C Standard did not include a boolean data type. C99 maintains compatibility with this existing definition.

C++

The type of the result is ***bool****.* 5.9p1

The difference in result type will result in a difference of behavior if the result is the immediate operand of the **sizeof** operator. Such usage is rare.

Other Languages

Languages that support a boolean type usually specify a boolean result type for these operators.

Coding Guidelines

Most occurrences of these operators are in controlling expressions (see Table 1197.3), and developers are likely to use a thought process based on this common usage. Given this common usage developers often don't need to consider the result in terms of delivering a value having a type, but as a value that determines the flow of control. In such a context the type of the result is irrelevant. Some of the issues that occur when the result of a relational operation is an operand of another operator (e.g., `x=(a<b)`) are discussed elsewhere. 476 boolean role

6.5.9 Equality operators

---

equality operators syntax

1212

```
equality-expression:
                relational-expression
                equality-expression == relational-expression
                equality-expression != relational-expression
```

Commentary

The use of the term *equality* is based on the most commonly occurring of the two operators. The terms *equals* and *not equals* are commonly used by developers.

Other Languages

Those languages that use the character sequence **:=** to represent assignment usually use the **=** character to represent the equality operator token. Some languages use the character sequence **<>** to represent the not equal operator. Fortran uses the tokens **.EQ.** and **.NE.** to represent the quality operators.

Pascal supports the **IN** operator. Instead of comparing one value against another, this operator provides a mechanism for testing whether a value is **IN** a set of values. For instance, `i IN [4, 6]` tests whether `i` has the value 4 or 6; `i IN [2..5]` tests whether `i` has a value between 2 and 5, inclusive.

Some languages offer a number of different ways of comparing for equality. For instance, in Scheme `(eq? X Y)` tests whether `X` and `Y` refer to the same object, but `(equal? X Y)` tests, recursively, whether `X` and `Y` have the same structure (which for linked data structures involves walking them, comparing each pair of nodes).

Perl supports the **<=>** operator, which returns -1 if the left operand is less than the right operand, 0 if they are equal, and 1 if the left operand is greater than the right.

Coding Guidelines

A study by Dehaene and Akhavein[339] asked subjects to make same/difference judgments for pairs of numeric values. The values were either presented in Arabic form (e.g., 2 2), as written words (e.g., TWO TWO), or in mixed form (e.g., 2 TWO, or TWO 2). The two numeric values were either the same, close to each other (e.g., 1 2), or not close to each other (e.g., THREE NINE). The time taken for subjects to make a same/different judgment was measured, along with their error rate.

distance effect 1197
numeric difference

The results (see Figure 1212.1) for different the kinds of numeric value pairings followed the same pattern. This pattern is consistent with both the Arabic and written-word representation being converted to a common, internal, magnitude representation (in the subject's head). This *distance effect* is discussed elsewhere.

Numeric values appear in source code in written form through the use of macro definitions. However, the common usage is to use a symbolic name to represent some numeric quantity, not the spoken words of the value; for instance, using the name `MAX_LINE_LENGTH` to denote the maximum number of characters that can appear on a line. Source code may contain a comparison of such a name against an integer constant (e.g., `#if MAX_LINE_LENGTH == 80`) or against another symbolic name (e.g., `#if MAX_LINE_LENGTH == XYZ_TERM_LINE_LENGTH`). Comparison of two decimal constants appearing in the visible source as Arabic numerals is rare. The affect of reader's prior knowledge of the current value of `MAX_LINE_LENGTH` on their processing of this equality operation is unknown. The Dehaene and Akhavein study showed that using symbolic names for numeric values does not prevent the distance effect from occurring.

An equality comparison may involve performing a mental calculation on one of the operands. Within source code, this may be a *what if?* kind of calculation or the values of the operands may be known at translation time and a reader may be attempting to verify if a condition is true or false (e.g., which arm of a conditional inclusion directive will be processed by a translator).

A study by Zbrodoff and Logan[1503] measured subjects' performance in arithmetic verification tasks (e.g., $3\times5 = 17$, true/false?). The intent was to test the hypothesis that such verification tasks consisted of two stages: first performing the arithmetic operation and then comparing the computed value against the value given. In most cases the results were not consistent with this two-stage production/comparison process, but were consistent with verification involving a comparison of all the information presented (i.e., including the putative answer) against memory.

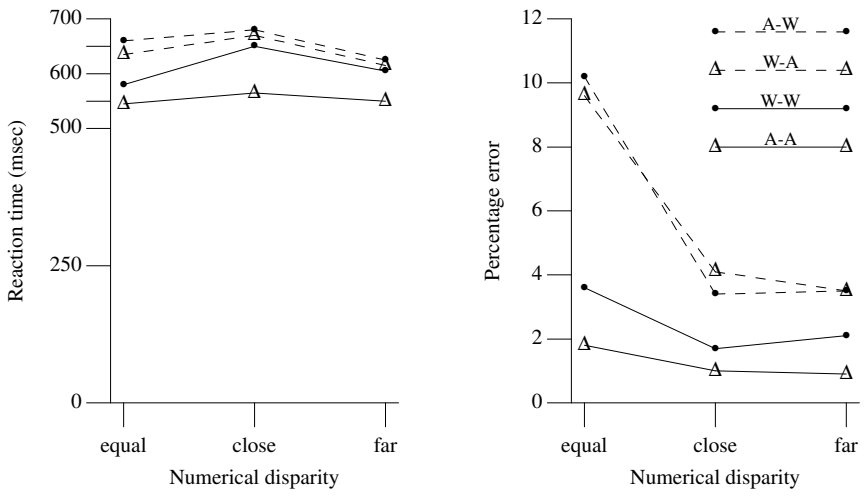

Figure 1212.1: Reaction time (in milliseconds) and error rates for same/different judgment for values between one and nine, expressed in *A*rabic or *W*ord form. Adapted from Dehaene and Akhavein.[339]

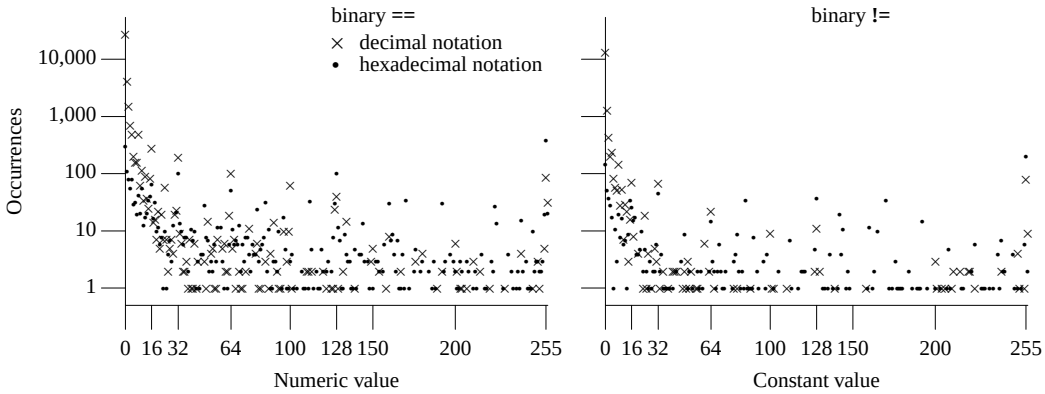

Figure 1212.2: Number of *integer-constant*s having a given value appearing as the right operand of equality operators. Based on the visible form of the `.c` files.

Table 1212.1: Common token pairs involving the equality operators (as a percentage of all occurrences of each token). Based on the visible form of the `.c` files. Note: entries do not always sum to 100% because several token sequences that have a very low percentage are not listed.

Token Sequence	% Occurrence of First Token	% Occurrence of Second Token	Token Sequence	% Occurrence of First Token	% Occurrence of Second Token
identifier `!=`	0.6	69.2	`]` `!=`	1.4	5.1
identifier `==`	1.2	67.9	`==` `-v`	2.6	3.5
`)` `==`	1.6	25.1	`==` *integer-constant*	25.5	2.0
`)` `!=`	0.8	24.7	`==` identifier	62.1	1.1
`==` *character-constant*	7.1	22.8	`!=` *integer-constant*	22.7	0.9
`!=` *character-constant*	5.3	8.4	`!=` identifier	65.0	0.6
`]` `==`	3.1	5.6			

Constraints

1213 One of the following shall hold:

equality operators constraints

Commentary

This list is very similar to that given for simple assignment, except that there is no support for equality operations on structure or union types.

1296 simple assignment constraints
1298 assignment structure types

The C89 Committee considered, on more than one occasion, permitting comparison of structures for equality. Such proposals foundered on the problem of holes in structures. A byte-wise comparison of two structures would require that the holes assuredly be set to zero so that all holes would compare equal, a difficult task for automatic or dynamically allocated variables. The possibility of union-type elements in a structure raises insuperable problems with this approach. Without the assurance that all holes were set to zero, the implementation would have to be prepared to break a structure comparison into an arbitrary number of member comparisons; a seemingly simple expression could thus expand into a substantial stretch of code, which is contrary to the spirit of C.

Rationale

C++

The `==` *(equal to) and the* `!=` *(not equal to) operators have the same semantic restrictions, conversions, and result type as the relational operators . . .*

5.10p1

See relational operators.

1198 relational operators constraints

Other Languages

Other languages include support for equality operations on structures, strings, sets, and even linked lists.

---

equality operators arithmetic operands — both operands have arithmetic type; 1214

Commentary

These operators are defined for operands having a complex type.

Coding Guidelines

The equality operators are different from the relational operators in that an exact match is being tested for. In the case of the real and complex types, testing for an exact match does not always make sense. Rounding and other types of error in operations on floating-point values means that an exact value can never be expected, only a very close approximation.

The equality operator is sometimes used to check a property of floating-point numbers. Is one value so small, compared to a second value, that the effect of adding them together is to deliver the larger one as the result? In other words is the smaller value insignificant, compared to the larger value? This test can be made because we are interested in the smaller value, not the larger one. The natural logarithm of one plus a very small value is equal, within a reasonable error bound, to that very small value.[500]

```
1  #include <math.h>
2
3  double log_x_plus_1(double x)
4  {
5  if (1.0 + x == 1.0)
6     return x;
7  else
8     return log(1.0 + x) * x / ((1.0 + x) - 1.0);
9  }
```

The above algorithm relies on the value of the expression `1.0+x` calculated in the equality test being identical to the value passed as an argument to the log function. The value passed to the `log` function has type **`double`**. If the equality test is carried out using a precision that is different from **`double`** (for instance, using an extended precision), it is possible that the extra bits available in the result will cause the equality test to fail, invoking the `log` function which returns zero (the *log* of 1.0, since rounding to **`double`** will remove any extended precision bits)— a value that has a relative error of one.

FLT_EVAL_METHOD 354

This example shows that using equality operators on values having real type requires more than a numerical analysis of the algorithm being used. (Goldberg[500] provides a readable analysis of error bounds.) What is also needed is knowledge of how an implementation actually performs the calculation. In this case use of extended precision can invalidate all of the error bounds deduced by careful numerical analysis.

Cg 1214.1 The operands of the equality operators shall not have floating-point or complex type.

Dev 1214.1 A numerical algorithm that performs equality tests on floating-point values may be used if an implementation always evaluates lexically identical expressions to the same result.

Comparing values having an enumerated type for equality (or inequality) need not imply any use of representation information (e.g., relative ordering of members).

Dev 569.1 Both operands of an equality operator may have an enumeration type or be an enumeration constant, provided it is the same enumerated type or a member of the same enumerated type.

Table 1214.1: Occurrence of equality operators having particular operand types (as a percentage of all occurrences of each operator). Based on the translated form of this book's benchmark programs.

Left Operand	Operator	Right Operand	%	Left Operand	Operator	Right Operand	%
ptr-to	!=	ptr-to	28.5	**char**	!=	**_int**	3.9
int	==	**_int**	21.1	ptr-to	!=	**_int**	3.5

unsigned int	==	**_int**	4.0				

1215 — both operands are pointers to qualified or unqualified versions of compatible types;

equality operators pointer to compatible types

Commentary

The rationale for supporting pointers to qualified or unqualified type is the same as for pointer subtraction and relational operators. Differences in the qualification of pointed-to types is guaranteed not to affect the equality status of two pointer values.

1159 subtraction pointer operands
1200 relational operators pointer operands
746 pointer converting qualified/unqualified

The operands may have a pointer to function type.

C++

1200 relational operators pointer operands

The discussion on the relational operators is applicable here.

Other Languages

Languages containing a pointer data type allow values having such types to be compared for equality and inequality.

Common Implementations

Because the operands need not refer to the same objects, it is necessary to compare all the information represented in a pointer value (e.g., segment and offset in a segmented architecture). The constraint that both pointers point to compatible types ensures that, in those cases where different representations are used for pointers to different types, an implementation does not have to concern itself with implicitly converting one representation to another.

590 pointer segmented architecture

In implementations that use a flat address space an equality operator is usually implemented using one of the unsigned integer comparison machine instructions.

Table 1215.1: Occurrence of equality operators having particular operand pointer types (as a percentage of all occurrences of each operator with operands having a pointer type; an _ prefix indicates a literal operand, *_int* is probably the 0 representation of the null-pointer constant). Based on the translated form of this book's benchmark programs.

equality operators pointer to incomplete type

— one operand is a pointer to an object or incomplete type and the other is a pointer to a qualified or unqualified version of **void**; or 1216

Commentary

This combination of operands supports the idea that pointer to **void** represents a generic container for any pointer type. Relaxing the constraint in the previous C sentence, requiring the pointer types to be compatible, removes the need for an explicit cast of the operand having pointer to **void** type. A pointer to **void** is only guaranteed to compare equal to the original pointer value when it is converted back to that value's original pointer type.

converted 745 via pointer to void compare equal

C++

This special case is not called out in the C++ Standard.

```
#include <stdlib.h>

struct node {
            int mem;
            };
void *glob;

void f(void)
{
/* The following is conforming */
// The following is ill-formed
struct node *p = malloc(sizeof(struct node));

/*
 * There are no C/C++ differences when the object being assigned
 * has a pointer to void type, 4.10p2.
 */
glob = p;
}
```

relational 1198 operators constraints

See relational operators for additional issues.

Other Languages

Some languages include the concept of a generic pointer type, with some operators handling operands having this type.

Coding Guidelines

The use of pointer to **void** as a generic pointer type is common developer knowledge. There is no benefit in casting the operand having this type to the type of the other operand. An explicit cast creates a possible future

maintenance cost, unless the pointer type is denoted by a typedef name. (In this case a single change to the definition of the typedef name changes all uses; otherwise, a change of pointer type requires all corresponding occurrences in the source to be changed.)

1217 — one operand is a pointer and the other is a null pointer constant.

equality operators null pointer constant

Commentary

The previous C sentence excluded the use of operands having pointer to function type. An equality test against the null pointer constant is a common loop termination condition when walking a dynamic data structure. This permission allows the loop termination test to include an operand having a pointer to function type. (It also covers the case of 0 being used to denote the null pointer constant.)

748 null pointer constant

Other Languages

Languages that support pointer data types invariably have some form of null pointer that can be compared for equality against all other pointer types.

Semantics

1218 The == (equal to) and != (not equal to) operators are analogous to the relational operators except for their lower precedence.[91)]

Commentary

They differ from the relational operators in their handling of NaN. The equality operators are defined not to raise an exception if one or more operators is NaNs, while the relational operators do raise an exception.

1210 relational operators result value

Common Implementations

The processor instructions also perform in an analogous way to the relational operator instructions and translators generate analogous instruction sequences.

Coding Guidelines

Equality testing is one of the most fundamental operations people perform. In many contexts it is possible to assign a generally accepted meaning to an equality comparison, but not to a relational comparison. The C equality operators support a small subset of the possible equality tests (i.e., those between values having arithmetic and pointer types). Within this subset, it is analogous to the relational operators. (However, these C relational operations differ from the equality operators in that they often make up a significant percentage of the relational tests performed in a program; the other tests usually are between strings, often performed by calls to library functions.)

In most cases developers have to write code to perform equality tests when the operands do not have arithmetic types (e.g., to test whether two lists, or two arrays, are equal). However, there is one nonarithmetic type that is sometimes represented in an object having an integer type— a set. Representing a set type using an integer type creates the possibility for the equality operators to be inappropriately used. The following discussion looks at some of the difficulties of working out whether the use of an equality operator was intended when the operands appear to be sets.

The enumeration constants defined in an enumerated type definition may be assigned values intended to fill a variety of roles. For instance, their representation may be numerically distinct because objects of that type are only intended to represent a single member, or the representation may be bitwise distinct, because objects of that type are intended to be able to represent more than one member at the same time. (A set type is created by ORing together different members.) In the latter case the operations performed by the C equality operators do not correspond to the most commonly seen tests, that of set membership (based on experience with Pascal, which supports a set type).

517 enumeration set of named constants

```
1  #define in_set(x, y)  (((x) & (y)) == (x))
2
3  enum T {mem_1 = 0x01, mem_2 = 0x02, mem_3 = 0x04, mem_4 = 0x10};
```

```
4
5  extern enum T glob;
6
7  void f(enum T p_1)
8  {
9  if (in_set(mem_2, p_1)) /* does p_1 include the member mem_2? */
10    ; /* ... */
11 /*
12  * The following test can be interpreted as either:
13  *    1) are the two sets equal?
14  *    2) does p_1 only include the member mem_2?
15  */
16 if (p_1 == mem_2)
17    ; /* ... */
18 }
```

How set types are represented as C types, and the interpretation given to C operators having operands of these types, is considered to be a level of abstraction that is outside the scope of these coding guideline subsections.

---

equality operators true or false

Each of the operators yields 1 if the specified relation is true and 0 if it is false. 1219

Commentary

`x != x` yields 0, except when `x` is a NaN (when it yields 1). `x == x` yields 1, except when `x` is a NaN (when it yields 0). Possible limits on how strongly equality can be interpreted are discussed elsewhere.

footnote 602 43 subtraction 1164 result of

C++

5.10p1 *The `==` (equal to) and the `!=` (not equal to) operators have the same . . . truth-value result as the relational operators.*

equality 1220 operators result type

This difference is only visible to the developer in one case. In all other situations the behavior is the same—false and true will be converted to 0 and 1 as needed.

Other Languages

Languages that support a boolean data type usually specify **`true`** and **`false`** return values for these operators.

Example

```
1  #include <math.h>
2
3  _Bool f(float x, float y)
4  {
5  if (isnan(x) && isnan(y))
6     return 1;
7  return x==y;
8  }
```

---

equality operators result type

The result has type **`int`**. 1220

Commentary

relational 1211 operators result type

The rationale for this choice is the same as for relational operators.

C++

5.10p1

The == (equal to) and the != (not equal to) operators have the same . . . result type as the relational operators.

The difference is also the same as relational operators.

1211 relational operators result type

Other Languages

Languages that support a boolean type usually specify a boolean result type for these operators.

Coding Guidelines

The coding guideline issues are the same as those for the relational operators.

1211 relational operators result type

1221 For any pair of operands, exactly one of the relations is true.

equality operators exactly one relation is true

Commentary

This is a requirement on the implementation. No equivalent requirement is stated for relational operators (and for certain operand values would not hold). It is a moot point whether this requirement applies if both operands have indeterminate values since accessing either of them causes undefined behavior. It might be more accurate to say "for an evaluation of any pair of operands . . . ", since one or more of the operands may be volatile-qualified.

1210 relational operators result value

1476 type qualifier syntax

C90

This requirement was not explicitly specified in the C90 Standard. It was created, in part, by the response to DR #172.

C++

This requirement is not explicitly specified in the C++ Standard.

Example

```
#include <limits.h>

void f(void)
{
int i = INT_MIN;

if (i != INT_MIN)
   printf("This sentence will never appear\n");
if ((float)i != INT_MIN)
   printf("This sentence might appear\n");

while ((i != 0) && (i == -i)) /* When using two's compliment this is an infinite loop. */
   { /* i not modified in loop. */ }
}
```

1222 If both of the operands have arithmetic type, the usual arithmetic conversions are performed.

Commentary

This may also cause the integer promotions to be performed.

710 arithmetic conversions integer promotions

C90

Where the operands have types and values suitable for the relational operators, the semantics detailed in 6.3.8 apply.

relational operators 1202
usual arithmetic conversions

Coding Guidelines

The unexpected results that can occur for the relational operators (when the operands have differently signed types), as a consequence of these conversions, are much less likely to occur for the equality operators. For instance, `signed_object == unsigned_object` is true when both objects have the same value and when the implicit conversion of a negative value to unsigned results in the same value (e.g., `UINT_MAX == -1`).

Values of complex types are equal if and only if both their real parts are equal and also their imaginary parts are equal. 1223

Commentary

complex 506
component representation

Given the representation used for complex types, this form of equality testing is the obvious choice (had polar form been used, the obvious choice would have been to compare their modulus and angles).

C90

Support for complex types is new in C99.

Any two values of arithmetic types from different type domains are equal if and only if the results of their conversions to the (complex) result type determined by the usual arithmetic conversions are equal. 1224

Commentary

usual arithmetic conversions 706
real type 700
converted to complex

The usual arithmetic conversions specifies the type of the result. The details of real type to complex type conversions are specified elsewhere.

C90

Support for different type domains, and complex types, is new in C99.

C++

real type 700
converted to complex

The concept of type domain is new in C99 and is not specified in the C++ Standard, which defines constructors to handle this case. The conversions performed by these constructions have the same effect as those performed in C.

equality operators 1214.1
not floating-point operands

Coding Guidelines

The guideline recommendation dealing with the comparison of floating-point values for equality is applicable here.

---

footnote 91

91) The expression **a<b<c** is not interpreted as in ordinary mathematics. 1225

Commentary

In mathematical notation this would probably be interpreted as equivalent to the C expression `(a < b) && (b < c)`.

C++

The C++ Standard does not make this observation.

Other Languages

Cobol has a **between** operator that enables this mathematical test to be performed. BCPL allows any number of relational operators in a sequence; they're ANDed together; for instance, the BCPL expression `x > y >= z == q < r` is equivalent to the C `x > y && y >= z && z == q && q < r`.

expression 943.1
shall be parenthesized

Coding Guidelines

This issue is covered by the guideline recommendation dealing with the use of parenthesis.

As the syntax indicates, it means **(a<b)<c**; 1226

Commentary

The **<** operator associates to the left.

1227 in other words, "if **a** is less than **b**, compare 1 to **c**; otherwise, compare 0 to **c**".

Commentary

As discussed elsewhere, the evaluation order of the operands is not guaranteed to be a, b, and c. 944 expression order of evaluation

1228 90) Because of the precedences, **a<b == c<d** is 1 whenever **a<b** and **c<d** have the same truth-value. footnote 90

Commentary

The grouping here is `(a<b) == (c<d)`.

Coding Guidelines

This issue is covered by the guideline recommendation dealing with the use of parentheses. 943.1 expression shall be parenthesized

1229 Otherwise, at least one operand is a pointer.

Commentary

The case where only one operand is a pointer is when the other operand is the integer constant 0 (which is interpreted as a null pointer constant). 748 null pointer constant

C++

The C++ Standard does not break its discussion down into the nonpointer and pointer cases.

1230 If one operand is a pointer and the other is a null pointer constant, the null pointer constant is converted to the type of the pointer. equality operators null pointer constant converted

Commentary

If different pointer types use different representations for the null pointer, this implicit conversion ensures that the equality test is performed against the appropriate representation. 750 null pointer conversion yields null pointer

C90

If a null pointer constant is assigned to or compared for equality to a pointer, the constant is converted to a pointer of that type.

In the case of the expression `(void *)0 == 0` both operands are null pointer constants. The C90 wording permits the left operand to be converted to the type of the right operand (type **int**). The C99 wording does not support this interpretation. 748 null pointer constant

C++

The C++ Standard supports this combination of operands but does not explicitly specify any sequence of operations that take place prior to the comparison. 1217 equality operators null pointer constant

Other Languages

Other languages do not always go into this level of detail. They usually simply specify that two null pointers compare equal, irrespective of the pointer types involved.

Coding Guidelines

The issue of using explicit casts in this case is discussed elsewhere. 1216 equality operators pointer to incomplete type

1231 If one operand is a pointer to an object or incomplete type and the other is a pointer to a qualified or unqualified version of **void**, the former is converted to the type of the latter. equality operators pointer to void

Commentary

A pointer to **void** is capable of representing all the information represented in any pointer type (any pointer converted to pointer to **void** and back again will compare equal to the original pointer). There is no guarantee that any other pointer type will be capable of representing all the information in the pointer to **void** (although pointer to character types have the same representation and alignment requirements). For this reason the other operand has to be converted to pointer to **void**.

pointer 744 converted to pointer to void
pointer 558 to void same representation and alignment as

C++

This conversion is part of the general pointer conversion (4.10) rules in C++. This conversion occurs when two operands have pointer type.

Coding Guidelines

The issue of using explicit casts in this case is discussed elsewhere.

equality operators 1216 pointer to incomplete type

---

equality operators pointer to object

For the purposes of these operators, a pointer to an object that is not an element of an array behaves the same as a pointer to the first element of an array of length one with the type of the object as its element type. 1232

Commentary

This wording was added by the response to DR #215 (the Committee response was to duplicate the wording from relational operators). The same sentence appears elsewhere in the standard and the issues are discussed there.

relational operators 1203 pointer to object
additive operators 1165 pointer to object

---

pointers compare equal

Two pointers compare equal if and only if both are null pointers, both are pointers to the same object (including a pointer to an object and a subobject at its beginning) or function, both are pointers to one past the last element of the same array object, or one is a pointer to one past the end of one array object and the other is a pointer to the start of a different array object that happens to immediately follow the first array object in the address space.[92)] 1233

Commentary

This is a requirement on the implementation. If the expression `px==py` returns 1 (with `px` and `py` both having pointer types), one of the conditions listed here must hold (the fact that two pointer values compare equal does not imply that they have the same value representation). In all other cases an implementation is required to return 0. All null pointers, whatever type they have been converted to, always compare equal. Here the phrase " . . . point to the same object . . . " means the same address.

pointer 590 segmented architecture
null pointer 750 conversion yields null pointer
object 761 lowest addressed byte
pointer 1169 one past end of object

The standard requires that pointers be able to point one past the last element of an array, but it does not place any requirements on the relative storage addresses of different objects. This can lead to the situation of a one past the last element pointer comparing equal to a pointer to a different object (which might not even be compatible with the pointed-to type). The standard does not require such behavior, it simply points out that it can occur in a strictly conforming program.

pointer subtraction 1173 point at same object

The relationship `p == q` does not imply `(p-q) == 0`, because the subtraction operator is only defined when its operands point at an object. If `p` and `q` have the null pointer value, the result is undefined behavior. The following equalities are true if `p != NULL`, but are not guaranteed to be true if `p == NULL` (although in practice they are always true on most implementations);

```
1  p - p == 0
2  p + 0 == p
```

C90

If two pointers to object or incomplete types are both null pointers, they compare equal. If two pointers to object or incomplete types compare equal, they both are null pointers, or both point to the same object, or both point

one past the last element of the same array object. If two pointers to function types are both null pointers or both point to the same function, they compare equal. If two pointers to function types compare equal, either both are null pointers, or both point to the same function.

The admission that a pointer one past the end of an object and a pointer to the start of a different object compare equal, if the implementation places the latter immediately following the former in the address space, is new in C99 (but it does describe the behavior of most C90 implementations).

C++

Two pointers of the same type compare equal if and only if they are both null, both point to the same object or function, or both point one past the end of the same array. 5.10p1

This specification does not include the cases:

- "(including a pointer to an object and a subobject at its beginning)", which might be deduced from wording given elsewhere,
- "or one is a pointer to one past the end of one array object and the other is a pointer to the start of a different array object that happens to immediately follow the first array object in the address space". The C++ Standard does not prevent an implementation from returning a result of **`true`** for the second case, but it does not require it. However, the response to C++ DR #073 deals with the possibility of a pointer pointing one past the end of an object comparing equal, in some implementations, to the address of another object. Wording changes are proposed that acknowledge this possibility.

761 object
lowest addressed byte

Other Languages

These requirements usually hold for implementations of other languages, but are rarely expressed explicitly.

Common Implementations

If two pointers point to the same object, and the lifetime of that object ends, most implementations will continue to compare those pointers as being equal, even though they no longer point at an object. If an integer value is cast to a pointer type and assigned to two pointers, most implementations will compare those pointers as equal, even though neither of them may be the null pointer constant or have ever pointed at an object.

6.5.10 Bitwise AND operator

1234 AND-expression
syntax
bitwise
&

```
AND-expression:
                equality-expression
                AND-expression & equality-expression
```

Commentary

From decvax!harpo!npoiv!alice!research!dmr Fri Oct 22 01:04:10 1982 Subject: Operator precedence Newsgroups: net.lang.c Dennis Ritchie

The priorities of && || vs. == etc. came about in the following way.

Early C had no separate operators for & and && or | and ||. (Got that?) Instead it used the notion (inherited from B and BCPL) of "truth-value context": where a Boolean value was expected, after "if" and "while" and so forth, the & and | operators were interpreted as && and || are now; in ordinary expressions, the bitwise

interpretations were used. It worked out pretty well, but was hard to explain. (There was the notion of "top-level operators" in a truth-value context.)

The precedence of & and | were as they are now.

Primarily at the urging of Alan Snyder, the && and || operators were added. This successfully separated the concepts of bitwise operations and short-circuit Boolean evaluation. However, I had cold feet about the precedence problems. For example, there were lots of programs with things like

if (a==b & c==d) . . .

In retrospect it would have been better to go ahead and change the precedence of & to higher than ==, but it seemed safer just to split & and && without moving & past an existing operator. (After all, we had several hundred kilobytes of source code, and maybe 3 installations. . . .)

Other Languages

Languages that support bitwise operators tend to either use the same operator as C, or the keyword **and**. Support for an unsigned integer type was added in Ada 95 and the definition of the logical operators was extended to perform bitwise operations when their operands had this type.

Coding Guidelines

logical-AND-expression 1248 syntax

The issue of rearranging expressions, involving bitwise operators, to reduce the number of operators they contain is discussed elsewhere.

controlling expression 1740 if statement

Experience shows that developers sometimes confuse the two operators **&** and **&&** with each other, and sometimes they intentionally swap the use of these operators. The confusion may be caused by their similar visual appearance, a temporary lapse of concentration, or some other reason. They may return different results for the same pair of operands, as the following example shows:

```
0x10 & 0x01  ⇒ 0
0x10 && 0x01 ⇒ 1
```

The two operators return the same numeric result when the evaluation of the second operand generates no side effects, and

- the value of either operand is 0,
- boolean role 476 the values of both operands is restricted to the range 0 or 1 (a boolean role represented as one of two values), and
- the least significant bit of both operands is set and the operands have no other set bits in common.

When there is no order dependency between the operands (i.e., the evaluation of the second operand is not conditional on the evaluation of the first), developers sometimes make use of one of these equivalencies to select what they consider to be the *most efficient* operator. For instance, if the one of the operands is a function call, **&&** might be used with the call as its right operand. Alternatively, if both operands are simple object accesses, the **&** operator might be used in the belief that unconditionally evaluating both operands is faster than a conditional evaluation (because of the conditional jump).

There are two checks that might be used to attempt to confirm that the operator appearing in the source is the one intended:

object 1352 role, boolean role 476, bit-set role 945, numeric role 945

1. *The roles of the operands.* If both operands have boolean roles, the operators **&** and **&&** both return the same result and the author is free to select which operator to use. Operands having a bit-set role might be expected to be operands of the **&** operator, while those having a numeric role appear as operands of the **&&** operator.

2. *The role played by the result.* The result of the **&** operator has a bit-set role, while that of the **&&** operator has a boolean role. For instance, the measurements in Table 1234.1 show that most occurrences of the **&&** operator are in a controlling expression (both are boolean roles).

The issue of operands having the same role is covered by the guideline recommendation dealing with objects having a single role (the definitions of bit-set and numeric roles are based on objects appearing as operands of certain kinds of operators. An object that appeared as the operand of both kinds of operator would have two roles).

role
operand matching
1352.1 object
used in a single role
945 bit-set role
945 numeric role

Other coding guideline documents sometimes specify that these two operators should not be confused, or list them in review guidelines.[1497] Using **&&** where **&** was intended, or vice versa, is clearly unintended (a fault) and these coding guidelines are not intended to recommend against the use of constructs that are obviously faults. However, it may be possible to reduce the likelihood of confusion by using the operator appropriate to the role. The issue of the role of operands matching that of their operators is discussed elsewhere.

Constraints

1235 Each of the operands shall have integer type.

& binary
operand type

Commentary

This constraint reflects the fact that processors very rarely contain instructions for performing this operation on non-integer types. In turn this reflects the fact that there is no commonly defined semantics for bitwise ANDing other types and that there are very few algorithms requiring values having other types to be treated as a sequence of bits.

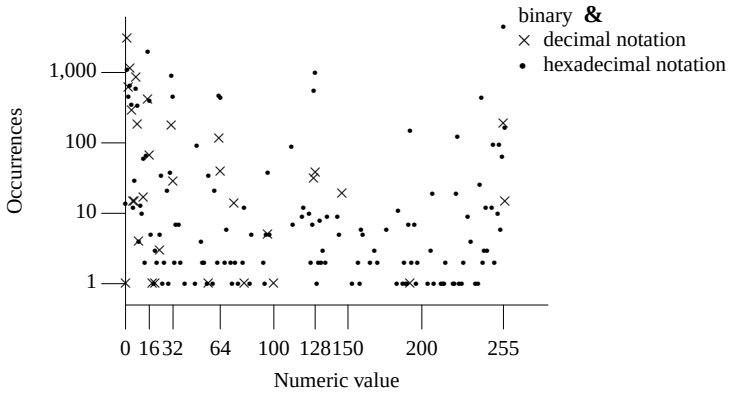

Figure 1234.1: Number of *integer-constant*s having a given value appearing as the right operand of the binary **&** operator. Based on the visible form of the `.c` files.

C++

The wording of the specification in the C++ Standard is somewhat informal (the same wording is given for the bitwise exclusive-OR operator, 5.12p1, and the bitwise inclusive-OR operator, 5.13p1).

5.11p1 *The operator applies only to integral or enumeration operands.*

Coding Guidelines

representation information using boolean role 476 bit-set role 945

The binary **&** operator operates on the bit representation of its operands. As such, the guideline recommendation on making use of representation information is applicable. However, deviations are suggested for operands having a boolean or bit-set role.

Table 1235.1: Occurrence of bitwise operators having particular operand types (as a percentage of all occurrences of each operator; an _ prefix indicates a literal operand). Based on the translated form of this book's benchmark programs.

Semantics

1236 The usual arithmetic conversions are performed on the operands.

& binary operands converted

Commentary

The rationale for performing these conversions is a general one that is not limited to the operands of the arithmetic operators.

702 operators cause conversions

C++

The following conversion is presumably performed on the operands.

The usual arithmetic conversions are performed; 5.11p1

Common Implementations

If one of the operands is positive and has a type with lower rank than the other operand, it may be possible to make use of processor instructions that operate on narrower width values. (Converting the operand to the greater rank will cause it to be zero extended, which will cancel out any ones in the other operand.) Unless both operands are known to be positive, there tend to be few opportunities for optimizing occurrences of the `^` and `|` operators (because of the possibility that the result may be affected by an increase in value representation bits).

Coding Guidelines

Unless both operands have the same type, which also has a rank at least equal to that of **`int`**, these conversions will increase the number of value representation bits in one or both operands. Given that the binary **`&`** operator is defined to work at the bit level, developers have to invest additional effort in considering the effects of the usual arithmetic operands on the result of this operator.

A probabilistic argument could be used to argue that of all the bitwise operators the **`&`** operator has the lowest probability of causing a fault through an unexpected increase in the number of value representation bits. For instance, the probability of both operands having a negative value (needed for any additional bits to be set in the result) is lower than the probability of one operand having a negative value (needed for a bit to be set in the result of the `^` and `|` operators).

Unless the operands have a bit-set role, the guideline recommendation dealing with use of representation information is applicable here.

945 bit-set role 569.1 representation information using

1237 The result of the binary `&` operator is the bitwise AND of the operands (that is, each bit in the result is set if and only if each of the corresponding bits in the converted operands is set).

Commentary

This information is usually expressed in tabular form.

	0	1
0	0	0
1	0	1

Common Implementations

The Unisys A Series[1390] uses signed magnitude representation. If the operands have an unsigned type, the bit used to represent the sign in signed types, which is present in the object representation on this processor, does not take part in the binary **`&`** operation. If the operands have a signed type, the sign bit does take part in the bitwise-AND operation.

Coding Guidelines

Although the result of the bitwise-AND operator is the common type derived from the usual arithmetic conversions, for the purpose of these guideline recommendations its role is the same as that of its operands.

706 usual arithmetic conversions 1352 object role

footnote 92

92) Two objects may be adjacent in memory because they are adjacent elements of a larger array or adjacent members of a structure with no padding between them, or because the implementation chose to place them so, even though they are unrelated. 1238

Commentary

array 526
contiguously allocated set of objects
structure 1206
members
later compare later
structure 1424
unnamed padding
storage 1354
layout

By definition elements of an array are contiguous and the standard specifies the relative order of members and their possible padding. Some implementations treat objects defined by different declarations in the same way as the declaration of members in a structure definition. For instance, assigning the same relative offsets to objects local to a function definition as they would the equivalent member declarations in a structure type. The issue of the layout of objects in storage is discussed elsewhere.

This footnote lists all the cases where objects may be adjacent in memory.

C90

The C90 Standard did not discuss these object layout possibilities.

C++

The C++ Standard does not make these observations.

Other Languages

Most languages do not get involved in discussing this level of detail.

Common Implementations

Most implementations aim to minimize the amount of padding between objects. In many cases objects defined in block scope are adjacent in memory to objects defined textually adjacent to them in the source code.

If prior invalid pointer operations (such as accesses outside array bounds) produced undefined behavior, subsequent comparisons also produce undefined behavior. 1239

Commentary

This describes a special case of undefined behavior. (It is called out because, in practice, it is more likely to occur for values having pointer types than values having integer types.) Once undefined behavior has occurred, any subsequent operation can also produce undefined behavior. The standard does not limit the scope of undefined behaviors to operations involving operands that cause the initial occurrence.

Common Implementations

On many implementations the undefined behavior that occurs when additive operations, on values having an integer type, overflow is *symmetrical*. That is, an overflow in one direction can be undone by an overflow in the other direction (e.g., `INT_MAX+2-2` produces the same result as `INT_MAX-2+2`). On implementations for processors using a segmented architecture this symmetrical behavior may not occur, for values having pointer types, because of internal details of how pointer arithmetic is handled on segment boundaries.

pointer 590
segmented architecture
arithmetic 687
saturated

On some processors additive operations, on integer or pointer types, saturate. In this case the undefined behavior is not symmetrical.

C90

The C90 Standard did not discuss this particular case of undefined behavior.

6.5.11 Bitwise exclusive OR operator

exclusive-OR-expression: 1240
AND-expression
exclusive-OR-expression ^ *AND-expression*

Commentary

The ^ operator can be replaced by a sequence of equivalent bitwise operators; for instance, `x ^ y` can be written `(x & (~y)) | ((~x) & y)`. However, most processors contain a bitwise exclusive-OR instruction and thus this operator is included in C. Being able to represent a bitwise operator using an equivalent sequence of other operators is not necessarily an argument against that operator being included in C. It is possible to represent any boolean expression using a sequence of NAND (*not and*, e.g., `!(x & y)`) operators; for instance, `!x` becomes `x NAND x`, `x & y` becomes `(x NAND y) NAND (x NAND y)`, and so on. Although this equivalence may be of practical use in hardware design (where use of mass-produced circuits performing a single boolean operation can reduce costs), it is not applicable to software.

Other Languages

Languages that support bitwise operations usually support an exclusive-OR operator. The keyword **xor** is sometimes used to denote this operator. The ^ character is used as a token to indicate pointer indirection in Pascal and Ada.

Coding Guidelines

The exclusive-OR operator is not encountered in everyday life. There is no English word or phrase that expresses its semantics. The everyday usage discussed in the subclause on the logical-OR operator is based on selecting between two alternatives (e.g., *either one or the other* which only deals with two of the four possible combinations of operand values). Because of the lack of everyday usage, and because it does not occur often within C source (compared with bitwise-AND and bitwise-OR (see Table 912.2)) it is to be expected that developers will have to expend more effort in comprehending the consequences of this operator when it is encountered in source code.

1256 logical-OR-expression syntax

The greater cognitive cost associated with use of the exclusive-OR operator is not sufficient to recommend against its use. Developers need to be able to make use of an alternative that has a lower cost. While the behavior of the exclusive-OR operator can be obtained by various combinations of other bitwise operators, it seems unlikely that the cost of comprehending any of these sequences of operators will be less than that of the operator they replace. If the exclusive-OR operator appears within a more complicated boolean expression it may be possible to rewrite that expression in an alternative form. Rewriting an expression can increase the cognitive effort needed for readers to map between source code and the application domain (i.e., if the conditions in the application domain are naturally expressed in terms of a sequence of operators that include exclusive-OR). The cost/benefit of performing such a rewrite needs to be considered on a case by case basis.

1248.1 boolean expression minimize effort

Example

The ^ operator is equivalent to the binary + operator if its operands do not have any set bits in common. This property can be used to perform simultaneous addition on eight digits represented in packed BCD[687] (i.e., four bits per digit).

```
int BCD_add(a, b)
{
int t1 = a + 0x06666666,
    t2 = t1 + b,
    t3 = t1 ^ b,
    t4 = t2 ^ t3,
    t5 = ~t4 & 0x11111110,
    t6 = (t5 >> 2) | (t5 >> 3);
return t2 - t6;
}
```

Usage

The ^ operator represents 1.2% of all occurrences of bitwise operators in the visible source of the `.c` files.

Constraints

1241 Each of the operands shall have integer type.

Commentary

& binary operand type 1235

The discussion for the various subsections is the same as those for the bitwise AND operator.

Semantics

---

^ operands converted

The usual arithmetic conversions are performed on the operands. 1242

Commentary

& binary operands converted 1236

The discussion in the various subsections is the same as that for the bitwise AND operator.

The result of the ^ operator is the bitwise exclusive OR of the operands (that is, each bit in the result is set if and only if exactly one of the corresponding bits in the converted operands is set). 1243

Commentary

This information is usually expressed in tabular form.

	0	1
0	0	1
1	1	0

Common Implementations

The Unisys A Series[1390] uses signed magnitude representation. If the operands have an unsigned type, the sign bit is not affected by the bitwise complement operator. If the operands have a signed type, the sign bit does take part in the bitwise complement operation.

The bitwise exclusive-OR instruction is sometimes generated, by optimizers, to swap the contents of two registers, without using a temporary register (as shown in the Example below).

Coding Guidelines

usual arithmetic conversions object role 706 1352

Although the result of the bitwise exclusive-OR operator is the common type derived from the usual arithmetic conversions, for the purpose of these guideline recommendations its role is the same as that of its operands.

Example

```
1  #define SWAP(x, y) (x=(x ^ y), y=(x ^ y), x=(x ^ y))
2  #define UNDEFINED_SWAP(x, y) (x ^= y ^= x ^= y) /* Requires right to left evaluation. */
```

6.5.12 Bitwise inclusive OR operator

inclusive-OR-expression syntax

1244

inclusive-OR-expression:
exclusive-OR-expression
inclusive-OR-expression | *exclusive-OR-expression*

Commentary

AND-expression syntax 1234

The discussion on AND-expression is applicable here.

Coding Guidelines

The | and || operators differ from their corresponding AND operators in that the zero/nonzero status of their result is always the same, even though the actual result values are likely to differ.

```
0x10 | 0x01  ⇒ 0x11
0x10 || 0x01 ⇒ 1
```

While it is possible to use either operators in a context where the result is compared against zero, the guideline recommendation dealing with matching an operator to the role of its result still applies. The pattern of operator context usage (see Table 1244.1) is similar to that of the two AND operators.

1234 role operand matching

Table 1244.1: Occurrence of the | and || operator (as a percentage of all occurrences of each operator; the parenthesized value is the percentage of all occurrences of the context that contains the operator). Based on the visible form of the `.c` files.

6.5.13 Logical AND operator

logical-AND-expression syntax

1248

```
logical-AND-expression:
                inclusive-OR-expression
                logical-AND-expression && inclusive-OR-expression
```

Commentary

The relative precedence of the binary **&&** and **||** operators is the same as that of the binary **&** and **|** operators.

Other Languages

In many languages the logical-AND operator has higher precedence than the logical-OR operator. In a few languages (Ada, Fortran which uses the keyword **.AND.**), they have the same precedence. Ada supports two kinds of logical-AND operations: **and** and **and then**, the latter having the same semantics as the logical-AND operator in C (short-circuit evaluation). These operators also have the same precedence as the logical-OR and logical-XOR operators.

bitwise & 1234

Coding Guidelines

AND-expression syntax 1234

The issue of swapping usages of the **&** and **&&** operators is discussed elsewhere.

There are a number of techniques for simplifying expressions involving boolean values. One of the most commonly used methods is the Karnaugh map.[714] (For equations involving more than five operands, the Quine-McCluskey technique[1357] may be more applicable; this technique is also capable of being automated.), while some people prefer algebraic manipulation (refer to Table 1248.1).

Although simplification may lead to an expression that requires less reader effort to comprehend as a boolean expression, the resulting expression may require more effort to map to the model of the application domain being used. For instance, `(A && (!B)) || ((!A) && B)` can be simplified to `A ^ B` (assuming `A` and `B` only take the values 0 and 1, otherwise another operation is required). However, while the use of the exclusive-OR operator results in a visually simpler expression, developers have much less experience dealing with it than the other bitwise and logical operators. There is also the possibility that, for instance, the expression `(A && (!B))` occurs in other places within the source and has an easily-deduced meaning within the framework of the application model.

mind logical operator

Logical operators are part of mathematical logic. Does the human mind contain special circuitry that performs this operation, just like most processors contain a group of transistors that perform this C operation? Based on experimental observations, the answer would appear to be no. So how does the human mind handle the logical-AND operation? One proposal is that people learn the rules of this operator by rote so that they can later be retrieved from memory. The result of a logical operation is then obtained by evaluating each operand's condition to true or false and performing a table lookup using previously the learned logical-AND table to find the result. Such an approach relies on short-term memory, and the limited capacity of short-term memory offers one explanation of why people are poor at evaluating moderately complex logical operators in their head. There is insufficient capacity to hold the values of the operands and the intermediate results.

The form of logical deduction that is needed in comprehending software rarely occurs in everyday life. People's ability to solve what appear to be problems in logic does not mean that the methods of boolean mathematics are used. A number of other proposals have been made for how people handle *logical* problems

in everyday life. One is that the answers to the problems are simply remembered; after many years of life experience, people accumulate a store of knowledge on how to deal with different situations.

Studies have found that belief in a particular statement being true can cause people to ignore its actual status as a mathematical expression (i.e., people believe what they consider to be true rather than logically evaluating the true status of an expression). Estimating developers' performance at handling logical expressions therefore involves more than a model of how they process mathematical logic.

While minimizing the number of operands in a boolean expression may have appeal to mathematically oriented developers, the result may be an expression that requires more effort to comprehend. It is not yet possible to calculate the reader effort required to comprehend a particular boolean expression. For this reason the following guideline recommendation relies on the judgment of those performing the code review.

Rev 1248.1

Boolean expressions shall be written in a form that helps minimize the effort needed by readers to comprehend them.

A comment associated with the simplified expression can be notated in at least two ways: using equations or by displaying the logic table. Few developers are sufficiently practiced at boolean algebra to be able to fluently manipulate expressions; a lot of thought is usually required. A logic table highlights all combinations of operands and, for small numbers of inputs, is easily accommodated in a comment.

Table 1248.1: Various identities in boolean algebra expressed using the `||` and **`&&`** operators. Use of these identities may change the number of times a particular expression is evaluated (which is sometimes the rationale for rewriting it). The relative order in which expressions are evaluated may also change (e.g., when `A==1` and `B==0` in `(A && B) || (A && C)` the order of evaluation is A⇒ B⇒ A⇒ C, but after use of the distributive law the order becomes A⇒ B⇒ C).

Relative Order Preserved	Expression ⇒ Alternative Representation
	Distributive laws
no	`(A && B) || (A && C)` ⇒ `A && (B || C)`
no	`(A || B) && (A || C)` ⇒ `A || (B && C)`
	DeMorgan's theorem
yes	`!(A || B)` ⇒ `(!A) && (!B)`
yes	`!(A && B)` ⇒ `(!A) || (!B)`
	Other identities
yes	`A && ((!A) || B)` ⇒ `A && B`
yes	`A || ((!A) && B)` ⇒ `A || B`
	The consensus identities
no	`(A && B) || ((!A) && C) || (B && C)` ⇒ `(A && B) || ((!A) && C))`
yes	`(A && B) || (A && (!B) && C)` ⇒ `(A && B) || (A && C)`
yes	`(A && B) || ((!A) && C)` ⇒ `((!A) || B) && (A || C)`

An expression containing a number of logical operators, each having operands whose evaluation involves relational or equality operators, can always be written in a number of different ways, for instance:

```
1  if ((X < 4) && !(Y || (Z == 1)))
2     /* ... */
3
4  if ((Y != 0) && (Z != 0) && (X < 4))
5     /* ... */
6
7  if (!((X >= 4) || Y || (Z == 1)))
8     /* ... */
9
10 if (X < 4)
11    if (!(Y || (Z == 1)))
12       /* ... */
```

An example of complexity in an English sentence might be "Suppose five days after the day before yesterday is Friday. What day of the week is tomorrow?" Whether the use of a less complex (i.e., having less cognitive load) expression has greater cost/benefit than explicitly calling out the details of the calculation needs to be determined on a case-by-case basis.

categorization performance predicting 0

A study by Feldman[414] found that the subjective difficulty of a concept (e.g., classifying colored polygons of various sizes) was directly proportional to its boolean complexity (i.e., the length of the shortest logically equivalent propositional formula).

Table 1248.2: Common token pairs involving **&&**, or **||** (as a percentage of all occurrences of each token). Based on the visible form of the **.c** files. Note: entries do not always sum to 100% because several token sequences that have very low percentages are not listed.

Token Sequence	% Occurrence of First Token	% Occurrence of Second Token	Token Sequence	% Occurrence of First Token	% Occurrence of Second Token
identifier **&&**	0.4	48.5	**&&** defined	0.9	6.2
) **||**	0.9	42.7	**||** **!**	11.3	6.0
identifier **||**	0.2	39.3	*character-constant* **||**	4.2	4.2

&& **!**	13.5	11.3	**||** identifier	51.8	0.3

Constraints

&& operand type

Each of the operands shall have scalar type. 1249

Commentary

The behavior is defined in terms of an implicit comparison against zero, an operation which is only defined for operands having a scalar type in C.

C++

5.14p1 *The operands are both implicitly converted to type* ***bool*** *(clause 4).*

Boolean conversions (4.12) covers conversions for all of the scalar types and is equivalent to the C behavior.

Other Languages

Languages that support boolean types usually require that the operands to their logical-AND operator have boolean type.

Coding Guidelines

& binary 1235 operand type if statement 1743 controlling expression scalar type

The discussion on the bitwise-AND operator is also applicable here, and the discussion on the comprehension of the controlling expression in an **if** statement is applicable to both operands.

Table 1249.1: Occurrence of logical operators having particular operand types (as a percentage of all occurrences of each operator; an _ prefix indicates a literal operand). Based on the translated form of this book's benchmark programs.

Left Operand	Operator	Right Operand	%	Left Operand	Operator	Right Operand	%
int	**||**	**int**	87.7	**_long**	**||**	**_long**	2.2
int	**&&**	**int**	73.9	**int**	**&&**	ptr-to	2.2
other-types	**&&**	other-types	12.8	**int**	**&&**	**char**	1.8
other-types	**||**	other-types	8.4	**int**	**||**	**_long**	1.7
ptr-to	**&&**	**int**	4.5	**int**	**&&**	**_int**	1.3
char	**&&**	**int**	2.3	ptr-to	**&&**	ptr-to	1.1

Semantics

1250 The **&&** operator shall yield 1 if both of its operands compare unequal to 0;

&& operand compare against 0

Commentary

The only relationship between the two operands is their appearance together in a logical-AND operation. There is no benefit, from the implementations point of view, in performing the usual arithmetic conversions or the integer promotions on each operand.

It is sometimes necessary to test a preliminary condition before the main condition can be tested. For instance, it may be necessary to check that a pointer value is not null before dereferencing it. The test could be performed using nested **if** statements, as in:

```
1   if (px != NULL)
2      if (px->m1 == 1)
```

More complex conditions are likely to involve the creation of a warren of nested **if** statements. The original designers of the C language decided that it was worthwhile creating operators to provide a shorthand notation (i.e., the logical-AND and logical-OR operators). In the preceding case use of one of these operators allows both tests to be performed within a single conditional expression (e.g., `if ((px != NULL) && (px->m1 == 1))`). The other advantage of this operator, over nested **if** statements, is in the creation of expressions via the expansion of nested macro invocations. Generating nested **if** statements requires the use of braces to ensure that any following **else** arms are associated with the intended **if** arm. Generating these braces introduces additional complexities (at least another macro invocation in the source) that don't occur when the **&&** operator is used.

C++

The result is ***true*** *if both operands are* ***true*** *and* ***false*** *otherwise.* 5.14p1

The difference in operand types is not applicable because C++ defines equality to return **true** or **false**. The difference in return value will not cause different behavior because **false** and **true** will be converted to 0 and 1 when required.

Other Languages

The mathematical use of this operator returns true if both operands are true. Languages that support a boolean data type usually follow this convention.

Common Implementations

As discussed elsewhere, loading a value into a register often sets conditional flags as does a relational operation comparing two values. This means that in many cases machine code to compare against zero need not be generated, as in, the following condition:

1111 logical negation result is 1210 relational operators result value

```
1   if ((a == b) && (c < d))
```

which is likely to generate an instruction sequence of the form:

```
                compare a with b
                if not equal jump to else_or_endif
                compare c with d
                if greater than or equal to jump to else_or_endif
                code for if arm
else_or_endif:  rest of program
```

Coding Guidelines

Should the operands always be explicitly compared against zero? When an operand is the result of a relational or equality operator, such a comparison is likely to look very unusual:

```
1   if (((a == b) == 0) && ((c < d) == 0))
```

It is assumed that developers think about the operands in terms of boolean roles and the result of both the relational and equality operators have a boolean role. In these cases another equality comparison is redundant. When an operand does not have a boolean role, an explicit comparison against zero might be appropriate (these issues are also discussed elsewhere).

! 1113 equivalent to selection statement 1739 syntax

---

otherwise, it yields 0. 1251

Commentary

That is, a value of zero having type **int**.

&& result type

The result has type **int**. 1252

Commentary

relational 1211 operators result type

The rationale for this choice is the same as for relational operators.

C++

5.14p2 *The result is a **bool**.*

The difference in result type will result in a difference of behavior if the result is the immediate operand of the **sizeof** operator. Such usage is rare.

Other Languages

In languages that support a boolean type, the result of logical operators usually has a boolean type.

Common Implementations

If the result is immediately cast to another type, an implementation may choose to arrange that other type as the result type; for instance, in:

```
1   float f(int ip)
2   {
3   return (ip > 0) && (ip < 10);
4   }
```

an implementation may choose to return `0.0` and `1.0` as the result of the expression evaluation, saving a cast operation.

Coding Guidelines

relational 1211 operators result type

The coding guideline issues are the same as those for the relational operators.

&& evaluation order

Unlike the bitwise binary **&** operator, the **&&** operator guarantees left-to-right evaluation; 1253

Commentary

The left-to-right evaluation order of the **&&** operator is required; it is what makes it possible for the left operand to verify a precondition for the evaluation of the right operand. There is no requirement that the evaluation of the right operand, if it occurs, take place immediately after the evaluation of the left operand.

Coding Guidelines

sequence 187.1 points all orderings give same value

This issue is covered by the guideline recommendation dealing with sequence points.

Example

In the following:

```
#include <stdio.h>

void f(void)
{
(printf("Hello ") && printf("World\n")) + printf("Goodbye\n");
}
```

possible output includes:

```
Hello World
Goodbye
```

and

```
Hello Goodbye
World
```

1254 there is a sequence point after the evaluation of the first operand.

&&
sequence point

Commentary

Unlike the nested **if** statement form, there is no guaranteed sequence after the evaluation of the second operand, if it occurs.

1250 && operand compare against 0

C++

All side effects of the first expression except for destruction of temporaries (12.2) happen before the second expression is evaluated.

5.14p2

The possible difference in behavior is the same as for the function-call operator.

1025 function call sequence point

Coding Guidelines

While the sequence point ensures that any side effects in the first operand have completed, relying on this occurring creates a dependency within the expression that increases the effort needed to comprehend it. Some of the issues involving side effects in expressions are discussed elsewhere.

941 object modified once between sequence points

Example

```
#include <stdio.h>

extern int glob;

void f(void)
{
if (--glob && ++glob)
   printf("The value of glob is neither 0 nor 1\n");
}
```

1255 If the first operand compares equal to 0, the second operand is not evaluated.

&&
second operand

Commentary

An alternative way of looking at this operator is that `x && y` is equivalent to `x ? (y?1:0) : 0`.

Common Implementations

This operand can be implemented, from the machine code generation point of view, as if a nested **`if`** construct had been written.

Coding Guidelines

Some coding guideline documents prohibit the second operand containing side effects. The rationale is that readers of the source may fail to notice that if the second operand is not evaluated any side effects it generates will not occur. The majority of C's binary operators (32 out of 34) always evaluate both of their operands. Do developers make the incorrect assumption that the operands of all binary operators are always evaluated? Your author thinks not. Many developers are aware that in some cases the **`&&`** operator is more efficient than the **`&`** operator, because it only evaluates the second operand if the first is not sufficient to return a result.

Although many developers may be aware of the conditional evaluation of the second operand, some will believe that both operands are evaluated. While a guideline recommendation against side effects in the second operand may have a benefit for some developers, it potentially increases cost in that the alternative construct used may require more effort to comprehend (e.g., the alternative described before). Given that the alternative constructs that could be used are likely to require more effort to comprehend and the unknown percentage of developers making incorrect assumptions about the evaluation of the operands, no guideline recommendation is given.

coverage testing

Coverage testing

There are software coverage testing requirements that are specific to logical operators. Branch condition decision testing involves the individual operands of logical operators. It requires that test cases be written to exercise all combinations of operands. In:

```
1  if (A || (B && C))
```

it is necessary to verify that all combinations of `A`, `B`, and `C`, are evaluated. In the case of the condition involving `A`, `B`, and `C` eight separate test cases are needed. For more complex conditions, the number of test cases rapidly becomes impractical.

Modified condition decision testing requires that test cases be written to demonstrate that each operand can independently affect the output of the decision. For the **`if`** statement above, Table 1255.1 shows the possible conditions. Using modified condition, *MC*, coverage can significantly reduce the number of test cases over branch condition, *BC*, coverage.

Table 1255.1: Truth table showing how each operand of `(A || (B && C))` can affect its result. Case 1 and 2 show that `A` affects the outcome; Case 2 and 3 shows that `B` affects the outcome; Case 3 and 4 shows that `C` affects the outcome.

Case	A	B	C	Result
1	FALSE	FALSE	TRUE	FALSE
2	TRUE	FALSE	TRUE	TRUE
3	FALSE	TRUE	TRUE	TRUE
4	FALSE	TRUE	FALSE	FALSE

The FAA requires[1183] that aviation software at Level A (the most critical, defined as that which could prevent continued safe flight and landing of the aircraft) have the level of coverage specified by MC/DC.[104] This requirement has been criticized as not having a worthwhile cost (money and time) and benefit (the number of errors found) ratio. An empirical evaluation of the HETE–2 satellite software[372] looked at the faults found by various test methods and their costs. Logical operators can also appear within expressions that are not a condition context. The preceding coverage requirements also hold in these cases.

Horgan and London[593] describe an Open Source tool that measures various dataflow coverage metrics for C source.

6.5.14 Logical OR operator

1256 logical-OR-expression syntax

logical-OR-expression:
logical-AND-expression
logical-OR-expression `||` *logical-AND-expression*

Commentary

The discussion on the logical-AND operator is applicable here. 1248 logical-AND-expression syntax

Other Languages

Ada supports two kinds of logical-OR operations: **`or`** and **`or else`**. The latter has the same semantics as the logical-OR operator in C (short-circuit evaluation). Support for an unsigned integer type was added in Ada 95 and the definition of the logical operators was extended to perform bitwise operations when their operands had this type.

Coding Guidelines

The issue of swapping usages of the `|` and `||` operators is discussed elsewhere. 1244 inclusive-OR-expression syntax

In English (and other languages) the word *or* is sometimes treated as having an exclusive rather than an inclusive meaning. For instance, "John has an M.D. or a Ph.D." is likely to be interpreted in the exclusive sense, while "John did not buy ice cream or chips" is likely to be interpreted in the inclusive sense (e.g., John did not buy ice cream and did not buy chips); the exclusive sense supports surprising possibilities (e.g., John buying ice cream and buying chips). A number of studies[403] have found that people make more mistakes when answering questions that involve disjunctive (i.e., the logical-OR operator) relationships than when answering questions that involve conjunctive (i.e., the logical-AND operator) relationships. conditionals conjunctive/disjunc

A study by Noveck, Chierchia, and Sylvestre[1018] (performed using French) found that the exclusive interpretation occurs when a conclusion $QorR$ is more informative or relevant and is prompted by an implication (e.g., *but not both*).

Usage

Usage information is given elsewhere. 1248 logical-AND-expression syntax

Constraints

1257 Each of the operands shall have scalar type.

Commentary

The discussions in the various subsections of the logical-AND operator are applicable here. 1249 && operand type

C++

The operands are both implicitly converted to **`bool`** *(clause 4).* 5.15p1

Boolean conversions (4.12) covers conversions for all of the scalar types and is equivalent to the C behavior.

Semantics

1258 The `||` operator shall yield 1 if either of its operands compare unequal to 0; || operand compared against 0

Commentary

The discussion on the logical-AND operator is applicable here. 1250 && operand compare against 0

C++

5.15p1 *It returns* **true** *if either of its operands is* **true**, *and* **false** *otherwise.*

The difference in operand types is not applicable because C++ defines equality to return **true** or **false**. The difference in return value will not cause different behavior because **false** and **true** will be converted to 0 and 1 when required.

Commentary

&& sequence point 1254 The discussion on the logical-AND operator is applicable here.

C++

5.15p2 *All side effects of the first expression except for destruction of temporaries (12.2) happen before the second expression is evaluated.*

&& sequence point 1254 The differences are discussed elsewhere.

If the first operand compares unequal to 0, the second operand is not evaluated. 1263

Commentary

&& second operand 1255 The discussion on the logical-AND operator is applicable here. An alternative way of looking at this operator is that `x || y` is equivalent to `x ? 1 : (y?1:0)`.

6.5.15 Conditional operator

1264

conditional-expression syntax

conditional-expression:
logical-OR-expression
logical-OR-expression **?** *expression* **:** *conditional-expression*

Commentary

The conditional operator is not necessary in that it is possible to implement the functionality it provides using other operators, statements, and sometimes preprocessing directives. However, C source code is sometimes automatically generated and C includes a preprocessor. The automated generation C source code is sometimes easier if conditional tests can be performed within an expression.

The second operand of a *conditional-expression* is *expression* which means that the **?** and **:** tokens effectively act as brackets for the second expression; no parentheses are required. For instance, `a ? (b , c) : d , e` can also be written as `a ? b , c : d , e`. The conditional operator associates to the right.

955 operator associativity

C++

5.16

conditional-expression: *logical-or-expression* *logical-or-expression* **?** *expression* **:** *assignment-expression*

By supporting an *assignment-expression* as the third operand, C++ enables the use of a *throw-expression*; for instance:

1288 assignment-expression syntax

```
1  z = can_I_deal_with_this() ? 42 : throw X;
```

Source developed using a C++ translator may contain uses of the conditional operator that are a constraint violation if processed by a C translator. For instance, the expression `x?a:b=c` will need to be rewritten as `x?a:(b=c)`.

Other Languages

In some languages (e.g., Algol 68) statements can return values (they are treated as expressions). For such languages the functionality of a conditional expression is provided by using an **if** statement (within an expression context). BCPL supports conditional expressions, using the syntax: *expression* `->` *expression* `,` *expression*.

Common Implementations

MetaWare High C (in nonstandard mode), some versions of `pcc`, and `gcc` support the syntax:

conditional-expression:
logical-or-expression
logical-or-expression `?` *expression* `:` *assignment-expression*

`gcc` allows the second operand to be omitted. The expression `x ? : y` is treated as equivalent to `x ? x : y`; `gcc` also supports compound expressions, which allow **if** statements to appear within an expression.

1313 compound expression

Coding Guidelines

Most developers do not have sufficient experience with the conditional operator to be familiar with its precedence level relative to other operators. Using parentheses removes the possibility of developers mistakenly using the incorrect precedence.

943.1 expression shall be parenthesized

Table 1264.1: Common token pairs involving `?` or `:` (to prevent confusion with the `:` punctuation token the operator form is denoted by `?:`) (as a percentage of all occurrences of each token). Based on the visible form of the `.c` files. Note: entries do not always sum to 100% because several token sequences that have very low percentages are not listed.

Token Sequence	% Occurrence of First Token	% Occurrence of Second Token	Token Sequence	% Occurrence of First Token	% Occurrence of Second Token
`)` `?`	0.4	44.7	`?` *string-literal*	20.1	1.5
identifier `?`	0.1	44.0	`?:` *integer-constant*	28.7	0.3

Constraints

The first operand shall have scalar type. 1265

Commentary

if statement 1743 controlling expression scalar type

This is the same requirement as that given for a controlling expression in a selection statement and is specified for the same reasons.

C++

5.16p1 *The first expression is implicitly converted to* ***bool*** *(clause 4).*

Boolean conversions (4.12) covers conversions for all of the scalar types and is equivalent to the C behavior.

Coding Guidelines

if statement 1743 controlling expression scalar type

Many of the issues that apply to the controlling expression of an **`if`** statement are applicable here.

conditional operator second and third operands

One of the following shall hold for the second and third operands: 1266

Commentary

conditional operator 1277 result

The result of the conditional operator is one of its operands. The following list of constraints ensures that the value of both operands can be operated on in the same way by subsequent operators (occurring in the evaluation of an expression).

Table 1266.1: Occurrence of the ternary `:` operator (denoted by the character sequence `?:`) having particular operand types (as a percentage of all occurrences of each operator; an _ prefix indicates a literal operand). Based on the translated form of this book's benchmark programs.

Left Operand	Operator	Right Operand	%	Left Operand	Operator	Right Operand	%
ptr-to	`?:`	ptr-to	29.5	**`int`**	`?:`	**`_int`**	5.7
other-types	`?:`	other-types	12.1	**`_char`**	`?:`	**`_char`**	3.4
`_int`	`?:`	**`_int`**	10.4	**`unsigned int`**	`?:`	**`unsigned int`**	2.2
`int`	`?:`	**`int`**	10.0	**`unsigned short`**	`?:`	**`unsigned short`**	1.2
`void`	`?:`	**`void`**	9.4	**`signed int`**	`?:`	**`_int`**	1.1
`unsigned long`	`?:`	**`unsigned long`**	7.9	**`char`**	`?:`	**`void`**	1.1
`_int`	`?:`	**`int`**	6.0				

— both operands have arithmetic type; 1267

Commentary

In this case it is possible to perform the usual arithmetic conversions to bring them to a common type.

Coding Guidelines

The guideline recommendation dealing with objects being used in a single role implies that the second and third operands of a conditional operator should have the same role.

1352.1 object used in a single role

1268 — both operands have the same structure or union type;

conditional operator structure/union type

Commentary

While the structure or union types may be the same, the evaluation of the expressions denoting the two operands may be completely different. However, a translator still has to ensure that the final result of both operands, used by any subsequent operators, is held in the same processor location.

1269 — both operands have void type;

Commentary

In this case the conditional operator appears either as the left operand of the comma operator, the top-level operator of an expression statement, or as the second or third operand of another conditional operator in these contexts. In either case alternative constructs are available. However, when dealing with macros that may involve nested macro invocations, not having to be concerned with replacements that result in operands having **void** type (invariably function calls) is a useful simplification.

1313 comma operator syntax

1270 — both operands are pointers to qualified or unqualified versions of compatible types;

conditional expression pointer to compatible types

Commentary

The discussion on the equality operators is applicable here.

1215 equality operators pointer to compatible types

C++

5.16p6

> *— The second and third operands have pointer type, or one has pointer type and the other is a null pointer constant; pointer conversions (4.10) and qualification conversions (4.4) are performed to bring them to their composite pointer type (5.9).*

These conversions will not convert a pointer to an enumerated type to a pointer to integer type.

If one pointed-to type is an enumerated type and the other pointed-to type is the compatible integer type. C permits such operands to occur in the same *conditional-expression*. C++ does not. See pointer subtraction for an example.

1159 subtraction pointer operands

1271 — one operand is a pointer and the other is a null pointer constant; or

Commentary

The discussion on the equality operators is applicable here.

1217 equality operators null pointer constant

1272 — one operand is a pointer to an object or incomplete type and the other is a pointer to a qualified or unqualified version of **void**.

Commentary

The discussion on the equality operators is applicable here.

1216 equality operators pointer to incomplete type

C++

The C++ Standard does not support implicit conversions from pointer to **void** to pointers to other types (4.10p2). Therefore, this combination of operand types is not permitted.

```
int glob;
char *pc;
void *pv;

void f(void)
{
glob ? pc : pv; /* does not affect the conformance status of the program */
                // ill-formed
}
```

Semantics

The first operand is evaluated; 1273

Commentary

selection statement 1739 syntax

Much of the discussion on the evaluation of the controlling expression of an **if** statement is applicable here.

Common Implementations

controlling expression 1740 if statement

register 209 spilling

The only difference between evaluating this operand and a controlling expression is that in the former case it is possible for more processor registers to be in use, holding results from the evaluation of other subexpressions. (This likelihood of increased register pressure may result in spilling for processors with relatively few registers— e.g., Intel x86.) However, whether the overall affect of using a conditional operator is likely to be small, compared to an **if** statement, will depend on the characteristics of the expression and optimizations performed.

---

conditional operator sequence point

there is a sequence point after its evaluation. 1274

Commentary

selection statement 1739 syntax

full expression 1712

&& 1254 sequence point

Unlike the controlling expression in a selection statement, this operand is not a full expression, so this specification of a sequence point is necessary to fully define the evaluation order. The discussion on the logical-AND operator is applicable here.

C++

5.16p1 *All side effects of the first expression except for destruction of temporaries (12.2) happen before the second or third expression is evaluated.*

function call 1025 sequence point

The possible difference in behavior is the same as for the function-call operator.

---

conditional operator operand only evaluated if

The second operand is evaluated only if the first compares unequal to 0; 1275

Commentary

Because the operand might not be evaluated, replacing a conditional operator by a function call, taking three arguments, would not have the same semantics.

Coding Guidelines

&& 1255 second operand

The guideline discussion on the logical-AND operator is applicable here.

---

the third operand is evaluated only if the first compares equal to 0; 1276

Commentary

Either the second or the third operand is always evaluated, but never both.

1277 the result is the value of the second or third operand (whichever is evaluated), converted to the type described below.[93)]

conditional operator result

Commentary

The conversion, to a common compatible type, ensures that the result of evaluating either operand has the same value representation.

Common Implementations

This places a requirement on the generated machine code to ensure that the result value is always left in the same register or storage location. Subsequent machine instructions will reference this single location.

Coding Guidelines

The difference between an **if** statement and a conditional operator is that in the latter case there is a result that can appear as the operand of another operator. Measurements of existing source suggest that developers have significantly more experience dealing with **if** statements than conditional operators. Using a conditional operator in a context in the visible source, where its result is not used (i.e., is not an operand to another operator), fails to take advantage of a developer's greater experience in dealing with **if** statements. However, such usage is rare and a guideline recommending the use of an **if** statement in this case is not considered worthwhile.

The conditional operator is not necessary for the writing of any program; it is always possible to rewrite source so that it does not contain any conditional operators. Similarly, source can be rewritten, replacing some **if** statements by conditional operators. How does the cost/benefit of using an **if** statement compare to that of using a conditional operator? The two main issues are comprehension and maintenance:

- From a reader's perspective, the comprehension of a conditional operator may, or may not, require more cognitive effort than comprehending an **if** statement. For instance, in the following example the use of an **if** statement highlights the controlling expression while the single assignment highlights that the array `a` is being modified (which needs to be deduced by reading two statements in the former case);

```
1  if (x)
2     a[y]=0;
3  else
4     a[z]=0;
5
6  a[x ? y : z]=0;
```

  When the expression being assigned to is complex, significant reader effort may be required to deduce that the two complex expressions are the same. Use of a conditional operator removes the need to make this comparison:

```
1  if (x)
2     a[complicated_expr]=y;
3  else
4     a[complicated_expr]=z;
5
6  a[complicated_expr]=(x ? y : z);
```

  When an expression in a substatement, of an **if** statement, contains a reference to an object that also occurs in the controlling expression, for instance:

1740 controlling expression if statement

```
1  if (x < 5)
2     a=10-x;
```

```
3   else
4      a=x;
5
6   a=(x < 5 ? 10-x : x);
```

readers may need to keep information about the condition in their minds when comprehending the source in both cases (i.e., maximum cognitive load is very similar, if not the same). When an expression in a substatement does not contain such a reference, readers do not need to evaluate information about the conditional to comprehend that statement. Compared to selection statements the maximum cognitive effort is likely to be less.

selection statement 1739 syntax

- In the following example a source modification requires that both `y` and `z` be assigned to `b`, instead of `a`, can be performed by editing one identifier in the case of the conditional operator usage, while the **`if`** statement usage requires two edits. However, a modification that required additional statements to be executed, if `x` were true (or false), would require far less editing for the **`if`** statement usage.

```
1   if (x)
2      a=y;
3   else
4      a=z;
5
6   a = (x ? y : z);
```

`if` statements occur in the visible source much more frequently than conditional operators. One reason is that in many cases the **`else`** arm is not applicable (only 18% of **`if`** statements in the visible form of the `.c` files contain an **`else`** arm). Because on this usage pattern readers receive more practice with the use of **`if`** statements. Given this difference in familiarity, it is not surprising that conditional operators are used less frequently than might be expected.

---

conditional operator attempt to modify

If an attempt is made to modify the result of a conditional operator or to access it after the next sequence point, the behavior is undefined. 1278

Commentary

function result 1007 attempt to modify

The discussion on the function-call operator result and its implementation details are applicable here.

C90

Wording to explicitly specify this undefined behavior is new in the C99 Standard.

C++

lvalue 721

The C++ definition of lvalue is the same as C90, so this wording is not necessary in C++.

Coding Guidelines

The code that needs to be written to generate this behavior is sufficiently obscure and unlikely to occur that no guideline recommendation is given here.

Example

```
1   typedef struct {
2                   int mem_1;
3                  } A_S;
4   extern int glob;
5   extern A_S s_1, s_2;
6
7   void f(void)
8   {
9   int *p_l = &(((glob == 1) ? s_1 : s_2).mem_1);
10
11  *p_l = 2; /* Undefined behavior. */
12  }
```

1279 If both the second and third operands have arithmetic type, the result type that would be determined by the usual arithmetic conversions, were they applied to those two operands, is the type of the result.

conditional operator arithmetic result

Commentary

There is no interaction between the types of the second and third operands and the first operand.

Other Languages

In Java:[508]

> *If one of the operands is of type T where T is* **byte**, **short**, *or* **char**, *and the other operand is a constant expression of type* **int** *whose value is representable in type T, then the type of the conditional expression is T.* 15.25

Coding Guidelines

If developers use the analogy of an **if** statement when reasoning about the conditional operator, they are unlikely to consider the effects of applying the usual arithmetic conversions to the operands (although your author is not aware of a case where a failure to take account of these conversions has resulted in a program fault). However, this may be due to use of the conditional operator being comparatively rare (and these guideline recommendations are not intended to cover rarely occurring construct).

1743 if statement controlling expression scalar type

0 guideline recommendations selecting

1234 role operand matching

For the purposes of these guideline recommendations, the role of the result is the same as the role of the second and third operands.

1280 If both the operands have structure or union type, the result has that type.

Commentary

Both operands are required to have the same structure or union type.

1268 conditional operator structure/union type

Common Implementations

The generated machine code may depend on what operation is performed on the result of the conditional operator. For instance, a simple member access `(x ? s1:s2).m` may generate the same machine code as if `(x ? s1.m : s2.m)` had been written. For more complicated cases, an implementation may load the address of the two operands into a register for subsequent indirect accesses.

Coding Guidelines

The form `(x ? s1:s2).m` has the advantage, over `(x ? s1.m : s2.m)`, that a change to the member selected only requires a single source modification (one of the two modifications needed in the latter form may be overlooked). Also the former form requires less effort to recognize as always accessing member `m`. (In the latter form the names of the two selected members needs to be checked.)

1281 If both operands have void type, the result has void type.

Commentary

This is one of the three cases where an operator does not return a value.

Coding Guidelines

If the operands have **void** type, the only affect on the output of the program is through the side effects of their evaluation. Such usage embedded in the visible form of an expression (that is not automatically generated, or the result of nested macro expansions) may be making assumptions about the order in which the operands of an expression are evaluated. This issue is covered by a guideline recommendation.

187.1 sequence points all orderings give same value

1282 If both the second and third operands are pointers or one is a null pointer constant and the other is a pointer, the result type is a pointer to a type qualified with all the type qualifiers of the types pointed-to by both operands.

conditional operator pointer to qualified types

Commentary

Specifying that the result has all the qualifiers of both operands requires that a translator make worst-case assumptions about subsequent operations. Type qualifiers on a pointed-to type do not affect the representation or alignment requirements of the pointer type, which means subsequent operators are able to treat either operand in the same way.

pointer 559 to qualified/unqualified types

In subsequent C sentences, in this C Standard paragraph, the term *appropriately qualified* refers to *all the type qualifiers* specified here (as is shown by the EXAMPLE).

EXAMPLE 1287 ?: common pointer type

Furthermore, if both operands are pointers to compatible types or to differently qualified versions of compatible types, the result type is a pointer to an appropriately qualified version of the composite type; 1283

Commentary

The specification for forming composite types lists a set of properties the result must have. The previous C sentence ensured that the resulting pointed-to type has all the qualifiers of the two operands (two types that are pointers to differently qualified compatible types are not compatible). The composite type will contain at least as much, if not more, information than either of the types separately and will therefore be as restrictive (with regard to type checking).

composite type 642

C90

Furthermore, if both operands are pointers to compatible types or differently qualified versions of a compatible type, the result has the composite type;

The C90 wording did not specify that the appropriate qualifiers were added after forming the composite type. In:

```
1  extern int glob;
2  const enum {E1, E2} *p_ce;
3  volatile int *p_vi;
4
5  void f(void)
6  {
7  glob = *((p_e != p_i) ? p_vi : p_ce);
8  }
```

the pointed-to type, which is the composite type of the **enum** and **int** types, is also qualified with **const** and **volatile**.

---

if one operand is a null pointer constant, the result has the type of the other operand; 1284

Commentary

This places a requirement on the implementation to implicitly convert the operand that is a null pointer constant to the type of the other operand (different pointer types may use different representations for the null pointer). The discussion on the equality operators is applicable here.

null pointer 750 conversion yields null pointer
equality 1230 operators null pointer constant converted

---

otherwise, one operand is a pointer to **void** or a qualified version of **void**, in which case the result type is a pointer to an appropriately qualified version of **void**. 1285

Commentary

Although the null pointer constant may be represented by a value having a pointer to **void** type, the previous C sentence takes precedence. The discussion on the equality operators is applicable here.

null pointer 748 constant
equality 1231 operators pointer to void

C90

otherwise, one operand is a pointer to ***void*** *or a qualified version of* ***void****, in which case the other operand is converted to type pointer to* ***void****, and the result has that type.*

C90 did not add any qualifies to the pointer to **void** type. In the case of the **const** qualifier this difference would not have been noticeable (the resulting pointer type could not have been dereferenced without an explicit cast to modify the pointed-to object). In the case of the **volatile** qualifier this difference may result in values being accessed from registers in C90 while they will be accessed from storage in C99.

C++

The C++ Standard explicitly specifies the behavior for creating a composite pointer type (5.9p2) which is returned in this case.

Coding Guidelines

The coding guideline discussion on the equality operators is applicable here.

1216 equality operators pointer to incomplete type

Example

```
1  const int *p_ci;
2  volatile int *p_vi;
3
4  void f(void)
5  {
6  const volatile int *p_cvi = ((p_vi != (void *)0) ?
7                               p_ci :
8                               (volatile void *)0); /* Not a null pointer constant. */
9  }
```

1286 93) A conditional expression does not yield an lvalue.

footnote 93

Commentary

This footnote points out a consequence of specifications appearing elsewhere in the standard.

725 lvalue converted to value
729 array converted to pointer

```
1  struct {
2          int m1[2];
3         } x, y;
4  int glob;
5
6  void f(void)
7  {
8  (glob ? x : y).m1; /*
9                      * An array not a pointer to the first element.  Converting the
10                     * array to a pointer to its first element requires an lvalue.
11                     */
12 }
```

C++

If the second and third operands are lvalues and have the same type, the result is of that type and is an lvalue. 5.16p4

5.16p5

Otherwise, the result is an rvalue.

Source developed using a C++ translator may contain instances where the result of the conditional operator appears in an rvalue context, which will cause a constraint violation if processed by a C translator.

```
1  extern int glob;
2
3  void f(void)
4  {
5  short loc_s;
6  int loc_i;
7
8  ((glob < 2) ? loc_i : glob) = 3;  /* constraint violation */
9                                    // conforming
10 ((glob > 2) ? loc_i : loc_s) = 3; // ill-formed
11 }
```

Common Implementations

Some implementations (e.g., `gcc`) support, as an extension, a conditional operator yielding an lvalue.

Example

Using indirection, it is possible to assign to objects appearing as operands of a conditional operator.

```
1  (x ?  y :  z) = 0;     /* Constraint violation. */
2  *(x ? &y : &z) = 0;    /* Strictly conforming.  */
```

EXAMPLE ?: common pointer type

EXAMPLE The common type that results when the second and third operands are pointers is determined in two independent stages. The appropriate qualifiers, for example, do not depend on whether the two pointers have compatible types. 1287

Given the declarations

```
const void *c_vp;
void *vp;
const int *c_ip;
volatile int *v_ip;
int *ip;
const char *c_cp;
```

the third column in the following table is the common type that is the result of a conditional expression in which the first two columns are the second and third operands (in either order):

```
c_vp      c_ip     const void *
v_ip      0        volatile int *
c_ip      v_ip     const volatile int *
vp        c_cp     const void *
ip        c_ip     const int *
vp        ip       void *
```

Commentary

The effect is to maximize the number of type qualifiers and minimize the amount of type representation information (i.e., pointer to **`void`** is a generic pointer type) in the common type.

C90

This example is new in C99.

6.5.16 Assignment operators

1288

assignment-expression syntax

```
assignment-expression:

                conditional-expression
                unary-expression assignment-operator assignment-expression
assignment-operator: one of
                =  *=  /=  %=  +=  -=  <<=  >>=  &=  ^=  |=
```

Commentary

The syntax is written so that these operators associate to the right. This means that in `x=y=z`, `z` is assigned to `y`, which is then assigned to `x`. Defining assignment as an operator is consistent with the specification that it returns a value. Its definition as an operator makes it possible for a full expression to contain more than one assignment.

955 operator associativity

1291 assignment value of

One benefit (to translator vendors) of compound assignment operators is that they remove the perceived need for translators to perform certain kinds of optimization. One potential disadvantage to developers of compound assignment operators is that they are likely to have the effect of causing vendors to write translators that do not search for certain kinds of optimization. The underlying reason is the same in both cases. The use of these operators affects the characteristics of the source that translator vendors expect to frequently encounter (e.g., because developers are expected to write `x*=3` rather than `x=x*3`). Thus vendors don't tune optimizers to search for assignments in code that don't make use of compound assignment operators (if this usage is possible).

0 source code characteristics

```
1  struct T {
2             struct fred *next;
3             /* ... */
4            } s_ptr;
5
6  s_ptr = s_ptr->next;
7  s_ptr ->= next;      /* There is no ->= operator. */
```

C++

```
assignment-expression:  conditional-expression logical-or-expression
assignment-operator assignment-expression throw-expression
```

5.17

For some types, a cast is an lvalue in C++.

1131 footnote 85

Other Languages

Most languages do not treat assignment as an operator, but as part of the syntax of the assignment statement. Languages in the Algol family use `:=` as the assignment token. The token `/=` denotes the not equal operator in some languages (e.g., Ada). Fortran contains the **`ASSIGN`** statement, which can be used to assign a label to an object having type **`INTEGER`**. Perl (and BCPL) support assigning multiple values to multiple objects within the same assignment (e.g., `v1, v2, v3 = e1, e2, e3`). Algol 68 does not treat assignment as an operator, but does treat compound assignment as operators. This results in `x +:= y := p -:= q := r` being parsed as `(x +:= y) := (p -:= q) := r`.

Common Implementations

base document 1

The base document supported `=+`, `=*`, and the reversed form of the other compound assignment operators.[723]

Coding Guidelines

What are the costs and benefits of using multiple assignment operators in the same full expression?

The potential benefits, compared to source code where full expressions contain at most one assignment operator, include:

- The resulting program image may contain higher-quality (faster and/or smaller) machine code. However, this benefit may not exist (if the translator used is sufficiently sophisticated that it generates comparable machine code for both cases). The benefit may also be of no significance— the difference in program performance is not noticeably different and the size savings is of no consequence.
- When carefully reading the source (rather than scanning it quickly), a multiple assignment may require less cognitive effort to comprehend than two assignments. For instance, if the objects being assigned to are denoted by some complicated expression, it is necessary to deduce that, for instance, `complicated_y` represents the same object in both cases. This deduction does not need to be performed when a multiple assignment is used:

```
1  complicated_x = complicated_y = some_expression;
2
3  complicated_y = some_expression;
4  complicated_x = complicated_y;
```

- Use of the form `x = y = exp` is not usually taken to imply a causal connection between `x` and `y`, while an assignment of the form `x=y` often implies a causal connection between the two objects. When `exp` is complicated, a multiple assignment may help clarify that any causal association should be to it, not between the two objects assigned to.

The main potential costs are reader miscomprehension of the expression and a possible increase in the maximum cognitive load required to comprehend the expression, as follows.

reading kinds of 770

- The miscomprehension can occur because of the techniques developers use to read source code. When searching for objects that are modified, developers often visually scan along the left edge of the source (making the assumption that all identifiers denoting modified objects appear along this edge). If multiple assignment operators occur within the same expression, it is possible that only the first one of them will be seen.

postfix ++ result 1047

- Increase in cognitive load can be caused by the task switch needed to update a reader's mental model of a program's state. This issue is discussed elsewhere.

Multiple objects are sometimes initialized to the same value in a single statement (e.g., `a=b=c=d=0;`). The developer has saved the typing of a few characters at the expense of less-readable source code and an increased likelihood that changes to the source lead to errors. For instance, assigning a different value to `c` implies that the original assignment to `c` would be removed; poor editing could create the expression `a=b==d=0;` (failure to spot the original assignment to `c`, resulting in it being left in the source, could introduce errors if it occurred after a different value had been stored into `c`).

Cg 1288.1

A full expression shall contain at most one assignment operator, and it shall occur as the *top-level* operator in that expression.

controlling expression if statement 1740

The issue of assignment operators occurring in other types of statements that contain expressions is discussed elsewhere.

Example

```
extern int ***x,
           *y;

void f(void)
{
**x+++=***x++;
*y*=*y;
*y-=***x---=*y--;
}
```

Usage

For a comparison with load frequencies see Table 976.2.

Table 1288.1: Common token pairs involving the assignment operators (as a percentage of all occurrences of each token). Based on the visible form of the `.c` files. Note: entries do not always sum to 100% because several token sequences that have very low percentages are not listed.

Constraints

assignment operator modifiable lvalue

An assignment operator shall have a modifiable lvalue as its left operand. 1289

Commentary

modifiable lvalue 724

An object declared using the **`const`** is an lvalue, but it is not modifiable.

C90

lvalue 721

The C99 Standard has removed the requirement, that was in C90, which lvalues refer to objects. This has resulted in the conformance status of the assignment `1=3` changing from a constraint violation to undefined behavior. The lvalue `1` does not designate an object and is not const-qualified. Therefore it is not ruled out from being modifiable in C99.

lvalue 721

Common Implementations

Some implementations support an extension that allows the result of the cast operator to be an lvalue (e.g., assignments of the form `(char)i = 3` are supported).

Example

In some cases an implementation is likely to diagnose a syntax violation, in an assignment expression, rather than this constraint violation.

```
1    (int)x = 0;   /* Syntax violation. */
2   +(int)x = 0;   /* Syntax is valid, but violates this constraint. */
```

Semantics

An assignment operator stores a value in the object designated by the left operand. 1290

Commentary

modified objects 192
received correct value
assignment 1293
when side effect occurs

The standard does not specify when the value is stored, only that it occurs between the previous and next sequence point. Neither does the standard specifies how the store should be implemented. For instance, storing into an object having a floating type does not require that the value be treated as having a floating type; simple assignment of `a` to `b` may be implemented using machine code that copies blocks of bits, or as the instruction sequence load floating value/store floating value. For floating types this difference can matter because assigning a signaling NaN will not raise an exception in the former case, but will in the latter.

Other Languages

Assignment is not universal to all programming languages. Some pure functional languages regard assignment as causing a side effect that make it difficult to mathematically prove the correctness of source code. They do not contain any means of assigning a value to an object.

Some languages, often used in distributed computing, perform what is sometimes known as *deep assignment*. For instance, if `X` refers to a tree-like data structure, then assigning `X` to `Y` has the effect of making a copy of the tree and assigning a reference to it to `Y`; `X` and `Y` will then point at different trees, which contain nodes having the same values (apart from the pointers to other nodes).

Common Implementations

Whether the store into an object specified in the source code actually occurs in the generated machine code is invisible to the developer. Optimizers frequently try to remove stores by keeping the value in a register (perhaps until a new value is assigned). For processors with many registers, functions containing a small number of automatic objects may never need to store assignments to those objects.

Usage

A study by Lepak, Bell, and Lipasti[835] investigated value locality with respect to store operations (using the SPEC95 benchmarks). They defined a *silent store* to be a store operation that does not change the system state (i.e., the value being written matches the value already held at the location being stored to). They also defined *program structure store value locality* (PSSVL) to refer to the same value being stored from the same program location and *message-passing store value locality* (MPSVL) to refer to the same value being stored to the same address in storage (which may be holding different objects at different times during the execution of a program).

976 value locality

Table 1290.1: Percentage of stores that are *silent*. The results from two instruction sets, the PowerPC (PPC) and SimpleScalar (SS), are given for silent stores. The measurements for Program Structure Store Value Locality (PSSVL) and Message-Passing Store Value Locality (MPSVL) are for the PowerPC only. Adapted from Lepak, Bell, and Lipasti.[835]

Program	Silent stores (PPC/SS)	PSSVL (PPC)	MPSVL (PPC)	Program	Silent stores (PPC/SS)	PSSVL (PPC)	MPSVL (PPC)
go	38/27	30	36	tomcatv	47/33	40	45
m88ksim	68/62	56	65	swim	34/26	20	19
gcc	53/46	37	49	mgrid	23/ 7	24	17
compress	42/39	35	16	applu	37/35	35	28
li	34/20	32	34	apsi	21/25	22	20
ijpeg	43/33	52	46	fpppp	15/15	15	14
perl	49/36	39	42	wave5	25/22	30	20
vortex	64/55	71	57				

Results for two processors and their associated translators are given in Table 1290.1. Differences in internal housekeeping operations, such as saving registers as part of a function-call operation, can affect the results. The same authors[110] found that zero was the most common silent store value (46% of silent stores), with one being 7%, 2 to 9 being 4%, and values greater than 100 million being 26%. For floating-point, values greater than 100 million were the most common at 65%, with zero being 37%.

1004 function call preparing for

1291 An assignment expression has the value of the left operand after the assignment, but is not an lvalue.

assignment value of

Commentary

Using the value of an assignment expression does not mean that the side effect of storing that value in the left operand has taken place.

If a guarantee is needed that the assignment will have taken place before the value is used, or an lvalue is required. The expression `((a=b), a)` *can be used.*

WG14/N847

Two interpretations have been put on this wording:

- *the value of the assignment expression is the value that will also be stored in the left operand ("same-value" semantics);*
- *the value of the assignment expression is the result of reading the left operand after storing the value in it ("write-then-read" semantics).*

These two have different results when the left operand is a volatile object that can be changed by external causes (such as a clock or a memory-mapped device register). This ambiguity needs to be resolved.

Consider the code:

```
int x;
extern volatile int system_timer;  // precision of 1 microsecond
extern volatile int serial_port;   // writing sends a word, reading
                                   //   returns the next word received
// ...
x = system_timer = 42;  // statement 1
serial_port = 66;       // statement 2
```

With same-value semantics, statement 1 will set x to 42 and will send the value 66 to the serial port. With write-then-read semantics, statement 1 will set x to some other value (the change in the timer between writing to it and reading it back).

*More important, though, is the effects of statement 2 in write-then-read semantics. Because a statement expression is evaluated for its side effects, it is reasonable to require the value of the assignment statement to be determined before being thrown away (in particular, there is *no* statement in the Standard as to when the value of the assignment expression is or is not evaluated). This means that statement 2 always has the side effect of reading a word from the serial port, and there is no way to write without reading.*

C++

5.17p1 *. . . ; the result is an lvalue.*

The C++ DR #222 (which at the time of this writing is at the drafting stage) queries some of the consequences of the result being an lvalue.

Source developed using a C++ translator may contain assignments that are a constraint violation if processed by a C translator.

```
1  extern int glob;
2
3  void f(void)
4  {
5  int x;
6  volatile int y;
7
8  (glob += 5) += 6; /* constraint violation */
9                    // current status undefined behavior, object modified
10                   // twice between sequence points.  The response to DR #222
11                   // may add a sequence point, making the behavior defined
12
13 x = y = 0; /* equivalent to y=0; x=0; */
14            // equivalent to y=0; x=y;
15 }
```

Other Languages

In the past languages have not generally treated assignment as an operator. Whether more recent languages are treating it as an operator because of the effects of the widespread teaching of C to students over several decades or for other reasons is not known.

Coding Guidelines

Experience shows that developers sometimes incorrectly assume that the result of the assignment operator is the value of the right operand before it is converted to the type of the left operand.

Rev 1291.1 If the result of an assignment operator is used and the types of its two operands are different, the source shall be checked to ensure that the value of the right operand is not being expected.

Example

In the first statement in the following the value of LONG_MAX will be implicitly converted (to the value 2147483647) and assigned to ui.

```
#include <limits.h>

void f(void)
{
unsigned char uc;  /* Assume 8 bits.  */
unsigned short us; /* Assume 16 bits. */
unsigned int ui;   /* Assume 32 bits. */

uc=us=ui=LONG_MAX;
ui=us=uc=LONG_MAX;
}
```

This value is what is assigned to us, but first it has to be converted, giving a value of 65535. This value is then assigned to uc, but first it must be converted, giving a value of 255. In the second statement the value 255 is assigned to all three objects.

1292 The type of an assignment expression is the type of the left operand unless the left operand has qualified type, in which case it is the unqualified version of the type of the left operand.

assignment result type

Commentary

This requirement is consistent with the value of an assignment expression being that of the left operand.

Other Languages

Algol 68 treats an assignment as returning an lvalue, so it is possible to write:

```
INT x;
REF INT r;
r := x := 42;
```

which causes r to point to x, which is assigned the value 42.

Coding Guidelines

The incorrect developer assumption described in the previous C sentence also applies to the type of the result.

Rev 1292.1 If the result of an assignment operator is used and the types of its two operands are different, the source shall be checked to ensure that the type of the right operand is not being expected.

Example

```
extern unsigned char uc;
extern float fl;

void f(void)
{
if ((fl += 1) == 3)           /* Equality comparison of floating type. */
   ;
if (((uc = 3.5) + 0.5) == fl) /* Adding 0.5 to an unsigned char?       */
   ;
}
```

assignment when side effect occurs

The side effect of updating the stored value of the left operand shall occur between the previous and the next sequence point. 1293

Commentary

This is a requirement on the implementation. Like other operators that generate side effects, the exact time when the side effect occurs is not specified, only the bounds between when it must occur. Most assignment operators occur in the context of an expression statement, which is a full expression and hence has a sequence point after its evaluation.

sequence 187 points expression 1731 statement syntax full expression 1715 expression statement full expression 1720 sequence point

C++

The C++ Standard does not explicitly state this requirement.

Other Languages

In languages that do not treat assignment as an operator, updating the stored value is the last operation performed in that statement (which may contain function calls that modify objects).

Coding Guidelines

sequence 187 points sequence 187.1 points all orderings give same value

It is not always possible to predict the ordering of sequence points chosen by a translator, and the guideline recommendation dealing with expression order evaluation is applicable here.

---

assignment operand evaluation order

The order of evaluation of the operands is unspecified. 1294

Commentary

Many developers have a mental model of assignment that involves evaluating one of the operands first. (This is often a hang over from how they were first taught to write programs.) The evaluation of the operands has the same behavior as most other binary operators in C. This sentence is simply a restatement of this fact.

expression 944 order of evaluation

C++

The C++ Standard does not explicitly make this observation.

Other Languages

Few languages specify an ordering on the evaluation of the left and right operands of an assignment, even if they do not consider assignment to be an operator. Java specifies a left-to-right evaluation order.

Common Implementations

Unsophisticated translators will evaluate the right operand first, on the basis that it is likely to be the most complex (and therefore require the greater number of temporary registers). More sophisticated translators will estimate the complexity of both operands and evaluate the most complex one first.

Coding Guidelines

The issues generated by some developers, who have a mental model of assignment that involves one operand always being evaluated before the other, are the same as for the other binary operators. The guideline recommendation dealing with expression order evaluation is applicable here.

expression 944 order of evaluation sequence 187.1 points all orderings give same value

Example

```
1  #include <stdio.h>
2
3  char arr[20];
4
5  void f(void)
6  {
7  arr[printf("Hello ")] = printf("World\n");
8  }
```

1295 If an attempt is made to modify the result of an assignment operator or to access it after the next sequence point, the behavior is undefined.

Commentary

In some cases it is possible to create an lvalue from the result returned by the assignment operator (these invariably involve constructs whose implementation involves the use of temporary storage locations). The order of evaluation of most operands is unspecified and when it is specified, a sequence point also occurs. This C sentence effectively specifies that there is no requirement for implementations to support developer access to these temporary objects.

C90

This sentence did not appear in the C90 Standard and had to be added to C99 because of a change in the definition of the term lvalue. 721 lvalue

C++

The C++ definition of lvalue is the same as C90, so this wording is not necessary in C++.

Common Implementations

The temporary storage locations used internally by an implementation are usually allocated within the stack frame of the function invocation that uses them. As such, they will cease to exist when that function returns. These storage locations may also be used to hold temporary results from the evaluation of other operations.

Coding Guidelines

For this undefined behavior to occur an expression must contain more than one assignment operator. The guideline recommendation dealing with the use of multiple assignment operators in the same expression is therefore applicable. The code that needs to be written to generate this behavior is sufficiently obscure and unlikely to occur that no guideline recommendation is given here. 1288.1 full expression at most one assignment

Example

```
struct {
        int m[10];
       } x, y;

void f(void)
{
unsigned char uc_1;
int *p_1 = &((x = y).m[3]);

*p_1 = 4;
p_1 = &((x = y).m[uc_1=0, 2]);

/*
 * Result accessed before sequence point, but behavior is unspecified(?)
 * because the object written to is also read from in the same subexpression.
 */
y.m[4] = (*p_1 = &((x = y).m[3])) + *(p_1++);
}
```

6.5.16.1 Simple assignment

Constraints

1296 One of the following shall hold:[94)] simple assignment constraints

Commentary

equality 1213 operators constraints

This list is very similar to that given for the equality operators.

C++

The C++ Standard does not provide a list of constraints on the operands of any assignment operator (5.17). Clause 12.8 contains the specification that leads the following difference:

C1.8 *The implicitly-declared copy constructor and implicitly-declared copy assignment operator cannot make a copy of a volatile lvalue. For example, the following is valid in ISO C:*

```
struct X { int i; };
struct X x1, x2;
volatile struct X x3 = {0};
x1 = x3;     // invalid C++
x2 = x3;     // also invalid C++
```

Rationale: Several alternatives were debated at length. Changing the parameter to volatile const X& would greatly complicate the generation of efficient code for class objects. Discussion of providing two alternative signatures for these implicitly-defined operations raised unanswered concerns about creating ambiguities and complicating the rules that specify the formation of these operators according to the bases and members.

— the left operand has qualified or unqualified arithmetic type and the right has arithmetic type; 1297

Commentary

operators 702 cause conversions modifiable lvalue 724 assignment 1289 operator modifiable lvalue

Any arithmetic value can be assigned to any object that has an arithmetic type. Conversions are specified to handle all cases where the two arithmetic types are not the same. This constraint does not prohibit the type of the left operand being const-qualified. However, such an object would not be a modifiable lvalue, and such usage would violate a constraint that applies to all assignment operators.

C++

5.17p3 *If the left operand is not of class type, the expression is implicitly converted (clause 4) to the cv-unqualified type of the left operand.*

The conversions in clause 4 do not implicitly convert enumerated types to integer types and vice versa.

```
1  extern int glob;
2
3  enum {E1, E2};
4
5  void f(void)
6  {
7  glob = E1; /* does not affect the conformance status of the program */
8             // ill-formed
9  }
```

Other Languages

Strongly typed languages sometimes require the names of the types used to declare the operands to be the same. There are usually special rules to cover literal values.

Common Implementations

Simple assignments of the form `x=y;` are very common. Some processors (e.g., the Motorola 68000[968]) support memory-to-memory copies (no implicit conversions are performed, so both operands must have the same representation). A processor that supports memory-to-memory copies needs to encode two addresses—the source and destination— within the instruction. Such encoding requires a large number of bits (some Motorola 68000 instructions are 13 bytes long). Considering the design of instruction encodings from a more global perspective, there are cost/benefit processor implementation advantages in having fixed-width instructions, and there is often a greater benefit to be had in using the available instruction bits to specify other operations. For these reasons it is very rare to find a modern processor that supports memory to memory operations. On most processors the assignment `x=y` is implemented as "load value into register, store register contents into object". Depending on the local source code context, optimizers may be able to reuse the value held in the register.

Coding Guidelines

The guideline recommendation for binary operators with an operand having an enumeration type is applicable here.

517.3 enumeration constant as operand

1298 — the left operand has a qualified or unqualified version of a structure or union type compatible with the type of the right;

assignment structure types

Commentary

Structure/union assignment was introduced in C90; it was not supported in the base document. Structure assignment was first specified in a document listing extensions made to the base document.

1 base document

Structure assignment can be more efficient than using the `memcpy` library function. This is because the implementation of `memcpy` has to assume worst-case alignment and copy a byte at a time (some very good implementations do better). The translator knows the alignment of an object having structure type and may be able to copy its contents in larger chunks. It may even be worthwhile to copy an element at a time.

601 footnote 42

Structures sometimes have an array as their only member, which effectively allows arrays to be assigned.

C++

Clause 13.5.3 deals with this subject, but does not discuss this particular issue.

Other Languages

It seems to be quite common for the first versions of a language definition to not support structure assignment. Such support is often added in later revisions of language definitions.

Common Implementations

Copying a structure a member at a time (or even in larger units— e.g., a long's worth of bits) produces the fastest code, but at the potential cost of a large number of instructions. Generating a loop is often more compact (except for the case of small structures), but runs more slowly because of the housekeeping overhead of controlling a loop (and the backward jump, potentially flushing the instruction cache). Most implementations generate machine code to copy a member at a time for small structure types and looping machine code for larger one. Depending on the method selected by the implementation padding bits, may or may not also be copied.

0 cache

Coding Guidelines

Use of the assignment operator can result in the object assigned to containing a different sequence of bits than if the `memcpy` library function had been used. In the former case a call to the `memcmp` library function may not return zero, while in the latter it will always return zero. The reason for using `memcmp` is that the equality operators do not support operands having a structure or union type. A strong case can be made for using `memcmp` to compare two structure objects, other than the (usually) spurious efficiency reason; if new members are added to a structure type, a comparison using `memcmp` will not have to be modified, while one that checks individual members will need to be updated to reflect the presence of the new member.

1213 equality operators constraints

Cg 1298.1

Objects having structure or union type that are compared using the `memcmp` library function shall not appear as the immediate operands of an assignment operator.

Example

```
#include <stdio.h>
#include <string.h>

struct {
        long m1;
        char m2;
       } x, y;

int main(void)
{
x = y;
if (memcmp(&x, &y, sizeof(x)) == 0)
   printf("either there are no padding bits, the assignment operator copies all"
          "padding bits, or the padding bits happen to be the same\n");

memcpy(&x, &y, sizeof(x));
if (memcmp(&x, &y, sizeof(x)) != 0)
   printf("something wrong here\n");

memcpy(&x, &y, sizeof(x));
x.m1=y.m1;
if (memcmp(&x, &y, sizeof(x)) != 0)
   printf("member assignment affects padding bits\n");
}
```

---

pointer qualified/unqualified versions

— both operands are pointers to qualified or unqualified versions of compatible types, and the type pointed to by the left has all the qualifiers of the type pointed to by the right; 1299

Commentary

Given the following declarations (where `Q_0` and `Q_1` represent zero or more qualifiers, and `T` is an unqualified type; with the lowercase names denoting the same entities):

```
T Q_1 * Q_0 left_operand;
t q_1 * q_0 right_operand;
```

compatible type 631 if assignment operator 1289 modifiable lvalue

this constraint requires that: the types `T` and `t` be compatible, and that all the qualifiers in `q_1` also be in `Q_1`. It is permitted for `Q_1` to contain qualifiers that are not in `q_1`. The case of `Q_0` containing the **`const`** qualifier is covered by wording given elsewhere.

C++

The C++ wording (5.17p3) requires that an implicit conversion exist.

pointer 746 converting qualified/unqualified

The C++ requirements (4.4) on which implicit, qualified conversions are permitted are those described in the Smith paper (discussed elsewhere).

The pointer assignments supported by C++ are a superset of those supported by C. Source developed using a C++ translator may contain constraint violations if processed by a C translator, because it contains assignments between incompatible pointer types. The following example illustrates differences between the usages supported by C and C++ when types using two levels of pointer are declared.

```
1  void Jon_Krom(void)
2  {
3  /*
4   * The issue of what is safe or unsafe is discussed elsewhere.
5   * An example of case 3 is given in the standard.
6   */
7
8  typedef int T; /* for any type T */
9
10 T       *       *  ppa  ;
11 T       *       *  ppb  ;
12
13 T       * const *  pcpa ;
14 T       * const *  pcpb ;
15
16 T const *       * cppa  ;
17 T const *       * cppb  ;
18
19 T const * const * cpcpa ;
20 T const * const * cpcpb ;
21
22                   //  Safe       Allowed     Allowed
23                   //   or         in          in
24                   // Unsafe       C99         C++
25                   // --------------------------------
26 ppb   = ppa ;     //  Safe        Yes         Yes      1
27 pcpb  = ppa ;     //  Safe        Yes         Yes      2
28 cppb  = ppa ;     //  Unsafe      No          No       3
29 cpcpb = ppa ;     //  Safe        No          Yes      4
30
31 ppb   = pcpa ;    //  Unsafe      No          No       5
32 pcpb  = pcpa ;    //  Safe        Yes         Yes      6
33 cppb  = pcpa ;    //  Unsafe      No          No       7
34 cpcpb = pcpa ;    //  Safe        No          Yes      8
35
36 ppb   = cppa ;    //  Unsafe      No          No       9
37 pcpb  = cppa ;    //  Unsafe      No          No      10
38 cppb  = cppa ;    //  Safe        Yes         Yes     11
39 cpcpb = cppa ;    //  Safe        Yes         Yes     12
40
41 ppb   = cpcpa ;   //  Unsafe      No          No      13
42 pcpb  = cpcpa ;   //  Unsafe      No          No      14
43 cppb  = cpcpa ;   //  Unsafe      No          No      15
44 cpcpb = cpcpa ;   //  Safe        Yes         Yes     16
45 }
```

Other Languages

Languages that support some form of type qualifier (e.g., **`readonly`**) usually have similar asymmetric constraints on pointer assignment.

Coding Guidelines

If differently qualified pointers are used to access the same object, in an overlapping time frame, it is possible that readers of the source will make an incorrect assumption about the type of one or more of them. For instance, if a pointer to **`const`** T and a pointer to T both point at the same object, a developer (who is not aware of this state of affairs) may assume that the pointer to const-qualified type cannot have its value changed. Qualified pointers are a special case of object aliasing and the conclusion reached there is applicable.

971 object aliased

1300 — one operand is a pointer to an object or incomplete type and the other is a pointer to a qualified or unqualified version of **`void`**, and the type pointed to by the left has all the qualifiers of the type pointed to by

the right;

Commentary

Either operand can have a pointer to **void** type. This combination of operands provides implicit support for the concept of a generic pointer type (no explicit casts are required).

generic pointer 523

The issues relating to qualifiers are the same as those in the previous C sentence.

C++

5.17p3 *If the left operand is not of class type, the expression is implicitly converted (clause 4) to the cv-unqualified type of the left operand.*

The C++ Standard only supports an implicit conversion when the left operand has a pointer to **void** type, 4.10p2.

```
1  char *pc;
2  void *pv;
3
4  void f(void)
5  {
6  pc=pv; /* does not affect the conformance status of the program */
7         // ill-formed
8  }
```

Coding Guidelines

The coding guideline discussion on the equality operators is applicable here.

equality operators pointer to incomplete type 1216

— the left operand is a pointer and the right is a null pointer constant; 1301

Commentary

A null pointer constant can be converted to any pointer type.

null pointer conversion yields null pointer 750

Other Languages

Languages that support pointer data types invariably have some form of null pointer that can be assigned to an object having any other pointer type.

Coding Guidelines

The issue of explicit casts is discussed elsewhere.

pointer converted to pointer to void 744

---

or— the left operand has type **_Bool** and the right is a pointer. 1302

Commentary

This specification is consistent with operands in other contexts having pointer type being implicitly compared for equality with 0 (the null pointer constant).

|| operand compared against 0 1258
&& operand compare against 0 1250
if statement operand compare against 0 1744
_Bool converted to 680

C90

Support for the type **_Bool** is new in C99.

C++

Support for the type **_Bool** is new in C99 and is not specified in the C++ Standard. However, the C++ Standard does specify (4.12p1) that rvalues having pointer type can be converted to an rvalue of type **bool**.

Other Languages

Other languages do not usually perform an implicit comparison when the operand has point type.

Coding Guidelines

Support for the `_Bool` type is new in C99 and at the time of this writing there is insufficient experience available in its use to know if any guideline recommendation is worthwhile.

Semantics

1303 In *simple assignment* (=), the value of the right operand is converted to the type of the assignment expression and replaces the value stored in the object designated by the left operand.

simple assignment

Commentary

This defines the term *simple assignment*. Because it is the most commonly seen form of assignment operator developers invariably shorten it to *assignment*. The less-frequent forms of assignment are known by longer terms (see Table 912.1).

The type of the result of the assignment operator is the unqualified type of its left operand. The standard does not guarantee that assignment is an atomic operation unless the left operand has type `sig_atomic_t`. Assigning an object having a structure type is not always identical to assigning its members individually. There may be an order dependency.

1292 assignment result type
192 modified objects received correct value

```
1  struct S_Pair;
2
3  typedef struct Object {
4                          struct S_Pair *addr;
5                          int tag;
6                         } Object;
7  struct S_Pair {
8                  Object car;
9                  Object cdr;
10                };
11
12 Object x;
13
14 void copy_obj(void)
15 {
16 x = x.addr->cdr;
17
18 /* is not the same as: */
19
20 x.addr = x.addr->cdr.addr;
21 x.tag  = x.addr->cdr.tag;
22 }
```

Common Implementations

In most implementations the store operation for an assignment operator, for scalar types whose bit representation is not wider than the width of the processor data bus (which is unlikely to include complex types), is an atomic operation. Unless objects having structure or union types that can fit in a single register, stores of their values are unlikely to be atomic operations.

A surprising number of assignment operations store a value that is equal to the value already held in memory. Researchers[278] are starting to adapt algorithms used to detect redundant load operations to optimize away such redundant store operations.

1288 assignment-expression syntax
190 redundant code

Coding Guidelines

If the right operand does not have the same type as the left operand, it will be implicitly converted to that type. Assignment is different from all other binary operators in that it can cause the value of one of its operands to be implicitly converted to a type that has a lower integer rank, or a narrower floating type. A consequence of such a conversion is that the assignment `x=y` does not guarantee that a subsequent equality operation `x==y` will be true. This situation does not occur if the guideline recommendation specifying the use of a single integer type is followed.

480.1 object int type only

operand 653 convert automatically

The guideline recommendations applicable to assignment include those given for conversions.

---

assignment value overlaps object

If the value being stored in an object is read from another object that overlaps in any way the storage of the first object, then the overlap shall be exact and the two objects shall have qualified or unqualified versions of a compatible type; 1304

Commentary

This requirement (on programs) is needed because implementations may choose to perform an assignment by copying values from the right operand to the left operand a byte at a time. It would be surprising if the assignment x=x did not always deliver the expected result (an unchanged x; unless it is declared with the **volatile** qualifier).

For a given implementation it is possible for two types to have the same size and to overlap exactly, but not be compatible (e.g., types **int** and **long**). The conformance status of a program cannot depend on the implementation, hence the additional requirement on compatible types. The issue of overlapping objects is primarily of importance when assigning members of an object having a union type.

```
union {
      int m_1;
      long m_2;
      int m_3;
      struct {
             char m_4;
             long m_5;
             } m_6;
      } x;

void f(void)
{
x.m_1=x.m_2;     /* Not compatible types. */
x.m_1=x.m_3;     /* Covered by this requirement. */
x.m_2=x.m_6.m_5; /* Overlap (if it exists) not exact. */
}
```

Requiring that all overlapping assignments work as expected would sometimes involve the use of temporary storage locations. Such an overhead during program execution was considered to be excessive. It would require the use of the `memmove` library function rather than the `memcpy` library function.

C++

object types 475

The C++ Standard requires (5.18p8) that the objects have the same type. Even though the rvalue may have the same type as the lvalue (perhaps through the use of an explicit cast), this requirement is worded in terms of the object type. The C++ Standard is silent on the issue of overlapping objects.

```
enum E {E1, E2};
union {
       int m_1;
       enum E m_2;
      } x;

void f(void)
{
x.m_1 = (int)x.m_2; /* does not change the conformance status of the program */
                    // not defined?
}
```

Other Languages

Some languages treat the value of the right operand as being independent of the object referred to by the left operand. In these languages if there is any possibility of overlap and the generated machine code has to

perform the assignment by copying multiple storage units of the value, then a temporary has to be used to hold the value so that partial stores into the object do not modify the value being assigned.

1305 otherwise, the behavior is undefined.

Commentary

Objects can overlap in a variety of ways and implementations can copy objects using a variety of techniques. The Committee chose not require implementations to support any particular set of behaviors.

Common Implementations

For objects having scalar types, the copying is likely to be performed by loading the value into a register. Once the value has been completely loaded, how the subsequent store is performed does not affect the final result. It is those assignments that require more than one load instruction (where the source and destination overlap) where the behavior can vary. The result will depend on the relative addresses of the objects and whether the copying starts at the lowest or the highest byte of the objects.

Coding Guidelines

No guideline recommendation is given for this situation because occurrences of this usage are assumed to be rare.

1306 EXAMPLE 1 In the program fragment

narrower example

```
int f(void);
char c;
/* ... */
if ((c = f()) == -1)
        /* ... */
```

the **int** value returned by the function may be truncated when stored in the **char**, and then converted back to **int** width prior to the comparison. In an implementation in which "plain" **char** has the same range of values as **unsigned char** (and **char** is narrower than **int**), the result of the conversion cannot be negative, so the operands of the comparison can never compare equal. Therefore, for full portability, the variable **c** should be declared as **int**.

Commentary

There are also less visibly obvious situations involving a value of -1. For instance, the EOF macro.

296 limit case labels

Coding Guidelines

The coding guideline discussion on the assignment operator appearing in a controlling expression is applicable here.

1740 controlling expression if statement

1307 94) The asymmetric appearance of these constraints with respect to type qualifiers is due to the conversion (specified in 6.3.2.1) that changes lvalues to "the value of the expression" ~~which~~and thus removes any type qualifiers ~~from the type category of the expression~~ that were applied to the type category of the expression (for example, it removes **const** but not **volatile** from the type **intvolatile*const**).

footnote 94

Commentary

The definition of type category does not include qualifiers. There is even a C sentence that says so. All of the contexts where the conversion is not performed do not apply to the immediate left operand of the assignment operator.

553 type category
556 qualifiers representation and alignment
725 lvalue converted to value

The wording was changed by the response to DR #272.

C++

Even though the result of a C++ assignment operator is an lvalue, the right operand still needs to be converted to a value (except for reference types, but they are not in C) and the asymmetry also holds in C++.

EXAMPLE 2 In the fragment: 1308

```
char c;
int i;
long l;

l = (c = i);
```

the value of **i** is converted to the type of the assignment expression **c = i**, that is, **char** type. The value of the expression enclosed in parentheses is then converted to the type of the outer assignment expression, that is, **long int** type.

Commentary

assignment 1291 value of

While C++ supports the form `(l = c) = i;`, C does not.

Coding Guidelines

full expression 1288.1 at most one assignment

The coding guideline discussion on the use of more than one assignment operator in an expression is applicable here.

EXAMPLE const pointer

EXAMPLE 3 Consider the fragment: 1309

```
const char **cpp;
char *p;
const char c = 'A';

cpp = &p;       // constraint violation
*cpp = &c;      // valid
*p = 0;         // valid
```

The first assignment is unsafe because it would allow the following valid code to attempt to change the value of the const object **c**.

Commentary

The term *unsafe* is often used to refer to an operation, which although itself is conforming, whose resulting value may subsequently be a cause of undefined behavior.

6.5.16.2 Compound assignment

Constraints

compound assignment constraints

For the operators += and -= only, either the left operand shall be a pointer to an object type and the right shall have integer type, or the left operand shall have qualified or unqualified arithmetic type and the right shall have arithmetic type. 1310

Commentary

addition 1154 operand types

The discussion on the constraints for the additive operators are applicable here.

Coding Guidelines

boolean role 476 symbolic name 822 addition 1154 operand types

The issue of operands having a boolean or symbolic role is discussed elsewhere.

Table 1310.1: Occurrence of assignment operators having particular operand types (as a percentage of all occurrences of each operator; an _ prefix indicates a literal operand, occurrences below 2.3% were counted as *other-types*). Based on the translated form of this book's benchmark programs.

For the other operators, each operand shall have arithmetic type consistent with those allowed by the corresponding binary operator. 1311

Commentary

The discussion in the respective C sentences for these corresponding binary operators also apply here.

C++

5.15p7 *In all other cases, E1 shall have arithmetic type.*

Those cases where objects may not have some arithmetic type when appearing as operands to operators (i.e., floating types with the shift operators) are dealt with using the equivalence argument specified earlier in 5.15p7.

Semantics

compound assignment semantics

A *compound assignment* of the form **E1** *op* = **E2** differs from the simple assignment expression **E1** = **E1** *op* **(E2)** only in that the lvalue **E1** is evaluated only once. 1312

Commentary

This defines the term *compound assignment*. The original rationale for this form of operator was that it removed the need for translators to spot the commonly occurring case of the value of an object being operated on and stored back into the original object (an optimization that is made by translators for other languages).

expression 944 order of evaluation

There is no requirement that the evaluation order of E1 and E2 in the expression E1 op= E2 be the same as in the expression E1 = E1 op E2. In compiler terminology, E1 is known as a *common subexpression*.

Other Languages

Java specifies a left to right evaluation order and so in the following example the final values assigned to a and b is 9 in both cases. The C behavior in both cases is undefined.

```
1  void f(void)
2  {
3  short a = 6;
4  int   b = 6;
5
6  a += (a=3);    /* Undefined behavior. */
7  b = b + (b=3); /* Undefined behavior. */
8  }
```

In Java compound assignment operators perform a (narrowing primitive) conversion:

Java 15.26.2 *A compound assignment expression of the form* ***E1*** *op* ***= E2*** *is equivalent to* ***E1 = (T)((E1)*** *op* ***(E2))****, where* ***T*** *is the type of* ***E1****, except that* ***E1*** *is evaluated only once.*

This implicit conversions means that the expression a += b is conforming, while a = a + b generates a translation time diagnostic and an explicit cast (to short) has to be added.

Common Implementations

Because of the availability of these operators many translators make no direct effort to detect the optimizations possible in expressions such as x=x*y (some cases may be detected as a consequence of common subexpression detection). For the simple cases there is unlikely to be any differences in the generated machine code. In the more complex cases (e.g., x is an array element or structure member access) the opportunity to reuse the calculated address of an object is self-evident when a compound assignment operator is used and has to be deduced when the equivalent longer form is used.

Coding Guidelines

Compound assignment requires less effort to comprehend than its equivalent two operator form. Readers only need to comprehend two operands, and there is no need to notice that one operand is the same as another. These operators directly represent the concept of performing an operation on the value held in an object and storing it back into that object. Measurements of existing source shows that developers regularly use compound assignment operators. A guideline recommending this usage would serve no worthwhile purpose.

6.5.17 Comma operator

comma operator syntax

1313

expression:

assignment-expression
expression , *assignment-expression*

Commentary

This operator is frequently seen in automatically generated source code. It is usually used to simplify the analysis that needs to be performed by the generator in deducing what it has to do. For instance, when generating an expression it is not necessary to look ahead to see if some other expressions need to be evaluated first. If such an expression is encountered, it can occur as the left operand of a comma expression (which can occur in any context an expression can occur in).

Other Languages

The comma operator is unique to C (and C++). However, some languages provide a mechanism for grouping multiple statements into an expression that returns a value.

Common Implementations

compound expression

gcc supports what it calls *compound expressions*. The following example— the compound expression is delimited by ({ and }) and its value is that of the last expression in the compound— could be written using comma and conditional operators (however, it is not possible to define local objects within these operators).

```
1  extern int foo(void);
2
3  void f(void)
4  {
5  int loc;
6
7  loc =({
8       int x = foo (),
9           y;
10      if (x > 0)
11         y = x;
12      else
13         y = -x;
14      y;
15      });
16 }
```

Compound expressions do not offer much benefit in the visible source, except for automatically generated code. However, the ability to define objects can be useful in macro definitions. The following definition is written so that its arguments are only evaluated once.

```
1  #define MAXINT(x,y) ({int _x = (x), _y = (y); _x > _y ? _x : _y; })
```

Coding Guidelines

The comma token is one of the visibly smallest characters (in terms of display area occupied) and usually appears among other characters (unlike the semicolon token, which usually appears at the end of a line). Although specialist fonts have been designed for a variety of domains (e.g., mathematics, linguistics), none have yet become generally available for displaying source code. Increasing the visible size of the comma character is only one of several display issues that could be addressed.

Most occurrences of the comma token in the visible source are as a punctuator (e.g., an argument separator in function calls, or a list of identifiers in a declaration), not as an operator. The C syntax requires that any use of this token as an operator in an argument expression be enclosed in parentheses.

EXAMPLE 1319
comma operator

Semantics

---

comma operator left operand

The left operand of a comma operator is evaluated as a void expression; 1314

Commentary

The intent is for the left operand to generate side effects, but for any value it might have, not to take part in forming the result of the expression that contains it.

Coding Guidelines

cognitive 0 switch

The purpose of the left operand is to generate side effects without contributing to the value of the containing expression. As such it requires readers to make a cognitive task switch between comprehending the expression and updating their mental model (based on the consequences of the side effects). Is the cost/benefit to using a comma operator more worthwhile than separating its components over two statements (the semicolon after the first statement provides a sequence point)? There are three contexts in which an expression can appear:

1. *An initializer.* Initialization is a construct where C99 offers a solution not available in C90.

```
1  extern int glob;
2
3  void f(void)
4  {
5  int loc_1 = (--glob , glob + 3);
6
7  /*
8   * Only possible in C99.
9   */
10 glob--;
11 int loc_2 = glob + 3;
12
13 /*
14  * A possible rewriting in C90.
15  */
16 int dummy = glob--;
17 int loc_3 = glob + 3;
18 }
```

   Recommending that a comma operator in an initializer be replaced by a statement and a declaration limits portability by requiring a C99 translator. Also given that developers are not yet accustomed to seeing statements before declarations, it is possible that such statements will be overlooked.

2. *An expression statement.* There are no obvious benefits to using a comma operator in an expression statement. The single sequence point guarantee can be obtained using other constructs (although developers sometimes make incorrect assumptions about the sequencing of other operand evaluations).

comma operator 1315
sequence point

3. *A controlling expression.* The use of the comma operator in this context is discussed under the cases in which they can occur, selection statements and iteration statements.

selection statement 1739
syntax
iteration statement 1763
syntax

Until C99 translators become more generally available, the following guideline recommendation limits itself to expression statements.

Cg 1314.1 The comma operator shall not appear in the visible form of an expression statement.

If the left operand of the comma operator does not generate a side effect, it is redundant code. 190 redundant code

---

1315 there is a sequence point after its evaluation. comma operator sequence point

Commentary

This sequence point guarantees that any side effects that occur in the evaluation of the left operand will have taken place before the right operand is evaluated. There is no other guarantee given for the order of evaluation of any other operands that may occur within the full expression containing the comma operator.

C++

All side effects (1.9) of the left expression, except for the destruction of temporaries (12.2), are performed before the evaluation of the right expression. 5.18p1

The discussion on the function-call operator is applicable here. 1025 function call sequence point

Common Implementations

Sequence points cut down on the opportunities for optimization, or at least make them harder to find. Long stretches of source code without sequence points provide an optimizer maximum flexibility in ordering the sequence of generated machine code. For this reason translators prefer to evaluate the left operand of comma operators as soon as possible (in some case they may evaluate it as late as possible, but that is less commonly optimal). In:

```
1  extern int glob_1,
2             glob_2;
3  extern int g(void);
4
5  void f(void)
6  {
7  int loc[4];
8  /* ... */
9  loc[++glob_1] = (glob_2 * loc[0]) + (g() , glob_2) + (loc[3] * 3);
10 }
```

the only requirement placed on the call to g is that it occurs before the right operand of the comma operator is evaluated. Calling g after any of the other operands had been evaluated would require saving their intermediate results. Looking at the visible source code, there are obvious optimization advantages to calling g before any other operands are evaluated. But then a more detailed analysis may show that the other operands are already available in registers, and ready to be used, in which case it may be more efficient to call g as late as possible.

Coding Guidelines

An incorrect assumption sometimes made by developers is to assume that all operands to the left of a comma operator will be evaluated (and side effects have occurred) before any of the operands to its right are evaluated. This issue is covered by the guideline recommendation dealing with sequence points. 187.1 sequence points all orderings give same value

---

1316 Then the right operand is evaluated;

Commentary

The word *then* is sometimes incorrectly interpreted to mean that the right operand is evaluated immediately after the evaluation of the left operand; that is, no other operand is evaluated between the left and right operand evaluations. As the following example illustrates, other operands may be evaluated between the evaluations of the two operands of a comma operator.

```
1  extern int glob_1,
2             glob_2;
3  extern int g(void),
4             h(void); /* Writing extern int h(void); would be idiomatic. */
5
6  void f(void)
7  {
8  int loc_1;
9  /*
10  * After glob_1 is incremented there is no guarantee that g will be
11  * called before glob_2 is incremented, or that after glob_2 is
12  * incremented that h will be called before glob_1 is incremented.
13  */
14 loc_1 = (glob_1++ , g()) + (glob_2++ , h());
15 }
```

---

the result has its type and value.[95)] 1317

Commentary

The right operand has the same type and value as if it had not occurred as an operand of the comma operator.

If an attempt is made to modify the result of a comma operator or to access it after the next sequence point, the behavior is undefined. 1318

Commentary

This specification is consistent with the right operand being the result of a binary operator. However, it would also have been possible to treat this operand as if it had not been operated on, but the Committee chose not to make that decision.

C90

This sentence did not appear in the C90 Standard and had to be added to C99 because of a change in the definition of the term lvalue. lvalue 721

C++

The C++ definition of lvalue is the same as C90, so this wording is not necessary in C++. lvalue 721

Common Implementations

Implementations are unlikely to use a temporary to store the value of the right operand. They will refer directly to the right operand.

Coding Guidelines

The code that needs to be written to generate this behavior is sufficiently obscure and unlikely to occur that no guideline recommendation is given here.

Example

```
1  struct {
2          int m[10];
3         } x;
```

```
4
5   void f(void)
6   {
7   int *p = &((x , x).m[2]);
8
9   *p = 1;
10  p = &(x.m[2]);
11  *p = 1;
12  }
```

1319 EXAMPLE

EXAMPLE
comma operator

As indicated by the syntax, the comma operator (as described in this subclause) cannot appear in contexts where a comma is used to separate items in a list (such as arguments to functions or lists of initializers). On the other hand, it can be used within a parenthesized expression or within the second expression of a conditional operator in such contexts. In the function call

```
f(a, (t=3, t+2), c)
```

the function has three arguments, the second of which has the value 5.

Commentary

Using an assignment operator in contexts other than an expression statement is discussed elsewhere.

1740 controlling expression
if statement

1320 95) A comma operator does not yield an lvalue.

footnote 95
comma operator
lvalue

Commentary

This is the one significant difference between an occurrence of the right operand on its own and as an operand of a comma operator. The former case could be an lvalue while the latter is not.

725 lvalue converted to value

C++

. . . ; the result is an lvalue if its right operand is. 5.18p1

```
1   #include <stdio.h>
2
3   void DR_188(void)
4   {
5   char arr[100];
6
7   if (sizeof(0, arr) == sizeof(char *))
8      printf("A C translator has been used\n");
9   else
10     if (sizeof(0, arr) == sizeof(arr))
11        printf("A C++ translator has been used\n");
12     else
13        printf("Who knows why we got here\n");
14  }
15
16  void f(void)
17  {
18  int loc;
19
20  (2, loc)=3; /* constraint violation */
21              // conforming
22  }
```

Forward references: initialization (6.7.8). 1321

6.6 Constant expressions

constant expression syntax

1322

```
constant-expression:
                conditional-expression
```

Commentary

constant expression not contain 1324

Syntactically specifying a *constant-expression* as a *conditional-expression* is consistent with constraints on operators that may appear in such an expression.

Coding Guidelines

How do people perform simple arithmetic? For operations involving small single-digit values, current models of human performance[60,817] are based on a network of connected arithmetic facts (e.g., $1 + 1 = 2$) stored in long-term memory. These *facts* are accessed by a process of spreading activation,[376,385] using as input the numbers and operators provided by the calculation. This process does not appear to require a person to have any understanding of the operation performed;[343] it is purely a fact-retrieval operation. People tend to use arithmetic procedures for larger values. The extent to which either a retrieval or procedural approach is used has been found to vary between cultures.[196] For a discussion of how people store arithmetic *facts* in memory, see Whalen.[1454] For a readable introduction to human processing of simple arithmetic quantities, see Dehaene.[338]

There have been some studies investigating people's eye movements while they performed simple arithmetic tasks.[1315] However, the operands in source code expressions are written on a horizontal line, not vertically under each other (as we are taught to do it in school). It is not known how this difference in operand layout will affect the sequence of eye movements that occur when performing simple arithmetic with source code expressions.

When a sequence of simple arithmetic operations are performed, the order in which they occur can affect the response time and error rate.[53] Other performance related behaviors include:

- *Problem size/difficulty.* Both the time taken to produce an answer and the error rate increase as the numeric value of the operands increases. It is thought that this effect occurs because operations on larger values are not as common as on smaller values; it is an amount-of-practice effect. Constants in C source code also tend to be small (see Figure 825.1).
- *Split effect.* People take longer to reject false answers that are close to the correct answer (e.g., $4\times7 = 29$) than those that are further away ($4\times7 = 33$).
- *Associative confusion effect.* Here people answer a different question from the one asked[543] (e.g., giving 12 as the answer to $4\times8 =?$, which would be true had the operation been addition).
- *Odd/even effect.*[834] Here people use a rule rather than retrieving a fact from memory to verify the answer to a question; for instance, adding an odd number to an even number produces an odd result.

developer errors memory overflow 0

The affect of working memory capacity limits on mental arithmetic performance is discussed elsewhere.

Description

A constant expression can be evaluated during translation rather than runtime, and accordingly may be used in any place that a constant may be. 1323

Commentary

The operative phrase here is *can be*. The standard specifies a number of contexts where a numeric value is required at translation time. In all other cases a translator need only act as if the expressions are evaluated during translation. The standard also gives implementations freedom to evaluate other expressions at translation time. There is no abstract machine state available during translation, which limits what can be considered to be a constant expression.

1334 footnote 96
1344 constant expression other forms

Here the term *constant expression* refers to the syntactic form `constant-expression`, while *constant* refers to the syntactic form `constant`. Evaluation of constant expressions, by a translator, is often called *constant folding* (particularly in compiler writing circles).

822 constant syntax

C++

The C++ Standard says nothing about when constant expressions can be evaluated. It suggests (5,19p1) places where such constant expressions can be used. It has proved possible to write C++ source that require translators to calculate relatively complicated functions. The following example, from Veldhuizen,[1413] implements the pow library function at translation time.

```
template<int I, int Y>
struct ctime_pow
   {
   static const int result = X * ctime_pow<X, Y-1>::result;
   };

// Base case to terminate recursion
template<int I>
struct ctime_pow<X, 0>
   {
   static const int results =- 1;
   };

const int x = ctime_pow<5, 3>::result; // assign five cubed to x
```

Other Languages

Some languages do not support the use of operators in constant expressions; which are essentially literals. For instance, the first standard for Pascal, ISO 7185, did not; many implementations added such support as an extension and the first revision of that language standard added support for such usage. Other languages (e.g., Ada) allow the value of a constant to be calculated during program execution.

Common Implementations

There are two ways of representing integer constants during translation. A translator can either use the representation of the host on which the translator is executing, or it can use its own internal format (potentially often supporting a greater range of values). The latter approach has the advantage of offering consistent behavior, a benefit for those vendors offering products on a variety of hosts.

There is no context where the standard requires a translator to support arithmetic operations on floating constants during translation. Many implementations choose to generate code to evaluate expressions containing floating-point operands during program startup

Some translators and static analysis tools issue diagnostics for operations they consider to be suspicious; for instance, a left-shift operation that results in all of the bits set in the left operand being shifted out of the result (which can occur for a shift amount less than the width of the promoted left operand).

Flow analysis is used by some translators to deduce that particular uses of objects have a single value (known as *constant propagation*). For instance, if x appears in an expression immediately after the value 3 is assigned to it, a read of x can be replaced by 3. Deducing whether an expression has a unique constant value during program execution is undecidable[558,980] (even if the interpretation of conditional branches is ignored). Rather than deducing a unique constant value, *generalized constant propagation* attempts to

estimate the range of values an object may have at a particular point in the source. Verbrugge, Co, and Hendren[1416] compare the performance of various algorithms on C programs of under 1,000 statements.

Example

```
extern int glob;

void f(void)
{
glob = 4;

struct {
        /*
         * It may be possible to deduce the value of glob at translation
         * time, but the standard does not require such deduction.
         */
        int mem :glob; /* Constraint violation. */
       } loc;
glob++; /* Can be implemented by assigning 5 to glob. */
}
```

Constraints

constant expression not contain

Constant expressions shall not contain assignment, increment, decrement, function-call, or comma operators, except when they are contained within a subexpression that is not evaluated.[96)] 1324

Commentary

constant expression 1322 syntax

While the syntax does not permit a constant expression to contain an assignment or comma operator at the outermost level, it does not prohibit them from occurring within a parenthesized expression. This constraint specifies these operators cannot occur in any contexts that are evaluated within a constant expression. Because they are evaluated at translation time, an attempt to generate a side effect in a constant expression, could not be interpreted to have any meaning. The C abstract machine does not exist during translation.

abstract machine 184 C

C90

. . . they are contained within the operand of a **`sizeof`** *operator.*[53)]

sizeof 1119 result of

With the introduction of VLAs in C99 the result of the **`sizeof`** operator is no longer always a constant expression. The generalization of the wording to include any subexpression that is not evaluated means that nonconstant subexpressions can appear as operands to other operators (the logical-AND, logical-OR, and conditional operators). For instance, `0 || f()` can be treated as a constant expression. In C90 this expression, occurring in a context requiring a constant, would have been a constraint violation.

C++

Like C90, the C++ Standard only permits these operators to occur as the operand of a **`sizeof`** operator.

See C90 difference.

Other Languages

Languages that support constant expressions that are evaluated during program execution may also support the occurrence of side effects.

Coding Guidelines

As footnote 96 points out, it is possible for a subexpression not to be evaluated and still affect to the final value of the expression that contains it. A subexpression that does not affect the final value of the expression is not redundant code in the sense that it does not form part of the program image. An expression containing identifiers that are expanded by the preprocessor may have a generalized form that has been designed to handle a variety of different translation and host environments. 190 redundant code

In the following example, a particular constant may only be available when translating for a particular host. The generalized case involves a function call during program execution. A macro definition hides some implementation details behind the name Y; however, if it needs to be used in a context where a constant is required, more complexity may be needed. In this case another macro, X, and a conditional expression has been used.

```
#if defined VENDOR_A
   #define X 0
   #define Y VENDOR_A_VALUE
#else
   #define X NON_ZERO_DEFAULT_VALUE
   #define Y get_value_during_execution()
#endif

int glob[X ? X : Y];
```

Although a subexpression that does not affect the final value of an expression and does not contain identifiers that are macro expanded involves a cost and probably has no benefit; such uses are rare. For this reason no guideline recommending against using such constructs is given.

Example

```
extern int glob;
extern int g(void);

int f(void)
{
switch (glob)
   {
   case 0 && g() : return 77;

   case 1 || g() : return 88;

   case 1 ? 2 : g() : return 99;

   case sizeof(g()) : return 111;
   }
}
```

1325 Each constant expression shall evaluate to a constant that is in the range of representable values for its type.

Commentary

If the evaluation of an expression, at execution time, would deliver a result that is not representable in its type, the behavior is undefined. The check on constant expressions can afford to be more rigorous because there is no execution-time penalty in translation-time checks on the evaluation of a constant expression. 947 exception condition

C++

The C++ Standard does not explicitly specify an equivalent requirement.

Example

```
1  #include <limits.h>
2
3  int a[INT_MAX * INT_MAX];
```

Semantics

An expression that evaluates to a constant is required in several contexts. 1326

Commentary

The standard lists many of the contexts requiring integer constant expressions (additional ones include the *constant-expression* in a designator and the expression that controls conditional inclusion). All initializers for objects having static storage duration must be constant.

footnote 1334 96
designator 1646
constant-expression
conditional 1869
inclusion
constant expression
initializer 1644
static storage duration object

Other Languages

A few languages do not require constants in any contexts. However, the execution-time overhead on such a language design decision is often perceived to be much higher than users are willing to tolerate. It also complicates the job of writing a translator.

Common Implementations

Extensions created by vendors sometimes relax the contexts in which a constant expression is required. A common extension is to allow nonconstant expressions in initializers for objects having file scope (also supported in C++).

Coding Guidelines

As discussed elsewhere, expressions that evaluate to constants in other contexts are sometimes suspicious.

controlling 1740
expression
if statement

If a floating expression is evaluated in the translation environment, the arithmetic precision and range shall be at least as great as if the expression were being evaluated in the execution environment. 1327

Commentary

This is a requirement on the implementation. The prohibition against raising exceptions applies to floating constants, not to constant expressions.

floating 858
constant
conversion
not raise exception

To ensure adequate range and precision, a translator that evaluates floating expressions will need to be aware of the value of the FLT_EVAL_METHOD macro. Arithmetic range and precision are two attributes of floating-point expression evaluation. Others, not included by this requirement, are specified by the FLT_ROUNDS macro and the FLT_RADIX macro. Also, while the status of FENV_ACCESS macro is known to the implementation, the affect of any execution-time calls to the floating-point status library functions will not.

FLT_EVAL_METHOD 354
FLT_ROUNDS 352
FLT_RADIX 366

C++

This requirement is not explicitly specified in the C++ Standard.

Other Languages

Very few languages require floating expressions to be evaluated during translation.

Common Implementations

A few implementations (e.g., gcc) do evaluate floating expressions during translation. Translators may, or may not, provide an option to control the optimization of floating-point operations (gcc provides many).

---

integer constant expression

An *integer constant expression*[97] shall have integer type and shall only have operands that are integer constants, enumeration constants, character constants, **sizeof** expressions whose results are integer constants, and floating constants that are the immediate operands of casts. 1328

Commentary

This defines the term *integer constant expression*.

The restriction on floating constants only being the *immediate operands of casts* means that translators are not required to perform arithmetic operations on floating constants. Evaluating the result of casting of a floating-point constant to an integer type can be achieved by manipulating sequences of characters, starting with the initial token (no numeric representation of the floating constant need be created).

For the result of the **sizeof** operator to be an integer constant, its' operand cannot have a VLA type.

C++

> . . . , ***const*** *variables or static data members of integral or enumeration types initialized with constant expressions (8.5),* . . . 5.19p1

For conforming C programs this additional case does not cause a change of behavior. But if a C++ translator is being used to develop programs that are intended to be conforming C, there is the possibility that this construct will be used.

```
1  const int ten = 10;
2
3  char arr[ten]; /* constraint violation */
4                 // does not change the conformance status of the program
```

Other Languages

Some languages regard enumeration and character constants as different types and would require a cast for such constants to appear as operands in an integer constant.

Common Implementations

Some implementations map floating constant tokens to numeric values before casting them to an integer type.

Coding Guidelines

Any reader comprehension issues apply whether or not an expression can be evaluated to a constant; for instance, use of parentheses. 943.1 expression shall be parenthesized

Example

```
1  /*
2   * Both declarations define an array containing one element.
3   */
4  static int arr_1[2u + -1];
5  static int arr_2[1 + (int)0E99999999999999999999999999999999999999999];
```

1329 Cast operators in an integer constant expression shall only convert arithmetic types to integer types, except as part of an operand to the **sizeof** operator. integer constant cast of

Commentary

Supporting casts to a floating type would require translators to be capable of handling floating-point arithmetic (unless the only subsequent operation on the result was a cast to an integer type). Although address constants are supported, the model used is one where they are handled at link-time. This means their value is not available, during the translation of a source file, to be cast to an integer constant. 1341 address constant

The evaluation of the **sizeof** operator involves deducing the type of its operand, which does not necessarily involve evaluating any of the contained subexpressions.

Common Implementations

A few implementations (e.g., `gcc`) support casting constants to floating types.

More latitude is permitted for constant expressions in initializers. 1330

Commentary

program startup 150

The C language specification of initializers does not require translation-time knowledge of their values. The initialization can be evaluated as part of program's startup, allowing translators to treat initializers like any other expression. For instance, a translator need not concern itself with how many digits are significant in the evaluation of:

```
1  int x = (int)(1.0/3.0 + 2.0/3.0);
```

C++

5.19p2 *Other expressions are considered constant-expressions only for the purpose of non-local static object initialization (3.6.2).*

Other Languages

Most languages that support the use of initializers in declarations allow noninteger types to be assigned values having the appropriate type.

Such a constant expression shall be, or evaluate to, one of the following: 1331

Commentary

initializer type constraints 1660

As well as evaluating to one of the constructs on this list, the type of the constant expression also has to be compatible with the type of the object it is initializing.

— an arithmetic constant expression, 1332

Commentary

arithmetic constant expression 1339

This case is discussed elsewhere.

---

constant null pointer constant

— a null pointer constant, 1333

Commentary

null pointer constant 748

The standard specifies two possible token sequences that can be used to represent the null pointer constant.

---

footnote 96

96) The operand of a **`sizeof`** operator is usually not evaluated (6.5.3.4). 1334

Commentary

sizeof result of 1119
sizeof operand evaluated 1122

The only time the operand of a **`sizeof`** operator may need to be evaluated is if its operand contains a VLA. If the operand of the **`sizeof`** operator contains a VLA, it is not a constant expression and must be evaluated at execution time.

C90

*The operand of a **`sizeof`** operator is not evaluated (6.3.3.4) and thus any operator in 6.3 may be used.*

Unless the operand contains a VLA, which is new in C99, it will still not be evaluated.

C++

The operand is never evaluated in C++. This difference was needed in C99 because of the introduction of variable length array types.

1335 97) An integer constant expression is used to specify the size of a bit-field member of a structure, the value of an enumeration constant, the size of an array, or the value of a **case** constant.

footnote 97

Commentary

This is a partial list of all places where the standard requires an integer constant expression (arrays having block scope no longer require their size to be specified using an integer constant expression).

Other Languages

Some other languages require translation-time constant expressions (in some cases constants) in these contexts, while others support execution-time values in these contexts (or their equivalent forms).

1336 Further constraints that apply to the integer constant expressions used in conditional-inclusion preprocessing directives are discussed in 6.10.1.

Commentary

These constraints are a result of the preprocessor having less information available to it and are discussed elsewhere.

1869 conditional inclusion constant expression

1337 — an address constant, or

Commentary

This is discussed elsewhere.

1341 address constant

1338 — an address constant for an object type plus or minus an integer constant expression.

Commentary

An algorithm may call for the initialization value of the object being defined, with pointer type, to point to an element of an object other than its first. While recognizing the developer's desire for such functionality the Committee was aware that not all linkers were capable of providing it. They also recognized the commercial impracticality of requiring vendors to provide a linker to replace the one provided by the vendor of the host environment. It was believed that the majority of existing linkers supported a method of adding constant offsets to an existing address. This C sentence reflects this availability.

The requirement that the result of pointer arithmetic still point within (or one past the end) of the original object still apply.

1169 pointer one past end of object

C++

The C++ language requires that vendors provide a linker for a variety of reasons; for instance, support for name mangling.

Other Languages

Some languages effectively support such initializers because they allow the address of an element of an array or member of a structure to be used as an address constant.

Common Implementations

An implementation's support for additional forms of address constant is likely to be dictated by the functionality available in the linker used.

Example

```
1  extern int glob;
2
3  static int *p_g = &glob + (sizeof(int) * 2);
```

---

arithmetic constant expression

An *arithmetic constant expression* shall have arithmetic type and shall only have operands that are integer constants, floating constants, enumeration constants, character constants, and **sizeof** expressions. 1339

Commentary

integer constant expression 1328

This defines the term *arithmetic constant expression*. An arithmetic constant expression is a more general kind of constant expression than an integer constant expression in that the restrictions on operands having a floating type have been lifted. Annex F, of the C Standard, also discusses arithmetic constant expressions.

Cast operators in an arithmetic constant expression shall only convert arithmetic types to arithmetic types, except as part of an operand to a **sizeof** operator whose result is an integer constant. 1340

Commentary

integer constant cast of 1329

This specification is a more generalized form of the one given for integer constant expressions. It includes support for the conversion of arithmetic types to floating types.

---

address constant

An *address constant* is a null pointer, a pointer to an lvalue designating an object of static storage duration, or a pointer to a function designator; 1341

Commentary

This defines the term *address constant*. The term *scalar constant expression* would not be appropriate because arithmetic types are not included in the list. Common implementation practice (also for other languages) is for information on the storage address of objects having static storage duration and the address of the start of a function definition to be included in a program's image. This C definition of address constant reflects this existing implementation practice.

While objects having static storage duration are represented in a fixed, unique storage location, objects having other storage durations can be allocated storage at different locations every time their lifetime starts; the address of objects having automatic storage duration need not be unique (because of recursive invocations of the function that contains them).

The only context in which an address constant is required is the initializer for an object having a pointer type.

C90

The C90 Standard did not explicitly state that the null pointer was an address constant, although all known implementations treated it as such.

C++

The C++ Standard does not include (5.19p4) a null pointer in the list of possible address constant expressions. Although a null pointer value is listed as being a *constant-expression* (5.19p2). This difference in terminology does not appear to result in any differences.

Other Languages

Many languages only permit pointers to point at dynamically created objects. Such languages cannot contain address constants.

Common Implementations

program startup 150

In a hosted environment the relative addresses of objects, with static storage duration, and developer-written function definitions is usually decided by the linker. On program startup an area of storage is allocated to hold the objects having static storage duration. A fixed offset is added to the relative addresses of objects to obtain their actual addresses in the program's address space.

Library functions may be dynamically linked and their actual (possibly virtual) address is not known until they are called during program execution. In this case translators need to generate the machine code needed to ensure this execution-time address fix-up occurs.

In a freestanding environment the actual storage locations (addresses) assigned to objects (with static storage duration) and the machine code representing function definitions are usually known at link-time. For the other cases the complexity of program loading varies from always using a known fixed offset to the full virtual memory handling seen in hosted environments.

1342 it shall be created explicitly using the unary **&** operator or an integer constant cast to pointer type, or implicitly by the use of an expression of array or function type.

Commentary

These uses of the unary **&** operator are also techniques for generating addresses in nonconstant contexts. This list does not include using the value of an object to create an address (even if that object was assigned an address constant earlier in the same translation unit), or the value returned from a function call. Casts of integer constants to pointer types are often required in programs executing in freestanding environments, where it is known that certain addresses are mapped to hardware devices.

752 integer permission to convert to pointer

C90

Support for creating an address constant by casting an integer constant to a pointer type is new in C99. However, many C90 implementations supported this usage. It was specified as a future change by the response to DR #145.

C++

Like C90, the C++ Standard does not specify support for an address constant being created by casting an integer constant to a pointer type.

Other Languages

Expressions having array or function type are not usually implicitly converted to addresses in other languages. Support for casting integer constants to addresses varies between languages.

Common Implementations

Many implementations support, as an extension, the casting of address constants to different pointer types as also being address constants.

Example

```
1  extern int glob;
2  int *g_p = (int *)1;
3  char *g_c = (char *)&glob;
```

1343 The array-subscript **[]** and member-access **.** and **->** operators, the address **&** and indirection ***** unary operators, and pointer casts may be used in the creation of an address constant, but the value of an object shall not be accessed by use of these operators.

Commentary

The array-subscript **[]** and member-access **.** and **->** operators can all be used to specify particular subobjects within objects.

The operand used as the index in the array-subscript **[]** operator must be an integer constant expression if the resulting expression is to be an address constant.

The indirection ***** unary operator would normally be used to access the value of an object. However, when used in combination with the address **&** operator, the access can be *canceled out*.

1092 &*

The member-access -> operator requires a pointer type for its left operand. This will need to be an address constant if the resulting expression is to be an address constant.

Casts to structure type are not permitted in constant expressions, but casts of integer constants to pointer-to structures are permitted. A common implementation of the `offsetof` macro is:

```
#define offsetof(TYPE, MEMBER) ((size_t) &((TYPE *)0)->MEMBER)
```

Example

```
struct S {
          int m_1;
          short m_2[3];
         } x, y;

struct S *p1_s = &x;
int *p1_m1_s = &(y.m1);
int *p2_m1_s = &((&y)->m1);
int *p3_m1_s = &(((struct S *)0)->m1);
int *p4_m1_s = &(&*y.m1);

int arr[10];
int *p1_arr = arr;
int *p2_arr = &(arr[4]);

short *p3_m2_s = y.m_2;
short *p4_m2_s = &(y.m_2[0]);
```

---

constant expression other forms

An implementation may accept other forms of constant expressions. 1344

Commentary

Here the standard gives explicit permission for translators to extend the kinds of expressions that are translation-time constants.

C++

The C++ Standard does not given explicit latitude for an implementation to accept other forms of constant expression.

Other Languages

Translators for other languages sometimes include extensions to what the language specification defines as a constant expression. Not many language definitions explicitly condone such extensions.

Coding Guidelines

Developers may be making use of implementation-defined constant expressions when they use one of the standard macros (e.g., invoking the `offsetof` macro). In this case the choice is made by the implementation and is treated as being invisible to the developer (who may be able to make use of a translator option to save the output from the preprocessor to view the constant). The guideline recommendation dealing with the use of extensions is applicable here.

extensions 95.1 cost/benefit

Example

```
static int foo = 2;
static int bar = foo + 2; /* A constant in the Foobar, Inc. implementation. */
```

1345 The semantic rules for the evaluation of a constant expression are the same as for nonconstant expressions.[98)]

constant expression semantic rules
1869 conditional inclusion constant expression

Commentary

Additional constraints on constant expressions apply when they appear in conditional inclusion directives.

C++

The C++ Standard does not explicitly state this requirement, in its semantics rules, for the evaluation of a constant expression.

Common Implementations

Because the evaluation occurs during translation rather than during program execution, the effects of any undefined behaviors may be different. For instance, a translator may perform checks that enable a diagnostic to be generated, warning the developer of the conformance status of the construct.

1346 **Forward references:** array declarators (6.7.5.2), initialization (6.7.8).

1347 98) Thus, in the following initialization,

footnote 98

```
static int i = 2  || 1 / 0;
```

the expression is a valid integer constant expression with value one.

Commentary

While this usage is unlikely to appear in the visible source, as such, it can occur indirectly as the result of macro replacement.

C++

The C++ Standard does not make this observation.

6.7 Declarations

declaration syntax

1348

declaration:
declaration-specifiers *init-declarator-list*$_{opt}$;
declaration-specifiers:
storage-class-specifier *declaration-specifiers*$_{opt}$
type-specifier *declaration-specifiers*$_{opt}$
type-qualifier *declaration-specifiers*$_{opt}$
function-specifier *declaration-specifiers*$_{opt}$
init-declarator-list:
init-declarator
init-declarator-list , *init-declarator*
init-declarator:
declarator
declarator = *initializer*

Commentary

The intent of this syntax is for an identifier's declarator to have the same visual appearance as an instance of that identifier in an expression. For instance, in:

```
1  int x[3], *y, z(void);
2  char (*f(int))[];
```

the identifier `x` might appear in the source as an indexed array, `y` as a dereferenced pointer, and `z` as a function call. An example of an expression using the result of a call to `f` is `(*f(42))[1]`.

C90

Support for *function-specifier* is new in C99.

C++

The C++ syntax breaks declarations down into a number of different categories. However, these are not of consequence to C, since they involve constructs that are not available in C.

The nonterminal *type-qualifier* is called *cv-qualifier* in the C++ syntax. It also reduces through *type-specifier*, so the C++ abstract syntax tree is different from C. However, sequences of tokens corresponding to C declarations are accepted by the C++ syntax.

The C++ syntax specifies that *declaration-specifiers* is optional, which means that a semicolon could syntactically be interpreted as an empty declaration (it is always an empty statement in C). Other wording requires that one or the other always be specified. A source file that contains such a construct is not ill-formed and a diagnostic may not be produced by a translator.

Other Languages

Some languages completely separate the syntax of the identifier being declared from its type (requiring the type to appear to the left of the identifier being declared, or on the right). For instance, in the Pascal declaration:

```
1  x : array[1..3] of integer;
2  y : ^ integer;
3  function z() : integer; (* Function types don't follow the pattern. *)
```

the identifiers `x`, `y`, and `z` are separated from their type by a colon.

In a few languages the identifier being declared is also part of a declarator, which may include type information (e.g., an example array declaration in Fortran is `Integer Arr(3)`). Java syntax supports two methods of declaring objects to have an array type.

```
1  int [] a1,
2         a2[];
3  int b1[],    // has the same type as a1
4      b2[][];  // has the same type as a2
```

Ada does not allow object declarations to occur between function definitions. The intent[619] was to avoid the poor readability that occurs when items that are visibly smaller, because they contain few characters (an object declaration) are mixed with items that are visibly larger, because they contain many characters (a function definition). However, this restriction is cumbersome and was removed in Ada 95.

Common Implementations

object specifying address

Some implementations (e.g., most vendors target freestanding environments) support an extension that enables developers to specify the start address to be used for the object or function defined by the declaration. The token `@` is often used.

```
1  int i @ 0x800;
```

`gcc` supports the **`__attribute__`** in declarations. Quite a large number of different attributes are supported (an identifier denoting the attribute appears between a pair of parentheses). They can apply to functions, objects, or types. For instance, `int square (int) __attribute__((const));` specifies an attribute of the function `square`.

Coding Guidelines

The visual layout of declarations can affect the reader effort required to extract information and the likelihood of them making mistakes. Declaration layout has three degrees of freedom:

declarations in which source file 1810

1. The source file selected to contain the declaration. This issue is discussed elsewhere.

2. The order in which different declarations occur within the same file or block (individual declarations can often occur in many different orders with the same effect). Identifiers declared at file scope are often read by people having more diverse information-gathering needs than those declared at block scope (where the use is usually very specific). Also, long sequences of identifier declarations usually only occur, with any frequency, at file scope. The number of declarations a block scope tend to be small. The quantity of file scope declarations and the diverse needs of readers suggests that an investment in organizing these declarations and providing more detailed commenting will produce a worthwhile benefit.

286 identifiers number in block scope

3. The layout of a single declaration and the token sequence used to specify it. (It is often possible to use different token sequences to specify the same declaration.)

The ordering of declarations at file scope

There are a number of patterns, in declaration ordering, commonly seen in existing source code:

- **`#include`** preprocessing directives are invariably placed before most other declarations in a file. This directive occupies a single line and placing all of them first ensures that subsequent declarations will be able to reference the identifiers they declare.
- All declarations of macros, typedefs, objects, and function declarations usually occur before the function definitions. The issue of ordering function definitions is discussed elsewhere.

1821 function definition syntax

- The grouping of declarations of macros, typedefs, objects, and function declarations. This grouping may be by kind of declaration (e.g., all macros, all typedefs, etc.), or it may be by some internal subdomain (e.g., all declarations related to a tree data structure, or the organization of program output, etc.).
- New declarations of a particular kind of identifier (e.g., macro or object) are often added at the end of the list of existing declarations of those kinds of identifiers.

Peoples performance in recalling, recently remembered, words from a list has been found to have a number of characteristics. Studies by Howard and Kahana[597, 598] investigated the probability of a particular word on a list being recalled when subjects were given the name of another word. The results showed (see Figure 1348.1) that the words immediately following the words presented were most likely to be recalled.

When subjects were asked to perform free recall of a list of words they had seen, successive recalled words tended to be related in some way (responses could be given in any word order) rather than being completely unrelated. A measure of pairwise similarity between the words presented was calculated using latent semantic analysis. The results showed that these LSA similarity values were highly predictive of the order in which subjects recalled words.

792 latent semantic analysis

What are the costs and benefits of putting declarations in a particular order? As discussed elsewhere developers tend to read source on an as-needed basis. A developer is unlikely to need to read a declaration unless it declares an identifier that is referenced from other source that is currently being read. Reading an identifier's declaration, once found, may in turn create the need to read other identifier declarations.

770 reading kinds of

To locate an identifier using a text editor, a developer might go to the top of the file and use a search command to find the first occurrence. Within an IDE, it is often possible to click on an identifier to bring up a window containing its declaration. A developer might also perform a quick visual search.

121 IDE

If the information required relates to a single identifier, the cost is the search time for that identifier declaration. The cost of obtaining information on N identifiers can be much greater than N times the search cost of a single identifier declaration. Reading a declaration can be like walking a tree— one declaration leading to another and then back to the original for more information extraction.

Having all related declarations visible on the screen at the same time (perhaps in multiple windows) minimizes the keyboard and mouse activity needed to switch between different declarations.

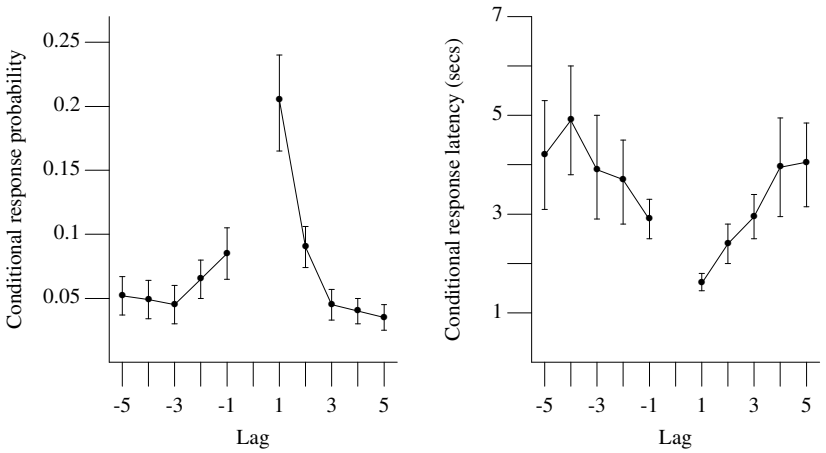

Figure 1348.1: The *lag recency effect*. The plot on the left shows the probability of a subject recalling an item having a given lag, while the plot on the right gives the time interval between recalling an item having a given lag (error bars give 95% confidence interval). If a subject, when asked to remember the list "ABSENCE HOLLOW PUPIL", recalled "HOLLOW" then "PUPIL", the recall of "PUPIL" would have a lag of one ("ABSENCE" followed by "PUPIL" would be a lag of 2). Had the subject recalled "HOLLOW" then "ABSENCE", the recall of "ABSENCE" would be a lag of minus one. Adapted from Howard and Kahana.[598]

How can declarations be ordered to minimize total cost? Answering this question requires usage information. What percentage of searches involve locating a single identifier declaration and what percentage involve reading multiple declarations? To what extent do related declarations require readers to visually skip back and forth between them? Unfortunately, this usage information is not available.

Ordering declarations alphabetically, based on the identifier declared, may improve the performance of some identifier search strategies (e.g., paging up/down until the appropriate sorted identifier is reached). However, such an ordering may be difficult to achieve in practice because of the need to declare an identifier before it is referenced and because of the complications introduced by those declarations that contain more than one identifier (e.g., enumeration types). Also there is nothing to suggest how large improvements in search performance will be, or whether it will give alphabetic ordering the edge over other orderings. Alphabetic ordering of identifier declarations is not discussed further here.

The following discussion assumes that for all ordering of declarations, developer search time is approximately the same. The important factor then becomes the ease with which developers can view multiple, related declarations.

If there is a dependency between two declarations, it is likely that a developer will want to read both of them. Placing dependent declarations sequentially next to each other in the visible source could reduce the need to switch between views of them (using the keyboard or mouse to change display contents). Both declarations being visible on the display at the same time. However, for all but the simplest declarations, placing dependent declarations sequentially next to each other is rarely possible:

- There may be many references to a particular identifier. How should the many declarations making these references be ordered?
- There may be many identifiers referred to in one declaration. For instance, the members of a structure type may have a variety of types. How would such multiple referenced identifiers be ordered?

categorization

Looking at existing source shows that in many cases declarations are grouped by categories (categorization is discussed in the Introduction). The chose of categories, by developers, seems to have been based on a variety of reasons, including:

- All objects declared to have the same type

- All function declarations
- Object declarations holding semantically related information (where it was not considered to worthwhile create a structure type to hold them)
- Objects having static linkage
- all declarations related to some data structure; for instance, types used in the manipulation of tree data structures may include one or more structure types, perhaps a union type, and a variety of enumeration or macro definitions (giving symbolic names to the numeric values used to denote various kinds of tree nodes)
- Grouped in the order in which they were originally written, which is likely to have been influenced by the order (both in time and space, within the file) in which function definitions were written

822 symbolic name

Placing declarations in the same category adjacent to each other is using an ordering relationship. (Alphabetic ordering is another one.) It might be claimed that category ordering is an effective heuristic for minimizing the developer cognitive and motor cost of switching between different views of the source while attempting to comprehend a declaration. However, there is no evidence to support this claim, or indeed any other claims of cost-effective declaration orderings.

Visual layout of adjacent and single declarations

declaration visual layout

It is quite common to see sequences of object declarations where the identifiers being declared are vertically aligned with each other. (A number of rationales can be heard for having such an alignment: ease of readability and "it looks nice" are both frequently given.) This discussion concentrates on the visual issues of adjacent identifier declarations. Vertical alignment creates an edge. When scanning the source, edges are something that readers can use to help control what they look at.

770 Edge detection
770 reading kinds of

The gestalt principle of continuation suggests that aligning identifiers creates an association between them. The principle of similarity (types in one set, objects being declared in the other) does not occur visually, although it may exist as a category in the reader's mind. Do we want to associate identifiers from different declarations with each other? The issue of these associations and reader categories are discussed elsewhere.

770 gestalt principles
770 continuation gestalt principle of
1358 declarator list of

Many declarations declare a single identifier on each source line. Developers often visually search lists of declarations by scanning up or down those declarations. Consequently, when a second identifier is declared on the same line, it is sometimes missed. As the following example shows, the surrounding declarations play an important role in determining how individual identifiers stand out, visually. A reader looking for the identifiers `c` or `total_count` is likely to notice that more than one declaration occurs on the same line. However, a search for `zap` may fail to notice it because of the degree to which its declaration blends in to give the appearance of a single declaration (perhaps `zip_zap`).

```
1  int a, b, c;
2
3  int foo_bar,
4      zip,zap,
5      win_lose;
6
7  int local_val,
8      max_count, total_count,
9      global_val;
10
11 void j(int k, int l);
```

A guideline recommendation based on visual appearance would be difficult to word and very difficult for developers to judge and for tools to enforce. The simple solution is to have a simple rule covering all cases (accepting that in some situations it is redundant).

Cg 1348.1 No more than one *init-declarator* shall occur on each visible source code line.

What about identifiers appearing in other kinds of declarations?

- *Preprocessor syntax* only permits one macro to be defined per line.
- *Function declarations.* The function name usually appears in the same location as it would in an object declaration (having the same type as the function return type). Additional information is provided by the parameter declarations. The parameter information is usually only read after the function name has been located; it is rarely searched for independently of the function name. Given the localized nature of visual searches of parameter information, there is no reason to split these declarations across multiple lines.
- *Function definitions.* The identifiers declared in a function definition's parameter list need to be included in any search of locally defined objects.

enumeration 517
set of named constants

- *Members of enumeration types.* This issue is discussed elsewhere.

struct-declarator 1390.1
one per source line

- *Members of structure and union types.* This issue is discussed elsewhere.

Cg 1348.2

For the purposes of visual layout the parameters in a function definition shall be treated as if they were *init-declarator*s.

type specifier 1378
syntax

The relative ordering of some tokens within a declaration is variable. The syntax does not impose any relative ordering on type specifiers, type qualifiers, or storage-class specifiers. This issue is discussed in elsewhere.

An object having static storage duration in block scope is rare. Whether there is a worthwhile cost/benefit in drawing attention to such a definition is open to debate.

identifier definition close to usage
grouping 1707
spatial location

There are benefits in visually grouping related items near each other. However, since it is often possible to comprehend statements without detailed knowledge of the identifiers they contain, the cost difference of them not being visually close may be small. Given that approximately 70% of block scope declarations (excluding parameters) occur in the outermost block scope (see Figure 408.1) and many function definitions are short enough (see Figure 1707.9) to be completed viewed on a display, the applicable definition may already be easy to locate (many identifiers are not declared within the minimum block scope required by their usage, Figure 190.1).

There is cost associated with declaring identifiers within the minimum required scope, compared to declaring them in the outermost block. When writing the body of a function definition a developer may be unsure of the minimal required scope of some identifiers. Developers might chose to move declarations on an as-needed basis or might choose to move declarations to the appropriate scope once the body is finalized. Whichever choice is made there is a cost that needs to be paid. Also during maintenance the required scope may change. This cost of deducing and maintaining local declarations in a *minimal* scope appears to be greater than the benefits.

Example

```
1  typedef int foo,
2              bar;
3
4  void f(void)
5  {
6  foo(bar);               /* Declare bar as an object.   */
7  extern int foo(void);   /* Declare foo as a  function. */
8  }
```

Table 1348.1: Occurrence of types used in declarations of objects (as a percentage of all types). Adapted from Engblom[389] and this book's benchmark programs.

Type	Embedded	Book's benchmarks
integer	55.97	37.5
float	0.05	1.6
pointer	22.08 (data)/0.23 (code)	48.2
struct/union	9.88	6.1
array	11.80	6.6

Table 1348.2: Occurrence of types used to declare objects in block scope (as a percentage of all such declarations). Based on the translated form of this book's benchmark programs.

Type	%	Type	%
`int`	28.1	`long`	3.0
`struct *`	27.7	`union *`	2.9
other-types	10.8	`unsigned short`	2.3
`unsigned int`	5.5	`unsigned char`	2.0
`struct`	4.9	`char`	1.8
`unsigned long`	4.8	`char []`	1.5
`char *`	3.5	`unsigned char *`	1.3

Table 1348.3: Occurrence of types used to declare objects with internal linkage (as a percentage of all such declarations). Based on the translated form of this book's benchmark programs.

Type	%	Type	%
`int`	20.9	`const char []`	2.4
other-types	14.4	`unsigned int`	1.8
`struct`	13.0	`const struct`	1.8
`struct *`	8.2	`void *()`	1.7
`struct []`	7.4	`const unsigned char []`	1.6
`( const char * const ) []`	4.0	`unsigned int []`	1.4
`unsigned char []`	3.4	`int *()`	1.4
`unsigned short []`	3.3	`( struct * ) []`	1.3
`int []`	2.9	`( char * ) []`	1.3
`char *`	2.8	`unsigned long`	1.2
`char []`	2.7	`const short []`	1.2

Table 1348.4: Occurrence of types used to declare objects with external linkage (as a percentage of all such declarations). Based on the translated form of this book's benchmark programs.

Type	%	Type	%
`int`	22.8	`char *`	3.2
`const char []`	15.4	`union *`	3.0
other-types	10.6	`enum`	2.4

`const struct`	10.2	`char []`	1.4
`struct`	8.2	`unsigned int`	1.2
`void *()`	4.6	`int []`	1.2
`struct []`	4.1		

Constraints

declaration shall declare identifier

A declaration shall declare at least a declarator (other than the parameters of a function or the members of a structure or union), a tag, or the members of an enumeration. 1349

Commentary

It is C's unusual declaration syntax that makes it possible to write a declaration that declares no identifier in the scope of the declaration. A declaration that did not declare a declarator might be regarded as simply redundant. However, such usage is suspicious; it is likely that the developer has made a mistake. This wording requires that a declaration declares an identifier that is visible in the scope of the declaration.

redundant code 190

C90

6.5 *A declaration shall declare at least a declarator, a tag, or the members of an enumeration.*

The response to DR #155 pointed out that the behavior was undefined and that a diagnostic need not be issued for the examples below (which will cause a C99 implementation to issue a diagnostic).

```
1  struct { int mbr; }; /* Diagnostic might not appear in C90. */
2  union { int mbr; };  /* Diagnostic might not appear in C90. */
```

Such a usage is harmless in that it will not have affected the output of a program and can be removed by simple editing.

Other Languages

The declaration syntax of most languages does not support a declaration that does not declare an identifier.

Example

```
1  struct {
2          int m1; /* Constraint violation. */
3         };
4  struct {
5          struct T {int m11;} m1; /* Declares a tag. */
6         };
7
8  typedef enum E { E1 }; /* Pointless use of a typedef. */
9
10 long int; /* No declarator. */
11
12 ; /* Syntactically a statement. */
```

declaration only one if no linkage

If an identifier has no linkage, there shall be no more than one declaration of the identifier (in a declarator or type specifier) with the same scope and in the same name space, except for tags as specified in 6.7.2.3. 1350

Commentary

linkage 421 kinds of

type 1454 contents defined once

Identifiers with no linkage include those having block and function prototype scope, those in the label name space, and typedef names. The special case for tags is needed to handle recursive declarations, which are discussed elsewhere.

C++

C++ one definition rule

This requirement is called the *one definition rule* (3.2) in C++. There is no C++ requirement that a typedef name be unique within a given scope. Indeed 7.1.3p2 gives an explicit example where this is not the case (provided the redefinition refers to the type to which it already refers).

A program, written using only C constructs, could be acceptable to a conforming C++ implementation, but not be acceptable to a C implementation.

```
typedef int I;
typedef int I; // does not change the conformance status of the program
               /* constraint violation */
typedef I I;   // does not change the conformance status of the program
               /* constraint violation */
```

Other Languages

Some languages only allow one declaration of the same identifier in the same scope and name space. Those that require declaration before usage and support recursive data structures or recursive function calls need to provide a *forward* declaration mechanism (Pascal actually uses the keyword **forward**). Use of this mechanism effectively creates two declarations of the same identifier.

1351 All declarations in the same scope that refer to the same object or function shall specify compatible types.

declarations refer to same object
declarations refer to same function

Commentary

Occurrences of multiple declarations specifying incompatible types are probably the result of some developer mistake. Specifying that an implementation choose one of them is unlikely to be of benefit to developers, while generating a diagnostic pointing out the usage enables the developer to correct the mistake.

C++

After all adjustments of types (during which typedefs (7.1.3) are replaced by their definitions), the types specified by all declarations referring to a given object or function shall be identical, except that declarations for an array object can specify array types that differ by the presence or absence of a major array bound (8.3.4). A violation of this rule on type identity does not require a diagnostic.

3.5p10

C++ requires identical types, while C only requires compatible types. A declaration of an object having an enumerated type and another declaration of the same identifier, using the compatible integer type, meets the C requirement but not the C++ one. However, a C++ translator is not required to issue a diagnostic if the declarations are not identical.

```
enum E {E1, E2};

extern enum E glob_E;
extern int glob_E; /* does not change the conformance status of the program */
                   // Undefined behavior, no diagnostic required

extern long glob_c;
extern long double glob_c; /* Constraint violation, issue a diagnostic message */
                           // Not required to       issue a diagnostic message
```

Other Languages

Languages that support some form of duplicate type declarations usually require that the types be the same.

Coding Guidelines

Adhering to the guideline recommendation specifying the placement of declarations of identifiers having file scope in a single file helps ensure this constraint is met.

422.1 identifier declared in one file

Semantics

1352 A declaration specifies the interpretation and attributes of a set of identifiers.

declaration interpretation of identifier

Commentary

value 73

For instance, the type of an object determines how its contents are to be interpreted. Attributes of the declaration of an object might be its storage class, while the textual location of the declaration decides the scope of the identifiers it declares.

Other Languages

Some languages do not require that identifiers appear in a declaration. Their interpretation and attributes are deduced from the context in which they occur and the operations performed on them. In other languages (e.g., Visual Basic, Perl, and Scheme) the type information associated with an object can change depending on the last value assigned to it. Values have type and this type information is assigned to an object, along with the value. Values are said to be tagged with their type. (The Scheme revised report[719] refers to the language as using *latent* types, while other terms include *weakly* or *dynamically* typed.) BCPL requires that identifiers be declared, but deduces their type from the usage.

Common Implementations

Extensions to C declarations often include creating additional specifiers that can appear in a declaration. For instance, the keywords **`near`**/**`far`**/**`huge`** used to specify how a pointer is to be interpreted.

Coding Guidelines

naming conventions 792

The issue of encoding information on some of these attributes is discussed elsewhere.

Judging whether an identifier is used in ways that involve different sets of semantic associations is something that is not yet possible, in general, using an automated tool.

object role

Some coding guideline documents recommend that instances of particular objects, within a program, only be used for a single purpose. For instance, as a loop counter, or to hold the running total of some quantity. Using the same object for both purposes, assuming the two uses do not overlap in the source code, may reduce the total amount of storage used but experience shows that it generally increases the effort needed to comprehend the code and the likelihood of faults being introduced.[1352.1]

boolean role 476
bit-set role 945

The *purpose* of an object is rather difficult to pin down. However, the way in which an object is used (its *role* in the source) often follows a pattern that can be categorized. The role categories discussed in other coding guideline subsections are based on the kinds of values an object might have (e.g., boolean and bit-set roles) and the operators that might be applied to them. Sajaniemi[1191] proposed a role classification scheme based on an analysis of a higher level of abstraction of how objects are used in the code. For instance:

- *constant*: an object whose value does not change after initialization,
- *stepper*: an object that iterates through a series of values that do not depend of the values of other nonconstant variables,
- *follower*: an object that iterates through a series of values that depended on the value of a stepper variable,
- *most-recent holder*: an object holding the latest value encountered during the processing of a sequence of values,
- *most-wanted holder*: an object holding the best value encountered during the processing of a sequence of values,
- *gatherer*: an object whose value represents the accumulated affect (e.g., the sum) of individual values encountered during the processing of a sequence of values,
- *one-way flag*: an object whose value is changed once, while processing some sequence of values,
- *temporary*: an object holding a value over a short sequence of code,

[1352.1] Programs written in dialects of Basic that limit the number of objects that can be used (e.g., using single letters of the alphabet to denote identifiers limits the number of objects to 26) are often forced to use the same object for different purposes in different parts of the source (e.g., using it as a loop counter, then to hold the result of some calculation, then as a flag, and so on).

- *other*: all other objects.

In other, more strongly typed, languages role information is sometimes encoded as part of the type. For instance, two different integer types representing apples and oranges might be defined, with the intent that any attempt to add an object having type apple to an object having type orange will cause a diagnostic to be issued.

Is there a worthwhile benefit in limiting every object to having a single role? Experience suggests that most objects are used in a way that involves a single role (at least in programs written by non-novice developers). The storage cost associated with defining additional objects is rarely a significant consideration (although there are application domains where this cost can be very significant; and some translators attempt to minimize the storage used by a program).

1354 storage layout

Experience shows that using the same object is more than one role increases the effort needed to comprehend the code and the likelihood of faults being introduced (e.g., developers be aware of and remember the disjoint regions of source code over which an object has a particular role). The concept of an objects role is relatively new and is not specified in these coding guidelines in sufficient detail to be automatically enforced. However, this is an issue that can be covered during code review.

Rev 1352.1

If an object has one of the roles defined by these coding guidelines it shall always be used in a way that is consistent with that role.

1353 A *definition* of an identifier is a declaration for that identifier that:

definition identifier

Commentary

This defines the term *definition*. It excludes some kinds of identifiers (labels and tags), which can be declared, and macros, which are said to be *defined* but are discussed in a separate subclause. It is common developer usage to refer to a declaration of an identifier as a label or tag— as its definition. The standard also defines the terms *external definition* (which is a definition) and *tentative definition* (which eventually might cause a definition to be created). Limits on the number of definitions of an identifier are specified elsewhere.

405 label declared implicitly
1463 tag declare
1931 macro object-like
1933 macro function-like
1848 object external definition
1817 external definition
1849 tentative definition
1812 definition one external
1813 internal linkage exactly one external definition

C++

The C++ wording is phrased the opposite way around to that for C:

> *A declaration is a definition unless . . .*

The C++ Standard does not define the concept of tentative definition, which means that what are duplicate tentative definitions in C (a permitted usage) are duplicate definitions in C++ (an ill-formed usage).

3.1p2 1849 tentative definition

```
1  int glob;     /* a tentative definition */
2                // the definition
3
4  int glob = 5; /* the definition */
5                // duplicate definition
```

Other Languages

Only languages that support separate translation of source files, or some form of forward declarations, need to make a distinction between declarations and definitions.

Coding Guidelines

Many developers do not distinguish between the use of the terms *declaration* and *definition* when discussing C language. While this might be technically incorrect, in the common cases the distinction is not important. The benefit of educating developers to use correct terminology is probably not worth the cost.

object reserve storage — for an object, causes storage to be reserved for that object; 1354

Commentary

declaration 1348 syntax lifetime 451 of object

The Declarations clause of the C Standard does not specify what causes storage to be reserved for an object. This information has to be deduced from the definition of an object's lifetime.

C++

The C++ Standard does not specify what declarations are definitions, but rather what declarations are not definitions:

3.1p2 *. . . , it contains the* **`extern`** *specifier (7.1.1) or a linkage-specification*[24] *(7.5) and neither an* `initializer` *nor a* `function-body`*, . . .*

7p6 *An object declaration, however, is also a definition unless it contains the* **`extern`** *specifier and has no initializer (3.1).*

Common Implementations

storage layout byte 54 address unique unary & 1090 operator register 1369 storage-class program 141 image operator 1000 () identifiers 286 number in block scope

Where is storage reserved for the object? The individual bytes of an object have a unique address, but unless its address is taken, storage need not be allocated for it. The issue of maintaining objects in registers only is discussed elsewhere.

In the majority of implementations storage for static duration objects is allocated in a fixed area of storage during program startup and that for automatic duration objects on a stack. Many translators assign storage to objects in the order in which they encounter their declarations during translation.

Most function definitions do not contain very many object definitions and the combined storage requirements of these definitions is not usually very large (see Figure 294.1). Many processors (including RISC) contain a form of addressing designed for efficient access to local storage locations allocated for the current function invocation— *register* + *offset* addressing mode. The processor designers choosing the maximum possible value of *offset* to be large enough to support commonly occurring amounts of locally allocated storage. In those cases where the offset of a storage location is outside of the range supported by a single instruction, multiple instructions need to be generated. The following are two opportunities for optimizing the allocation of locally defined objects to storage locations:

register 1000 + offset

1. When the quantity of local storage required by a function definition is larger than the maximum *offset* implicitly supported by the processor. Many processors designed for embedded systems applications support relatively small *offset*s. Accesses to objects with greater offsets require the use of multiple instructions, making them more costly in time and code size. Burlin[184] uses a greedy algorithm to assign storage locations to objects, based on their access costs and the amount of storage they required.

cache 0

2. On processors that contain a cache, reading a value from a storage location will also cause values from adjacent storage locations to be read (the number of storage locations read will depend on the size of a processor's cache line). Ordering objects in storage so that successive accesses to different storage locations, during program execution, are on the same cache line results in several savings.[1050] The access time to other storage locations on the same cache line is reduced and the turnover of cache lines (filling a new cache line requires the contents of an existing line to be overwritten) is reduced. The relative order of objects on a cache line may also need to be considered. On most processors the contents of a cache line are filled, from storage, in a particular order. In most cases the first location loaded is the one that caused the cache miss, followed by the next highest storage location, and so on (wrapping around to any lower addresses). For instance, assuming a 32-byte cache line filled 4 bytes at a time, a read from address xx04 that causes a cache miss, will result in storage locations xx00 through

xx1f being loaded in the order xx04, xx05, . . . , xx1f, xx00, xx01, xx02, xx03. Some processors fill the cache line completely before its contents become available, while others (e.g., IBM PowerPC) forward bytes as soon as they become available. Four successive bytes will become available on each of eight successive clock cycles. (There will be some storage latency before the first four bytes arrive.) Matching the order of objects in the cache line to the order in which they are most frequently accessed at execution-time minimizes latency. Knowing which objects are frequently accessed requires information on the execution time behavior of a program.[1186]

The assignment of objects, with static storage duration, to storage locations is usually performed by the linker. The relative ordering is often the same as the order in which the linker encounters object definitions within object files, which may or may not be the order in which the translator encounters them in the source file. The following are three main opportunities for optimizing the allocation of objects with static storage duration.

1. Some implementations use *absolute* addressing to access objects and others use *register+offset* (where the register holds the base address of storage allocated to global data). In both cases there will be a limit on the maximum offset that can be accessed using a single instruction— a larger offset requires more instructions.

   1000 register + offset

2. The cache issues are the same as for local objects.

3. Some processors (usually those targeted at embedded systems[612]) include a small amount of on-chip storage. Also some processors support pointers of different sizes (i.e., 8-bit and 16-bit representations), with the smaller size executing more quickly but only being able to access a relatively small area of storage. Deciding what objects to allocate to those storage locations that can be accessed the quickest requires whole program analysis. Sjôdin and von Platen[1250] mapped this optimal storage-allocation problem to an integer linear-programming problem and were able to achieve up to 8% reduction in execution time and 10% reduction in machine code size. Avissar, Barua, and Stewart[66] also used linear programming to obtain an 11.8% reduction in execution time, but by distributing the stack over different storage areas obtained a 44.2% reduction in execution time.

Optimizing storage layout for embedded applications can involve trading off execution time performance, amount of storage required, and power consumption.[1049] Some processors use banked storage, which can offer a potential solution to the problem of the growing difference in performance between the time taken to execute an instruction and the time taken to access a storage location. Optimizing the allocation of objects across banked storage is an active research area.[96]

559 banked storage

The total amount of physical storage available to a program never seems to be enough for some applications. In most cases developers rely on a host's support for virtual memory management. Alternative solutions are for the program to explicitly manage its own large storage requirements, or for the translator to provide a mechanism that allows developers to specify what objects should be swapped to disk and when (this usually involves the use of extensions[262]).

Many storage allocation algorithms,[1471] for allocated storage duration, are based on measurements of programs that have relatively short running times. Programs with long running times (e.g., server applications,[1138] and multithreaded applications[845]) are less well represented.

A storage allocation policy based on *best fit* (i.e., using the smallest available free storage large enough to satisfy the request) has been found to give good results in practice.[679] The `CustoMalloc`[526] tool uses dynamic profile information, on the size of the object requests made, to build a custom storage allocator tuned to a given program (or at least the profiling data). Execution time profiling of references to objects with allocated storage duration can also be used to improve a program's performance by segregating objects with similar behaviors (leading to improved reference locality).[1211]

Various other storage layout issues are discussed in other C sentences.

0 cache
39 alignment
530 structure type
sequentially allocated objects
994 array

Coding Guidelines

For a variety of reasons some developers take advantage of the relative addresses of storage allocated to objects. There is no guarantee where block scope objects will be allocated storage relative to each other, and the relative addresses of objects having static storage duration is even more unpredictable. There is a simpler method of outlawing such usage than enumerating all cases where a program could depend on the layout of block scope storage. The following guideline renders any such dependence useless.

Cg 1354.1 Arbitrarily reordering the object declarations in the same scope shall not result in a change of program output.

Dev 1354.1 When an object declaration contains a dependency on another object declared in the same scope the arbitrary reordering may be restricted to those orderings that do not result in a constraint violation.

Example

```
1  #include <string.h>
2
3  extern int e_g_1;  extern int e_g_2;
4  static int s_g_1;  static int s_g_2;
5
6  void f(void)
7  {
8         int loc_1;         int loc_2;
9
10 if ((&e_g_1 + 1) == &e_g_2)
11    {
12    memset(&e_g_1, sizeof(e_g_1) * 2, 0xff);
13    /*
14     * No requirement that (&s_g_1 + 1) == &s_g_2) be true.
15     */
16    memset(&s_g_1, sizeof(e_g_1) * 2, 0xff);
17    /*
18     * No requirement that (&loc_1 + 1) == &loc_2) be true.
19     */
20    memset(&loc_1, sizeof(e_g_1) * 2, 0xff);
21    }
22 }
```

— for a function, includes the function body;[99)] 1355

Commentary

function definition 1821 syntax

A function definition is intended to contain executable statements (that may perform some action) which occupy storage space.

C++

The C++ Standard does not specify what declarations are definitions, but rather what declarations are not definitions:

3.1p2 *A declaration is a definition unless it declares a function without specifying the function's body (8.4), . . .*

Other Languages

Languages that have a mechanism to support the building of programs from separately translated source files usually refer to the function declaration that contains its body as its definition.

1356 — for an enumeration constant or typedef name, is the (only) declaration of the identifier.

Commentary

Since only one declaration is allowed in the same scope for these kinds of identifiers it might be more accurate to always call it a definition. However, using this convention would create more wording in the standard than it saves (because some of the wording that applies to declarations would then need to be extended to include definitions; specifying these identifiers to be both declarations and definitions removes the need for this additional wording).

C90

The C90 Standard did not specify that the declaration of these kinds of identifiers was also a definition, although wording in other parts of the document treated them as such. The C99 document corrected this defect (no formal DR exists). All existing C90 implementations known to your author treat these identifiers as definitions; consequently, no difference is specified here.

C++

A declaration is a definition unless . . . , or it is a **`typedef`** *declaration (7.1.3), . . .* 3.1p2

A typedef name is not considered to be a definition in C++. However, this difference does not cause any C compatibility consequences. Enumerations constants are not explicitly excluded in the *unless* list. They are thus definitions.

Other Languages

Languages that contain these constructs usually refer to their declarations as definitions of those identifiers.

1357 The declaration specifiers consist of a sequence of specifiers that indicate the linkage, storage duration, and part of the type of the entities that the declarators denote.

declaration specifiers

Commentary

This says in words what the syntax specifies. Like the syntax there are no restrictions placed on the ordering of specifiers.

C++

The C++ Standard does not make this observation.

Common Implementations

Some implementations contain extensions that add to the list of attributes that can be specified by sequences of specifiers. These are dealt with in their respective sentences.

Coding Guidelines

Are there any advantages to imposing some kind of ordering on declaration specifiers? There would be if all developers used the same ordering (on the basis that source code readers would not have to scan a complete declaration looking for the information they wanted; like looking a word up in a dictionary, it would be in an easy-to-deduce position). Analysis of existing source (see Table 1364.1, Table 1378.1, and Table 1476.1) shows that the most commonly seen ordering is *`storage-class-specifier type-qualifier type-specifier`*. Given developers' existing experience with this ordering, the likelihood that it will be the ordering they are most likely to encounter in the future, and the lack of any obvious benefit to using another ordering, the recommendation is to continue using this ordering.

Cg 1357.1 Within a declaration the declaration specifiers shall occur in the order *`storage-class-specifier type-qualifier type-specifier`*.

storage-class specifiers 2039
future language directions
type specifiers 1381
ordering

Placing a storage-class specifier other than at the beginning of the declaration specifiers in a declaration is specified as being obsolescent (the same specification also appeared in C90). The relative ordering of *type-specifier* is discussed elsewhere.

Example

```
int const typedef I;
double const long static J;
int volatile long extern long const unsigned K;
```

---

declarator list of

The init-declarator-list is a comma-separated sequence of declarators, each of which may have additional type information, or an initializer, or both. 1358

Commentary

This says in words what is specified in the syntax.

C++

The C++ Standard does not make this observation.

Coding Guidelines

The C declaration syntax allows type information to be specified in the *declarator*. It is possible for different *init-declarator*'s, each declaring a different identifier, in an *init-declarator-list* to declare identifiers having different types.

```
int i_1,
    *p_1,        /* *p_1 is the declarator, a pointer to ... */
    **p_2,       /* **p_2 is the declarator, a pointer to pointer to ... */
    * const p_3, /* * const p_3 is the declarator, a const pointer to ... */
    a_1[10],     /* a_1[10] is the declarator, an array of ... */
    *(a_p_1[4]); /* *(a_p_1[4]) is the declarator, an array of pointer to ... */

char *pc_1,
      pc_2;
```

A mistake commonly made by inexperienced developers is to assume that pc_2, in the above example, has type pointer to **char**. A similar mistake does not seem to occur very often for array types. This may be due to the significantly smaller number of array declarations, compared to pointer declarations, in C or because the additional tokens are not visually contiguous with the declaration specifiers but to the right of the identifier being declared.

Cg 1358.1

A *declarator* specifying a pointer type shall not occur in the same *init-declarator-list* as *declarator*s not specifying a pointer type or specifying a different pointer type.

Objects that are used to store the same set of values are usually declared to have the same type. A change to the set of values that needs to be represented usually requires changing the declarations of all the associated objects. The following are a number of techniques that can be used to declare more than one object:

- Multiple *declaration*s each of whose *init-declarator-list* contains a single *init-declarator*.

```
int i;
int j;
int k;
```

Some coding guideline documents recommend this technique. The rationale is that it reduces the likelihood of cut-and-paste editor operation mistakes, or modifications to the *declaration-specifiers* having unexpected results. (Because a single object is declared, it is not possible to affect the declaration of another object.) The disadvantage of this approach is that, if it is necessary to change the *declaration-specifiers* associated with a set of object declarations, each *declaration* has to be modified (it is possible this change will not be applied to some of them).

- A single *declaration* whose *init-declarator-list* contains more than one *init-declarator*.

```
1  int i,
2      j,
3      k;
```

The advantages and disadvantages of this technique are those of the above, reversed. Experienced developers will be familiar with cut-and-paste mistakes when modifying this kind of declaration. The extent to which either form of declaration forms a stronger visual association, or reduces the effort needed to read the identifier list, is not known.

- Multiple *declaration*s using a typedef name.

```
1  typedef int francs; /* French francs */
2
3  francs i;
4  francs j;
5  francs k;
```

This approach appears to solve the *declaration-specifiers* modification disadvantages associated with the first technique and yet has its advantages, but only because it associates a unique name, `francs`, with the type that is common to the three declared objects.

822 symbolic name

- Some combination of the above.

Without any experimental evidence, or record of faults introduced, it is not possible to verify any claims about either of the first two techniques being more or less prone to the creation of faults.

Some coding guideline documents recommend that *type-specifier*s other than *typedef-name* only appear in the definition of a typedef name. Such a guideline recommendation is easily followed without addressing the underlying issues. For instance, in the `francs` example above, using a typedef name of `INT` does not solve any of the problems. Because the name `INT` is not specific to the information represented in `i`, `j`, and `k` only. Such a typedef name is also likely to be used to declare objects that do not hold values denoting French francs. This issue is discussed in more detail elsewhere.

1629 typedef name syntax

1359 99) Function definitions have a different syntax, described in 6.9.1.

footnote 99

Commentary

During syntactic analysis of a sequence of tokens, the first difference between a function declaration and a function definition occurs when either a **;** or **{** token is encountered (which in the case of **;** is the last token of a function declaration).

1821 function definition syntax

Other Languages

In most languages the syntax for function definitions is usually very different from object definitions. The evolving designs of object-oriented languages is starting to blur the distinction.

1360 The declarators contain the identifiers (if any) being declared.

Commentary

A declarator always declares at least one identifier. However, a declaration need not include a declarator, although it must declare some identifier. An abstract declarator need not declare any identifiers.

1349 declaration shall declare identifier
1624 abstract declarator syntax

object type complete by end

If an identifier for an object is declared with no linkage, the type for the object shall be complete by the end of its declarator, or by the end of its init-declarator if it has an initializer; 1361

Commentary

incomplete types 475
footnote 109 1465

The rationale behind the support of incomplete types does not apply to objects having no linkage. Objects with other kinds of linkage may be declared to have an incomplete type. An initializer can only complete an incomplete array type in this context. Requirements on the completion of types of objects having external and internal linkage are discussed elsewhere.

object type for internal linkage 1851

C++

3.1p6 *A program is ill-formed if the definition of any object gives the object an incomplete type (3.9).*

The C++ wording covers all of the cases covered by the C specification above.

A violation of this requirement must be diagnosed by a conforming C++ translator. There is no such requirement on a C translator. However, it is very unlikely that a C implementation will not issue a diagnostic in this case (perhaps because of some extension being available).

Other Languages

Those languages supporting declarations that need storage allocation decisions to be made at translation time (in nearly all cases this applies to locally declared objects) have similar requirements.

Common Implementations

Although not required to do so, all known implementations issue a diagnostic if this requirement is not met.

Coding Guidelines

array of unknown size initialized 1683

The issues associated with using the number of initializers to specify the number of elements in an array type are the same for declarations having any linkage, and are discussed elsewhere.

---

in the case of function ~~arguments~~ parameters (including in prototypes), it is the adjusted type (see 6.7.5.3) that is required to be complete. 1362

Commentary

array converted to pointer 729

parameter adjustment in definition 1595

Any adjusted parameter type (the case applies to function parameters, not arguments; this is a typo in the standard) will have converted incomplete array types into pointers to their element types (there are no incomplete, or complete, function types and their adjusted type is not relevant here). No other kind of incomplete types can be completed by such adjustments. The constraint in clause 6.7.5.3 applies to function definitions.

The wording was changed by the response to DR #295.

C90

This wording was added to the C99 Standard to clarify possible ambiguities in the order in which requirements, in the standard, were performed on parameters that were part of a function declaration; for instance, `int f(int a[]);`.

C++

The nearest the C++ Standard comes to specifying such a rule is:

5.2.2p4 *When a function is called, the parameters that have object type shall have completely-defined object type. [Note: this still allows a parameter to be a pointer or reference to an incomplete class type. However, it prevents a passed-by-value parameter to have an incomplete class type.]*

Other Languages

Most other languages do not treat the type of function arguments any different from other object types.

Example

```
1  extern int f_1(int p_1[]);
2  extern int f_2(int p_1[4]);     /* Number of elements is not considered. */
3
4  extern int f_3(struct foo p_1); /* foo cannot be completed. */
```

1363 **Forward references:** declarators (6.7.5), enumeration specifiers (6.7.2.2), initialization (6.7.8).

6.7.1 Storage-class specifiers

1364

storage-class specifier syntax

storage-class-specifier:
typedef
extern
static
auto
register

Commentary

The character sequence *regist* is not generated by the algorithms commonly used by speakers of English for abbreviating *register*.

792 abbreviating identifier

C++

The C++ Standard classifies **typedef** (7.1p1) as a *decl-specifier*, not a *storage-class-specifier* (which also includes **mutable**, a C++ specific keyword).

Other Languages

Languages often use the keyword **type** to denote that a type is being declared, although a few languages (e.g., Algol 68 and CHILL) use **mode**, or some variation of that word. Java is unusual, in a modern language, in not providing a mechanism for defining a name to have a primitive (scalar in C terminology) type or array type.

Some languages also use the keyword **extern**. Fortran uses the keyword **extern** to declare a parameter as denoting a callable function (it does not have function types as such).

Some languages (e.g., CHILL) provide a mechanism for specifying which registers are to be used to hold objects (CHILL limits this to the arguments and return value of functions). The keyword **register** is unique to C (and C++).

Pascal requires that the keyword **forward** on procedure and function declarations that are defined later in the same source file.

Coding Guidelines

The standard only uses the keyword **auto** in a few places (outside of comments in examples). However, the phrase *automatic storage duration* occurs much more often. An occurrence of the keyword **auto** in the visible source provide little additional information to a reader. A declaration's lexical position with respect to being inside/outside of a function definition, or the presence of other storage-class specifiers provides all the information required by a reader. As the Usage figures show (see Table 1364.1) existing practice is not to use this keyword. A guideline recommending against its use would be redundant.

Constraints

At most, one storage-class specifier may be given in the declaration specifiers in a declaration.[100)] 1365

Commentary

storage 448
duration
object
linkage 420

The storage-class specifier can be used in a declaration to specify two attributes: the storage duration, and linkage. There is only one context where the appearance of a storage-class specifier in a declaration can affect the storage duration of the object being declared. An object declared in block scope has automatic storage duration unless either of the keywords **extern** or **static** appear in its declaration. In which case it has static storage duration. The presence of the storage-class specifiers **typedef**, **extern**, and **static** may cause the default linkage given to an identifier, because of where it is declared in the source, to be changed.

C++

While the C++ Standard (7.1.1p1) contains the same requirement, it does not include **typedef** in the list of *storage-class-specifiers*. There is no wording in the C++ limiting the number of instances of the **typedef** *decl-specifier* in a declaration.

Source developed using a C++ translator may contain more than one occurrence of the **typedef** *decl-specifier* in a declaration.

Other Languages

In many languages the location of an objects declaration in the source code is used to specify its storage class. Like C, some languages provide keywords that enable the default storage class to be overridden, e.g., Fortran **common**.

Coding Guidelines

Should a storage-class specifier ever appear in a declaration? The only two that are ever necessary are **typedef** and **static** (to change default behavior; **extern** in block scope is not necessary because the declaration can be moved to file scope). All other uses are related to coding guidelines issues. The use of **extern** is covered by the guideline recommendation dealing with a single point of declaration.

422.1 identifier declared in one file

The storage duration and linkage issues associated with the storage-class specifier **static** are discussed elsewhere. The efficiency issues associated with the storage-class specifier **register** are discussed elsewhere.

425 static internal linkage
455 static storage duration
1369 register storage-class

Semantics

1366 The **typedef** specifier is called a "storage-class specifier" for syntactic convenience only;

Commentary

The keyword **typedef** is not really a storage class as such. However, the syntax for typedef name declarations is the same as that for object and function declarations. The committee considered it a worthwhile simplification to treat **typedef** as a storage class.

C++

It is called a *decl-specifier* in the C++ Standard (7.1p1).

Other Languages

In other languages the keyword used to define a new type is rarely placed in the same syntactic category as the storage-class specifiers.

1367 it is discussed in 6.7.7.

1368 The meanings of the various linkages and storage durations were discussed in 6.2.2 and 6.2.4.

1369 A declaration of an identifier for an object with storage-class specifier **register** suggests that access to the object be as fast as possible.

register storage-class

Commentary

It is the developer who is making the *suggest*ion to the translator (sometimes the term *hint*) is used). The original intent of this storage-class specifier was to reduce the amount of work a translator vendor needed to do when implementing a translators machine code generator (which also contributed to keeping the overall complexity of a C translator down). This suggestion is often interpreted by developers to mean that translators will attempt to keep the values of objects declared using it in registers. Had C been designed in the 1990s the keyword chosen might have been **cache**.

0 cache

The standard does not permit declarations at file scope to include the storage-class specifier **register**.

1811 external declaration not auto/register

C++

> *A* ***register*** *specifier has the same semantics as an* ***auto*** *specifier together with a hint to the implementation that the object so declared will be heavily used.* 7.1.1p3

Translator implementors are likely to assume that the reason a developer provides this hint is that they are expecting the translator to make use of it to improve the performance of the generated machine code. The

C++ hint does not specify implementation details. The differing interpretations given, by the two standards, for hints provides to translators is not likely to be significant. The majority of modern translators ignore the hint and do what they think is best.

Other Languages

While it might be possible to make use of particular techniques (e.g., defining the most frequently accessed objects first) to improve the quality of machine code generated by translators of any language, the specification of a language's semantics rarely includes such hint mechanisms.

Common Implementations

Processors rarely perform operations directly on values held in storage, they move them to temporary working locations first. In nearly all cases these temporary working locations are a small set of storage areas, known as *registers*, in the processor itself. Some processors have an architecture that is stack-based[762] rather than register-based and the Bell Labs C Machine[363] was a stack-based processor specifically designed to execute C. However, experience with the two architectural choices has shown that the register-based approach yields better overall performance and the majority of modern processes use it. Stack-based processors are not as common as they once were, although new ones are still occasionally built.

expression 940 processor evaluation

What is a register? The documentation for the Ubicom IP2022[1384] says it has 255 registers. However, the transistors used to represent the values of these registers (at least in the current implementation) are in the same area of the chip as the rest of storage. In fact these *registers* occupy the lower portion of the processors address space. They are accessed using a direct addressing mode (the same could be said about registers in other processors, except that rarely share an address with the rest of storage).

Customer demand for higher-performance (in the generated machine code) and competition between translator vendors means that vendors desire to minimize the cost of producing a code generator no longer includes not implementing a sophisticated register allocator.

Using the storage-class specifier **`register`** to help improve the performance of the generated machine code can be a difficult process that sometimes has the reverse affect (programs that execute more slowly). Translator implementors are aware that developers expect objects declared using **`register`** to have their values kept in registers when possible. Some implementors have decided to attempt to meet this expectation, for the duration of the objects lifetime. The result can be a decrease in performance, because a register is used to hold a particular objects value during a sequence of statements where it would have been better for that register to be holding a different objects value. Other translator implementors believe that the known register allocation algorithms produce better results and ignore any developer provided hints.

The values of objects are not the only things that may be worth trying to keep in registers. If a sequence of code performs the same operation on two operands, whose values have not changed between the two occurrences (a common subexpression), keeping the result in a register and reusing it may be more efficient than performing the operation again. Use of the **`register`** storage-class specifier can have an indirect benefit. An optimizer does not need flow analysis to deduce that the object is not aliased; it is not permitted to as the operand of the address-of operator.

common 1712 subexpression

unary & 1088 operand constraints

register optimizing allocation

A number of algorithms have been proposed for allocating values to registers (it is known that optimal register allocation is NP-hard[408]). An equivalence between this problem and the pure mathematics problem of graph coloring has been shown to exist.[159] So called *register coloring* algorithms have proved to be very popular for one class of processors (those having many registers that are treated orthogonally) and a variety of different variations on this approach have been used. When the time taken to translate code is important (e.g., just in time compilation) *linear scan* register allocation[1099] is much faster than register coloring and has been found to result in code that executes only 12% slower than an aggressive register allocator.

expression 940 optimal evaluation

It has proved difficult to find general algorithms for register allocation on processors having few registers, or where there are restrictions on the operations that can be performed using some registers. In many cases the allocation algorithms are hand tailored for each processor. Mapping the problem to one in integer linear programming has produced worthwhile results for processors having few registers, such as the Intel Pentium.[51]

array element held in register

Register allocation algorithms generally only consider trying to maintain objects having a scalar type in registers. A study by Li, Gu, and Lee[854] evaluated the benefits of doing the same for array elements, known as *scalar replacement* (see Chapter 8 of Allen[17]). They used trace driven simulations of a variety of Fortran benchmark programs to obtain idealised (tracing the actual data references) measurements to obtain the best results that could be achieved, if an optimizer optimally assigned objects to registers. The results showed that having between 48 and 96 registers available, for holding scalar and array element values, had the most impact (savings were even possible with 32 available registers). On five C based multimedia kernels an implementation of scalar replacement by So and Hall[1262] reduced memory accessed by 58% to 90% and saw speedups of between 2.34 and 7.31.

A number of studies have investigated the affects of increasing or decreasing the number of registers available to a translator on the performance of the generated machine code. Having sufficient registers to be able to keep all object values in one of them may be the ideal. In practice optimizers are limited by the analysis they perform on the source. For instance, if it is not possible to deduce whether a particular object is referenced via a pointer, an optimizer has to play safe and access the value from storage. Performance improvements have been found to more or less peak at 17 registers using lcc,[112] later analysis using more sophisticated optimizations (including inlining and allocating globals to registers) found that effective use could be made of 64 registers.[1110]

Many early processors tended to have few registers because of hardware complexity and cost considerations. The relative importance of these considerations has decreased over time and having 32 registers is a common theme among modern processors. However, in practice once function calling conventions are taken into account and various registers reserved (for a variety of reasons, for instance holding the stack pointer) there are rarely more than 16, out of 32, truly temporary registers available to a translator.

485 ABI
1811 external declaration not auto/register

Some implementations support the use of the **`register`** storage-class specifier on declarations at file scope. Such declarations are usually specifications of which register should be dedicated to holding a particular object.[55, 623]

Franklin and Sohi[442] measured register usage while programs from the SPEC89 benchmark executed on a MIPS R2000 (see Table 1369.1).

Table 1369.1: Degree of use of floating-point and integer register instances (a particular value loaded into a register). Values denote the percentage of register instances with a particular degree of use (listed across the top), for the program listed on the left. For instance, 15.51% of the integer values loaded into a register, in `gcc`, are used twice. Left half of table refers to floating-point register instances, right half of table to integer register instances. Zero uses of a value loaded into a register occur in situations such as an argument passed to a function that is never accessed. Adapted from Franklin and Sohi.[442]

Usage	0	1	2	3	≥4	Average	0	1	2	3	≥4	Average

1370 The extent to which such suggestions are effective is implementation-defined.[101)]

register extent effective

Commentary

All translators need to have a register allocation algorithm to be able to generate executable machine code. The extent to which the **`register`** storage-class specifier affects the behavior of this algorithm needs to be documented. A translator's documented behavior is unlikely to be sufficient to enable a developer to predict

which values will be held in which processor register. The possible permutations are rarely sufficiently small that the behavior is easily enumerated.

C++

The C++ Standard gives no status to a translator's implementation of this hint (suggestion). A C++ translator is not required to document its handling of the **register** storage-class specifier and often a developer is no less wiser than if it is documented.

Coding Guidelines

Those coding guideline documents that base their recommendations on the list given in annex I are likely to recommend against the use of the **register** storage-class specifier. The only externally visible affect of using the **register** storage-class specifier is a possible change in execution time performance or size of program image. In both cases the changes are unlikely to be worth a guideline.

program image 141

Example

Macros provide a flexible method of controlling the definitions that contain the **register** storage-class specifier.

```
#if EIGHT_BIT_CPU != 0
#define REG1 register
#define REG2
#define REG3
#define REG4
#endif

#if MODERN_DSP != 0
#define REG1 register
#define REG2 register
#define REG3
#define REG4
#endif

#if RISC_CHIP != 0
#define REG1 register
#define REG2 register
#define REG3 register
#define REG4 register
#endif

void f(void)
{
REG1 int total_valu;
REG2 short intermediate_valu;
REG3 int the_valu;
REG4 long less_often_used_value;

/* ... */
}
```

---

block scope storage-class use

The declaration of an identifier for a function that has block scope shall have no explicit storage-class specifier other than **extern**. 1371

Commentary

There is a lot of existing source containing function declarations at block scope using the **extern** storage-class specifier. The Committee did not want to render such usage as undefined behavior and decided to permit it.

Other Languages

Most languages do not support the declarations of identifiers for functions in block scope. Although some languages do support nested function definitions.

Common Implementations

Translators usually flag an occurrence of this undefined behavior.

Coding Guidelines

If the guideline recommendation dealing with function declarations at file scope is followed this requirement is not an issue.

422.1 identifier declared in one file

1372 100) See “future language directions” (6.11.5).

footnote 100

1373 101) The implementation may treat any **register** declaration simply as an **auto** declaration.

footnote 101

Commentary

That is to say, an implementation may treat such a declaration as an **auto** declaration for the purposes of storage allocation. However, the various constraints and other kinds of behavior associated with an object declared using the **register** storage class still apply.

1088 unary & operand constraints

1374 However, whether or not addressable storage is actually used, the address of any part of an object declared with storage-class specifier **register** cannot be computed, either explicitly (by use of the unary **&** operator as discussed in 6.5.3.2) or implicitly (by converting an array name to a pointer as discussed in 6.3.2.1).

Commentary

A constraint violation occurs if the operand of the address-of operator has been declared using storage-class specifier **register**.

1088 unary & operand constraints

This observation applies when the type category is an array type. But, it does not apply to the case where a member of a structure or union type has an array type. For instance:

553 type category

```
1  struct {
2          register int mem[100];
3          } x;
4  &x.mem;     /* &     applied to an array type. */
5  &x;         /* & not applied to an array type. */
```

C++

This requirement does not apply in C++.

1088 unary & operand constraints

1375 Thus, the only operator that can be applied to an array declared with storage-class specifier **register** is **sizeof**.

Commentary

An operand having an array type is not converted to pointer type when it is operated on by the address-of or **sizeof** operator. The former would be a constraint violation, leaving the latter.

729 array converted to pointer
1088 unary & operand constraints

C++

This observation is not true in C++.

1088 unary & operand constraints

1376 If an aggregate or union object is declared with a storage-class specifier other than **typedef**, the properties resulting from the storage-class specifier, except with respect to linkage, also apply to the members of the object, and so on recursively for any aggregate or union member objects.

Commentary

member 433
no linkage
storage 448
duration
object

Members of a structure or union type always have no linkage.

Another property resulting from the presence of a storage-class specifier is the storage duration of an object. The other properties might more properly be called *consequences*. The consequences arising from wording in other parts of the Standard, such as Constraints, undefined and implementation-defined behaviors. For instance, while placing the **register** storage-class specifier on the declaration of an object having a structure type may not result in any of its members being held in processor registers, the associated constraints still apply (it is a constraint violation for the result of a member selection operator to appear as the operand of the address-of operator).

register 1369
storage-class

C90

This wording did not appear in the C90 Standard and was added by the response to DR #017q6.

C++

The C++ Standard does not explicitly specify the behavior in this case.

Other Languages

In many object-oriented languages it is possible to specify that members of classes have a different storage-class, or linkage, than the class itself.

Forward references: type definitions (6.7.7). 1377

6.7.2 Type specifiers

type specifier
syntax

1378

type-specifier:
void
char
short
int
long
float
double
signed
unsigned
_Bool
_Complex
~~**_Imaginary**~~
struct-or-union-specifier
enum-specifier
typedef-name

Commentary

declaration 1348
syntax

The syntax of *type-specifier* does not enumerate all possible combinations of keywords that may be used to specify an arithmetic type. The syntax for *declaration-specifiers* supports the occurrences of more than one *type-specifier* in a single declaration.

The wording was changed by the response to DR #207.

C90

Support for the *type-specifiers* **_Bool**, **_Complex**, and **_Imaginary** is new in C99.

C++

The nonterminal for these terminals is called *simple-type-specifier* in C++ (7.1.5.2p1). The C++ Standard does contain a nonterminal called *type-specifier*. It is used in a higher-level production (7.1.5p1) that includes *cv-qualifier*.

The C++ Standard includes **wchar_t** and **bool** (the identifier bool is defined as a macro in the header **stdbool.h** in C) as *type-specifiers* (they are keywords in C++). The C++ Standard does not include **_Bool**, **_Complex** and **_Imaginary**, either as keywords or type specifiers.

Other Languages

Equivalent *type-specifiers* seen in other languages include: **integer**, **short real**, **real**, **double precision**, **boolean**, **character**, **ptr**, and **complex**.

Common Implementations

Implementations add additional type specifiers, as extensions, either to support some special purpose hardware functionality (e.g., the Intel 8051 processor[625] has an area of storage containing what are known as *special function registers*). Some vendors (e.g., Keil,[717] Tasking[20]) have added type specifiers (e.g., **sfr** and **sbit**) to provide a mechanism for declaring objects denoting locations in this storage area, or to give special semantics to objects that are application specific.

Motorola added some vector functionality (what it calls AltiVec Technology Resources[971]) to its implementation (the MPC7400) of the IBM PowerPC instruction set. This enabled 128 bits of storage to be treated as either: sixteen 8-bit objects, eight 16 bit objects, or four 32-bit objects. Their translator for this processor supports the keyword **__vector** as an extension. This keyword acts as a type specifier, indicating that for instance an object is composed of 16 unsigned chars. Operations on and between objects declared with this type specifier operate on all of the subobjects at the same time. For instance, an add operation will add corresponding unsigned chars from each of the two operands. The streaming SIMD extensions (SSE)[627] to the Intel x86 instruction set support a similar set of operations (see Figure 1378.1) on blocks of 128 bits and a few translators[630] make use of them.

Coding Guidelines

A guideline recommendation dealing with the use of a subset of the available type specifiers is discussed elsewhere.

Constraints

1379 At least one type specifier shall be given in the declaration specifiers in each declaration, and in the specifier-qualifier list in each struct declaration and type name.

declaration at least one type specifier

Commentary

C no longer supports any form of implicit declaration.

A *specifier-qualifier-list* is the production used in the syntax for structure and union specifiers. It denotes an optional list of *type-specifier* and *type-qualifier*.

1390 struct/union syntax

C90

This requirement is new in C99.

In C90 an omitted *type-specifier* implied the type specifier **int**. Translating a source file that contains such a declaration will cause a diagnostic to be issued and are no longer considered conforming programs.

C++

At least one type-specifier *that is not a* cv-qualifier *is required in a declaration unless it declares a constructor, destructor or conversion function.*[80)]

7.1.5p2

Although the terms used have different definitions in C/C++, the result is the same.

Other Languages

Most languages require that declarations contain some form of type specification (although some of them will create an implicit declaration if an identifier is referenced without first being declared). Some languages have no means of explicitly declaring the type of an object. For instance, ML implementations need to deduce the type of an object from the context in which it is used. Fortran uses the first character of an identifier to implicitly give it a type, if it is not given one explicitly through a declaration. Identifiers starting with any of the letters `I` through `N`, inclusive, having integer type and all other identifiers having real type. There is even an **IMPLICIT** statement that allows the developer to control the types implicitly chosen for identifiers starting with different alphabetic letters.

Common Implementations

Most C90 implementations do not issue a diagnostic for the violation of this C99 constraint. It is expected that most C99 translators will continue to treat such declaration as implying the type **int**.

Coding Guidelines

Many developers will continue to use C90 translators for years to come and these will not check for a violation of this constraint. Some static analysis tools do not check source for violations of constraints on the basis that this check is performed by translators (thus reducing the amount of work that implementors of such tools need to do). The existing C90 behavior is well defined, experienced developers will be familiar with it, and it is simple for developers new to C to learn. Occurrences of an omitted type specifier in existing code is rare. Given this rarity and the small cost paid by readers of the source (often a slight confusion causing a task switch followed by the realization that the **int** *type-specifier* has been omitted).

0 cognitive switch

1380 Each list of type specifiers shall be one of the following sets (delimited by commas, when there is more than one set on a line);

type specifiers sets of

Commentary

A set is an unordered collection of items (tokens in this case). The syntax permits an arbitrary long sequence of different type specifiers. This constraint delimits the set of possible type specifier combinations that can appear in a conforming program.

Other Languages

Few languages support the large number of different combinations of type specifiers available in C. Algol 68 was unusual in that its use of a two level grammar permitted families of an infinite number of types, e.g., **int**, **short int**, **short short int**, **short short short int**, . . . , and **int**, **long int**, **long long int**, **long long long int**, and so on (implementations were allowed to specify a *shortest* and *longest* type, after which additional **short** and **long** had no affect on representation).

Coding Guidelines

If developers followed the principle of least effort, when typing source, we would expect the type specifiers most often used to be the first one listed on each line and the ones least often used to be the last on the line. With one exception existing code appears to overwhelmingly use the shortest form (see Table 1378.1). The exception is the type **unsigned int**. Developers appear to use the **unsigned** type specifier for all unsigned types. While developers will be most practiced using the shorter forms, the additional cost of using any of the longer forms is likely to be small. For this reason a guideline recommendation would not appear to have a worthwhile cost/benefit.

---

type specifiers ordering

the type specifiers may occur in any order, possibly intermixed with the other declaration specifiers. 1381

Future language directions

Commentary

There is no future language direction specifying any change in this behavior.

Other Languages

Most languages require a fixed order for type specifiers. Even though they may contain of more than one token, they are usually treated, by the syntax, as if they were a single token. Very few languages allow other declaration specifiers to be intermixed with type specifiers.

Coding Guidelines

Existing code rarely contains a list of type specifiers having an order that is not one of those specified in the C Standard (see Table 1378.1). Based on this common practice in existing code the possibility that readers will only read what they consider to be the minimum number of tokens needed to deduce an objects integer type has to be considered. For instance, readers may believe that the declaration `long unsigned id_name` declares an object to have type **long**.

Cg 1381.1

If more than one type specifier occurs in a declaration the order used shall be one of those listed in the Standard.

---  long double _Complex
---float _Imaginary
---double _Imaginary
---long double _Imaginary
---  struct or union specifier
---  enum specifier
---  typedef name
```

Commentary

The keyword **signed** can only make a difference to the type in two cases (depending on implementation-defined behavior it may not make any difference), (1) when it appears with **char**, and (2) when it appears in the declaration of a bit-field. However, support for its use creates a symmetry with the keyword **unsigned**.

516 char range, representation and behavior
1387 bit-field int

Rationale

Some pre-C89 implementations allowed type specifiers to be added to a type defined using **typedef**. Thus

```
typedef short int small;
unsigned small x;
```

would give x the type **unsigned short int**. The C89 Committee decided that since this interpretation may be difficult to provide in many implementations, and since it defeats much of the utility of **typedef** as a data abstraction mechanism, such type modifications are invalid.

The wording was changed by the response to DR #207.

C90

Support for the following is new in C99:

— **long long**, **signed long long**, **long long int**, or **signed long long int**
— **unsigned long long**, or **unsigned long long int**
— **_Bool**
— **float _Complex**
— **double _Complex**
— **long double _Complex**

Support for the *no type specifiers* set, in the **int**, **signed**, **signed int** list has been removed in C99.

```
1  extern x;   /* strictly conforming C90  */
2              /* constraint violation C99 */
3  const  y;   /* strictly conforming C90  */
4              /* constraint violation C99 */
5         z;   /* strictly conforming C90  */
6              /* constraint violation C99 */
7         f(); /* strictly conforming C90  */
8              /* constraint violation C99 */
```

C++

The list of combinations, given above as being new in C99 are not supported by C++.

Like C99, the C++ Standard does not require a translator to provide an implicit function declaration returning **int** (footnote 80) being supplied for a missing type specifier.

Other Languages

Most languages use only one sequence of tokens to represent a given type and have a relatively small number of different integer types (often only one). Cobol allows the number of digits used in the representation of decimal types to be specified and many Fortran implementations support more than one integer type. Languages that support integer subranges allow millions of integer types to be defined, although implementations invariably map these to the same underlying representations that are used by C implementations. PL/1 uses a precision specifier rather than keywords to indicate the number of bits (or digits) in various types (e.g., `BINARY(16)` specifies a binary (integer) type represented in nine bits).

Common Implementations

Support for **long long** existed in some vendors implementations for a number of years before C99 was ratified. The set **short double** was supported as a synonym for **float** in a few prestandard implementations. Some implementations continue to support this set for backwards compatibility.

Table 1382.1: Occurrence of *type-specifier* sequences (as a percentage of all type specifier sequences; cut-off below 0.1%). Based on the visible form of the `.c` files.

Type Specifier Sequence	%	Type Specifier Sequence	%
int	39.9	**long**	2.2
void	24.3	**unsigned**	1.6
char	15.6	**unsigned short**	0.9
unsigned long	6.2	**float**	0.6
unsigned int	4.0	**short**	0.5
unsigned char	3.4	**double**	0.5

The type specifiers ~~_Complex and _Imaginary~~ shall not be used if the implementation does not provide ~~those~~ complex types.[102)] 1383

Commentary

This is a constraint that depends on a feature being available in the implementation being used.

The wording was changed by the response to DR #207.

C90

Support for this type specifier is new in C99.

C++

Support for these type specifiers is new in C99 and are not specified as such in the C++ Standard. The header **<complex>** defines template classes and associated operations whose behavior provides the same functionality as that provided, in C, for objects declared to have type **_Complex**. There are no equivalent definitions for **_Imaginary**.

Other Languages

implementation two forms complex types 92 500

Cobol and Fortran (77) support optional type specifiers. Only a few languages support complex types.

Coding Guidelines

Source code that uses the specifier **_Complex** or **_Imaginary** has a dependence on implementations providing the necessary support. Translating source code containing one of these type specifiers, using an implementation that does not support them, will result in a diagnostic being issued. The behavior is either defined, or a diagnostic is issued. There is no benefit from having a guideline recommendation.

Semantics

1384 Specifiers for structures, unions, and enumerations are discussed in 6.7.2.1 through 6.7.2.3.

Commentary

See subclauses 6.7.2.1 through 6.7.2.3 for the discussion.

1390 struct/union syntax
1439 enumeration specifier syntax
1454 type contents defined once

1385 Declarations of typedef names are discussed in 6.7.7.

Commentary

See subclause 6.7.7 for the discussion

1629 typedef name syntax

1386 The characteristics of the other types are discussed in 6.2.5.

Commentary

See subclause 6.2.5 for the discussion

472 types

1387 Each of the comma-separated sets designates the same type, except that for bit-fields, it is implementation-defined whether the specifier **int** designates the same type as **signed int** or the same type as **unsigned int**.

bit-field int

Commentary

That is, the sets appearing on the same line designate the same type.

The treatment of bit-field types is not quiet the same as the treatment of character types, although it has been influenced by similar historical factors (variations between early implementations). While an **int** bit-field is the same type as either the signed or unsigned forms, the type **char** is a different type from the signed and unsigned character types (although it is capable of representing the same range of values as one of them).

515 character types
516 char range, representation and behavior

C90

Each of the above comma-separated sets designates the same type, except that for bit-fields, the type ***signed int*** *(or* ***signed****) may differ from* ***int*** *(or no type specifiers).*

C++

Rather than giving a set of possibilities, the C++ Standard lists each combination of specifiers and its associated type (Table 7).

Other Languages

Languages that offer some mechanism for controlling the number of storage bits allocated to an object, do not usually allow that mechanism to change the underlying type of the object.

Common Implementations

Many translators support an option that enables the developer to control how this choice is made.

Coding Guidelines

Most operands having a bit-field type promote to the type **int**. The only bit-field type that does not is one declared with the type specifier **unsigned int**, using a width that is the same as that of the type **unsigned int** (which can occur in source designed to be ported to a variety of architectures through the use of macros to defined the field width). While occurrences of operands having a bit-field type may promote to **int**, the underlying value representation supports a limited range of values. It is possible that translating the same source using different implementations will result in a dramatic change in the range of representable values (in the case of signed to unsigned, negative values being unrepresentable).

Cg 1387.1 The declaration of a bit-field type shall always include one of the type specifiers **signed** or **unsigned**.

footnote 102

102) ~~101)Implementations are not required to provide imaginary types.~~ Freestanding implementations are not required to provide complex types. 1388

Commentary

conforming 94 freestanding implementation

Complex types are one of many features a freestanding implementation does not have to provide. Not being able to accept a program that uses such types does not affect such an implementation's conformance status.

The wording was changed by the response to DR #207.

C90

Support for complex types is new in C99.

C++

There is no specification for imaginary types (in the **<complex>** header or otherwise) in the C++ Standard.

Forward references: enumeration specifiers (6.7.2.2), structure and union specifiers (6.7.2.1), tags (6.7.2.3), type definitions (6.7.7). 1389

6.7.2.1 Structure and union specifiers

struct/union syntax

1390

struct-or-union-specifier:
struct-or-union *identifier*$_{opt}$ **{** *struct-declaration-list* **}**
struct-or-union *identifier*
struct-or-union:
struct
union
struct-declaration-list:
struct-declaration
struct-declaration-list *struct-declaration*
struct-declaration:
specifier-qualifier-list *struct-declarator-list* **;**
specifier-qualifier-list:
type-specifier *specifier-qualifier-list*$_{opt}$
type-qualifier *specifier-qualifier-list*$_{opt}$
struct-declarator-list:
struct-declarator
struct-declarator-list **,** *struct-declarator*
struct-declarator:
declarator
declarator$_{opt}$ **:** *constant-expression*

Commentary

The use of **{** and **}** to delimit the sequence of members is consistent with them being used to delimit the sequence of statements in a compound statement.

C++

The C++ Standard uses the general term *class* to refer to these constructs. This usage is also reflected in naming of the nonterminals in the C++ syntax. The production *struct-or-union* is known as *class-key* in C++ and also includes the keyword **class**. The form that omits the brace enclosed list of members is known as an *elaborated-type-specifier* (7.1.5.3) in C++.

Other Languages

Some languages (e.g., Pascal) use the keyword **record** to denote both types and the keyword **end** to denote the end of the declaration (which is consistent with the delimiters used in these languages for compound statements, e.g., **begin/end**). The following example shows how Ada permits developers to specify which word, and bits within a word, are occupied by a member.

```
WORD : constant := 4;

type STATUS_WORD is
   record
   system_mask : array(0..7) of BOOLEAN;
   key         : INTEGER range 0..3;
   inst_addr   : ADDRESS;
   end record;

for STATUS_WORD use
   record at mod 8  -- address at which object is allocated storage
   system_mask at 0*WORD range  0.. 7; -- occupies bits 0 through 7, inclusive
   key         at 0*WORD range 10..11; -- occupies 2 bits
   inst_addr   at 1*WORD range  8..31; -- allocate member in second word
   end record;
```

The following is an example of a record declaration in Cobol.

```
        01 WEEKLY-SALES
           05 SALES-TABLE          OCCURS 50 TIMES.
              10 PRODUCT-CODE         PIC X(10).
              10 PRODUCT-PRICE        PIC S9(4)V99.
              10 PRODUCT-COUNT        PIC XXX.
                 88 LAST_PRODUCT                    VALUE "999".
```

Common Implementations

Some translators (`gcc`, and Plan 9 C[1350]) support the concept of anonymous structure and union members. In the example below the member name of a union type is omitted. When resolving names along a chain of selections a translator has to deduce when a member of a union is intended.

```
struct {
       int mem1;
       union {
              char mem2;
              long mem3;
             }; /* anonymous */
       } x;

void f(void)
{
x.mem3=3;
}
```

Cyclone C[668] supports tagged union types, using the keyword **tunion**, which contain information that identifies the current member.

Coding Guidelines

The visibility issues associated with object identifiers declared in an *init-declarator* also apply to identifiers declared in a *struct-declarator*.

1348.1 init-declarator one per source line

Cg 1390.1 No more than one *struct-declarator* shall occur on each visible source code line.

The discussion on the layout of declarators also applies to declarators in structure definitions. Deciding which members belong in which structure type can involve trade-offs amongst many factors. This issue is discussed in more detail elsewhere.

1358 declarator list of
299 limit struct/union nesting

Usage

A study by Sweeney and Tip[1324] of C++ applications found that on average 11.6% of members were dead (i.e., were not read from) and that 4.4% of object storage space was occupied by these dead data members. Usage information on member names and their types is given elsewhere (see Table 443.1 and Table 443.2).

Table 1390.1: Number of occurrences of the given token sequence. Based on the visible source of the `.c` files (`.h` files in parentheses).

Token Sequence	Occurrences	Token Sequence	Occurrences
enum {	456 (1,591)	**struct** id **;**	76 (13,384)
enum id **;**	0 (0)	**struct** id id	122,974 (27,589)
enum id **{**	474 (1,059)	**union {**	297 (725)
enum id id	2,922 (633)	**union** id **;**	0 (11)
struct {	1,567 (6,503)	**union** id **{**	105 (2,624)
struct id **{**	4,407 (1,311)	**union** id id	330 (231)

Constraints

member not types

A structure or union shall not contain a member with incomplete or function type (hence, a structure shall not contain an instance of itself, but may contain a pointer to an instance of itself), except that the last member of a structure with more than one named member may have incomplete array type; 1391

Commentary

Allowing structure or union members to have an incomplete type creates complications (the types would have to be completed at some point and a mechanism would need to be created to perform it) for little benefit. Requiring that the members have a complete type also simplifies the job of the translator. It becomes be possible to assign offsets, relative to the first member, to each member as it is encountered. The exception is for the last member where there is no following member requiring an offset. The requirement on there being at least one other named member, when the last member has an incomplete type, arises because of how the size of the declared type is calculated.

flexible array member 1430

structure size with flexible member 1432

The intent of the exception case is to support an implementation model where the storage for the last member follows the storage allocated to the other members in the same type (i.e., the storage for the last member does not need to be allocated in a separate storage area, with references to the member being implicitly dereferenced), but the amount allocated is decided during program execution.

Members having function type are supported in object-oriented languages. Although a proposal was submitted to the C committee, WG14/{N424, N445, N446, N447}, to add classes to C99 the additional complexity was not considered to be in the spirit of C.

spirit of C 14

C90

Support for the exception on the last named member is new in C99.

C++

It is a design feature of C++ that class types can contain incomplete and function types. Source containing instances of such constructs is making use of significant features of C++ and there is unlikely to be any expectation of being able to successfully process it using a C translator.

The exception on the last named member is new in C99 and this usage is not supported in the C++ Standard.

The following describes a restriction in C++ that does not apply in C.

annex C.1.7p3

Change: *In C++, a* **`typedef`** *name may not be redefined in a class declaration after being used in the declaration*

Example:

```
typedef int I;
struct S {
          I i;
          int I;  // valid C, invalid C++
         };
```

Rationale: *When classes become complicated, allowing such a redefinition after the type has been used can create confusion for C++ programmers as to what the meaning of 'I' really is.*

Other Languages

Other languages follow C in requiring members to be declared with complete types. Object-oriented language allow class definitions to include function definitions.

Example

An awkward edge case that needs to be handled by any implementation claiming to support incomplete member types.

```
1  struct x { struct y y; }; /* Constraint violation in Standard C. */
2  struct y { struct x x; };
```

1392 such a structure (and any union containing, possibly recursively, a member that is such a structure) shall not be a member of a structure or an element of an array.

Commentary

This requirement applies to the exception case and it describes contexts that all require types of known size. Requiring support for this usage would require the array storage for the last member to be allocated somewhere other than after the storage for the member that preceded it.

1393 The expression that specifies the width of a bit-field shall be an integer constant expression that has a nonnegative value that shall not exceed the ~~number~~width of ~~bits in~~ an object of the type that ~~is~~would be specified ~~if~~were the colon and expression ~~are~~ omitted.

bit-field maximum width

Commentary

The intent of a bit-field declaration is to specify the number of bits in a types value representation, a negative value has no meaning. Objects having a bit-field type can be used wherever expressions having certain integer types can be used. This usage can only be guaranteed to be defined if bit-fields do not have a width greater than these types. Implementations are required to supported a width of at least 1 for bit-fields of type **_Bool**. However, they may also support greater widths, up to a maximum of CHAR_BIT.

575 bit-field value is m bits

670 expression wherever an int may be used

666 _Bool rank

The wording was changed by the response to DR #262 (making it clear that any padding bits are not counted).

C90

The C90 wording ended with " . . . of bits in an ordinary object of compatible type.", which begs the question of whether bit-fields are variants of integer types or are separate types.

C++

The C++ issues are discussed elsewhere.

575 bit-field value is m bits

Coding Guidelines

Specifying a width equal to the number of bits that would have been used in the value representation, had the colon and expression been omitted, would appear to be redundant. However, the source may be translated

using a variety of different implementations in different host environments and the equality in the number of bit-field int 1387 bits used may not apply to all of them. Also, when declared using plain **int** the signedness of a bit-fields type will be the same as other bit-fields declared using plain **int**. How the width is specified (through the replacement of a macro name, or a constant expression) ties in with the general software engineering topic of source configuration and is outside the scope of these coding guidelines.

If the value is zero, the declaration shall have no declarator. 1394

Commentary

bit-field zero width 1415 This construct is discussed elsewhere.

C++

9.6p2 *Only when declaring an unnamed bit-field may the* `constant-expression` *be a value equal to zero.*

Source developed using a C++ translator may contain a declaration of a zero width bit-field that include a declarator, which will generate a constraint violation if processed by a C translator.

```
struct {
        int mem_1;
        unsigned int mem_2:0; //                  no diagnostic required
                              /* constraint violation, diagnostic required */
       } obj;
```

There is an open C++ DR (#057) concerning the lack of a prohibition against declarations of the form:

```
union {int : 0;} x;
```

---

bit-field shall have type

A bit-field shall have a type that is a qualified or unqualified version of **_Bool**, **signed int**, **unsigned int**, or some other implementation-defined type. 1395

Commentary

In this context use of the type specifier **int** is equivalent to either **signed int** or **unsigned int**. It is not a different type (as **char** is from **signed char** and **unsigned char**) and so need not appear in the list here.

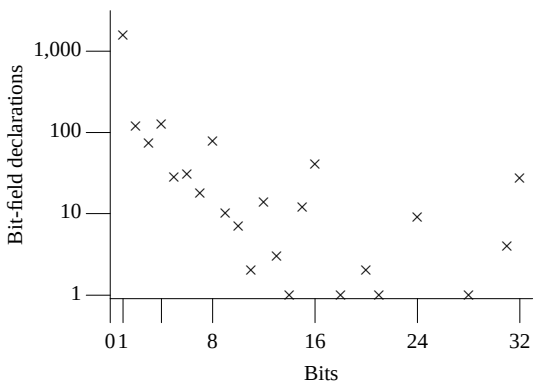

Figure 1393.1: Number of bit-field declarations specifying a given number of bits. Based on the translated form of this book's benchmark programs. (Declarations encountered in any source or header file were only counted once, the contents of system headers were ignored.)

The phrase *implementation-defined type* refers to any other standard integer type that an implementation chooses to support in a bit-field declaration, or any an implementation-defined extended integer type. Using " . . . some other implementation-defined type." is making use of implementation-defined behavior.

493 standard integer types
493 extended integer types

C90

The following wording appeared in a semantics clause in C90, not a constraint clause.

> *A bit-field shall have a type that is a qualified or unqualified version of one of* **int**, **unsigned int**, *or* **signed int**.

Programs that used other types in the declaration of a bit-field exhibited undefined behavior in C90. Such programs exhibit implementation-defined behavior in C99.

C++

> *A bit-field shall have integral or enumeration type (3.9.1).* 9.6p3

Source developed using a C++ translator may contain bit-fields declared using types that are a constraint violation if processed by a C translator.

```
enum E_TAG {a, b};

struct {
        char m_1  : 3;
        short m_2 : 5;
        long m_3  : 7;
        enum E_TAG m_4 : 9;
       } glob;
```

Other Languages

Languages that provide a mechanism for specifying the layout of aggregate types (e.g., Ada and CHILL) do not usually place restrictions on the types that the objects may have. Although they may limit the range of possible widths for some types.

Common Implementations

Some implementations support bit-fields declared using other integer types (`gcc` and the SVR4 C compiler). This usage is not purely to intended to support value representations containing a greater number of bits. Implementations often use the alignment of the type specifier used as the alignment of the addressable storage unit to be used to hold the bit-field. For instance, if the alignment used for the type **short** was 2 and that for **int** 4, then the alignment of the addressable storage unit used to hold bit-fields declared using the two types would be 2 and 4 respectively.

While some processors (e.g., Intel Pentium) include instructions for operating on what are sometimes called *packed floating-point* values, the representation used for these *packed* values is the same as that used for their *unpacked* form. The term *packed* being applied in the case where instructions operate on two or more floating-point values as a single unit (e.g., four 32-bit values, represented in 128 bits, are added to another four 32-bit values being represented in 128 bits).

Coding Guidelines

The discussion leading to the guideline recommendation dealing with the use of a single integer type is applicable here.

480.1 object int type only

Use of implementation-defined integer types, whose rank is less than that of **int**, almost certainly implies that a developer is trying to control the layout of objects in storage. While there is a guideline recommendation

1354 storage layout

covering this usage, bit-fields are often treated as a special case. There are sometimes application domain storage layout requirements. For instance, interpreting different sequences of bits at various bit offsets, from some starting point, as corresponding to different value representations.

extensions 95.1 cost/benefit

An alternative to declaring members as bit-field types is to declare them as non-bit-field integer types and use bitwise operations to extract the required sequence of value bits. This approach removes any dependency on how implementations allocate bit-field members to storage locations. The costs are a potential increase in effort needed to comprehend the source (unless the details of the bit sequence selection are hidden behind a macro call) and a potential increase in execution time (it is likely to be easier to optimize the generated machine code for an access using a member selection operator than a sequence of developer selected bitwise operations). Provided macros are used to hide the implementation details, neither of these costs is likely to be significant.

A developer may want to minimize the amount of storage used by a type and have no interest in the actual storage layout selected. Recommending against the use of other implementation-defined type because storage minimization is not guaranteed on other implementations is a rather rigid interpretation of guidelines.

storage 1354 layout

Dev 95.1 A bit-field may be declared using a type whose rank is less than that of **int** provided no use is made of member layout information.

Dev 95.1 A bit-field may be declared using a type whose rank is greater than that of **int**.

Semantics

As discussed in 6.2.5, a structure is a type consisting of a sequence of members, whose storage is allocated in an ordered sequence, and a union is a type consisting of a sequence of members whose storage overlap. 1396

Commentary

These issues are discussed elsewhere.

structure type 530 sequentially allocated objects
union type 531 overlapping members

C++

This requirement can be deduced from 9.2p12 and 9.5p1.

Structure and union specifiers have the same form. 1397

Commentary

They have the same syntactic form (the only syntactic difference is the keyword used). As types both structures and unions are either identified by their tag name, a typedef name, or are anonymous, within individual translation units (their members are not used to determine type compatibility). However, between different translation units, type compatibility includes requirements on the members in a structure or union type.

types 472
footnote 650 46
compatible 633 separate translation units

C++

The C++ Standard does not make this observation.

Other Languages

In some languages (e.g., Pascal and Ada) a variant record (union) can only occur within a record (structure) declaration. It is not possible to declare the equivalent of a union at the outer most declaration level.

The keywords **struct** and **union** indicate that the type being specified is, respectively, a structure type or a union type. 1398

Commentary

This sentence was added by the response to DR #251. The reason for it is discussed elsewhere.

tag name 1455 same struct, union or enum

1399 The presence of a struct-declaration-list in a struct-or-union-specifier declares a new type, within a translation unit.

Commentary

This wording specifies that the form: *struct-or-union identifier*$_{opt}$ **{** *struct-declaration-list* **}** declares a new type. Other forms of structure declaration that omit the braces either declare an identifier as a tag or refer to a previous declaration.

Other Languages

Whether or not a structure or union type definition is a new type may depend on a languages type compatibility rules. Languages that use structural equivalence may treat different definitions as being the same type (usually employing rules similar to those used by C for type compatibility across translation units).

633 compatible separate translation units

1400 The struct-declaration-list is a sequence of declarations for the members of the structure or union.

Commentary

Say in words what is specified in the syntax.

1401 If the struct-declaration-list contains no named members, the behavior is undefined.

Commentary

The syntax does not permit the *struct-declaration-list* to be empty. However, it is possible for members to be unnamed bit-fields.

1414 bit-field unnamed

C++

An object of a class consists of a (possibly empty) sequence of members and base class objects. 9p1

Source developed using a C++ translator may contain class types having no members. This usage will result in undefined behavior when processed by a C translator.

Other Languages

The syntax of languages invariably requires at least one member to be declared and do not permit zero sized types to be defined.

Common Implementations

Most implementations issue a diagnostic when they encounter a *struct-declaration-list* that does not contain any named members. However, many implementations also implicitly assume that all declared objects have a nonzero size and after issuing the diagnostic may behave unpredictably when this assumption is not met.

Coding Guidelines

A discussion of the cost/benefit of the use of such a construct (perhaps based on its apparent harmlessness versus possible unpredictable translator behavior). In practice occurrences of this construct are rare (until version 3.3.1 `gcc` reported "internal compiler error" for many uses of objects declared with such types) and is not worth a guideline recommendation.

Example

```
1  #include <stdio.h>
2
3  struct S {
4            int : 0;
```

```
5           };
6
7   void f(void)
8   {
9   struct S arr[10];
10
11  printf("arr contains %d elements\n", sizeof(arr)/sizeof(struct S));
12  }
```

struct type incomplete until

The type is incomplete until after the **}** that terminates the list. 1402

Commentary

tag 1458 incomplete until

This sentence is a special case of one discussed elsewhere.

Example

```
1   struct S {
2             int m1;
3             struct S m2; /* m2 refers to an incomplete type (a constraint violation). */
4           }             /* S is complete now. */;
5   struct T {
6             int m1;
7           } x = { sizeof(struct T) }; /* sizeof a completed type. */
```

In the second definition the closing **}** (the one before the x) completes the type and the **sizeof** operator can be applied to the type.

struct member type

A member of a structure or union may have any object type other than a variably modified type.[103] 1403

Commentary

member 1391 not types

Other types are covered by a constraint. As the discussion for that C sentence points out, the intent is to enable a translator to assign storage offsets to members at translation time. Apart from the special case of the last member, the use of variably modified types would prevent a translator assigning offsets to members (because their size is not known at translation time).

C90

Support for variably modified types is new in C99.

C++

Support for variably modified types is new in C99 and they are not specified in the C++ Standard.

Other Languages

Java uses references for all non-primitive types. Storage for members having such types need not be allocated in the class type that contains the member declaration and there is no requirement that the number of elements allocated to a member having array type be known at translation time.

Table 1403.1: Occurrence of structure member types (as a percentage of the types of all such members). Based on the translated form of this book's benchmark programs.

Type	%	Type	%	Type	%	Type	%
int	15.8	**unsigned short**	7.7	**char** *	2.3	**void** *()	1.3
other-types	12.7	**struct**	7.2	**enum**	1.9	**float**	1.2
unsigned char	11.1	**unsigned long**	5.2	**long**	1.8	**short**	1.0
unsigned int	10.4	**unsigned**	4.0	**char**	1.8	**int** *()	1.0
struct *	8.8	**unsigned char** []	3.1	**char** []	1.5		

Table 1403.2: Occurrence of union member types (as a percentage of the types of all such members). Based on the translated form of this book's benchmark programs.

Type	%	Type	%	Type	%	Type	%
`struct`	46.9	`unsigned int`	3.8	`double`	1.9	`char []`	1.3
other-types	11.3	`char *`	2.8	`enum`	1.7	`union *`	1.1
`struct *`	8.3	`unsigned long`	2.4	`unsigned char`	1.5		
`int`	6.0	`unsigned short`	2.1	`struct []`	1.3		
`unsigned char []`	4.3	`long`	2.1	`( struct * ) []`	1.3		

1404 In addition, a member may be declared to consist of a specified number of bits (including a sign bit, if any).

Commentary

The ability to declare an object that consists of a specified number of bits is only possible inside a structure or union type declaration.

Other Languages

Some languages (e.g., CHILL) provide a mechanism for specifying how the elements of arrays are laid out and the number of bits they occupy. Languages in the Pascal family support the concept of subranges. A subrange allows the developer to specify the minimum and maximum range of values that an object needs to be able to represent. The implementation is at liberty to allocate whatever resources are needed to satisfy this requirement (some implementations simply allocate an integers worth of storage, while others allocate the minimum number of bytes needed).

Coding Guidelines

Why would a developer want to specify the number of bits to be used in an object representation? This level of detail is usually considered to be a low level implementation information. The following are possible reasons for this usage include:

- *Minimizing the amount of storage used by structure objects.* This remains, and is likely to continue to remain, an important concern in applications where available storage is very limited (usually for cost reasons).
- *There is existing code*, originally designed to run in a limited storage environment. The fact that storage requirements are no longer an issue is rarely a cost effective rationale for spending resources on removing bit-field specifications from declarations.
- *Mapping to a hardware device.* There are often interfaced via particular storage locations (organized as sequences of bits), or transfer data is some packed format. Being able to mirror the bit sequences of the hardware using some structure type can be a useful abstraction (which can require the specification of the number of bits to be allocated to each object).
- *Mapping to some protocol imposed layout of bits.* For instance, the fields in a network data structure (e.g., TCP headers).

The following are some of the arguments that can be made for not using bit-fields types:

- Many of the potential problems associated with objects declared to have an integer type, whose rank is less than `int`, also apply to bit-fields. However, one difference between them is that developers do not habitually use bit-fields, to the extent that character types are used. If developers don't use bit-fields out of habit, but put some thought into deciding that their use is necessary a guideline recommendation would be redundant (treating guideline recommendations as prepacked decision aids).
- It is making use of representation information.

480.1 object int type only
0 coding guidelines introduction
569 types representation

- The specification of bit-field types involves a relatively large number of implementation-defined behaviors, dealing with how bit-fields are allocated in storage. However, recommending against the use of bit-fields only prevents developers from using one of the available techniques for accessing sequences of bits within objects. It is not obvious that bit-fields offer the least cost/benefit of all the available techniques (although some coding guideline documents do recommend against the use of bit-fields).

Dev 569.1 Bit-fields may be used to interface to some externally imposed storage layout requirements.

---

bit-field

Such a member is called a *bit-field*;[104)] 1405

Commentary

This defines the term *bit-field*. Common usage is for this term to denote bit-fields that are named. The less frequently used unnamed bit-fields being known as *unnamed bit-fields*.

bit-field unnamed 1414

Other Languages

Languages supporting such a type use a variety of different terms to describe such a member.

---

its width is preceded by a colon. 1406

Commentary

Specifying in words the interpretation to be given to the syntax.

Other Languages

Declarations in languages in the Pascal family require the range of values, that need to be representable, to be specified in the declaration. The number of bits used is implementation-defined.

---

bit-field interpreted as

A bit-field is interpreted as a signed or unsigned integer type consisting of the specified number of bits.[105)] 1407

Commentary

Both the value and object representation use the same number of bits. In some cases there may be padding between bit-fields, but such padding cannot be said to belong to any particular member.

value representation 595

object representation 574

C++

The C++ Standard does not specify (9.6p1) that the specified number of bits is used for the value representation.

Coding Guidelines

Using a symbolic name to specify the width might reduce the effort needed to comprehend the source and reduce the cost making changes to the value in the future.

symbolic name 822

If the value 0 or 1 is stored into a nonzero-width bit-field of type **_Bool**, the value of the bit-field shall compare equal to the value stored. 1408

Commentary

This is a requirement on the implementation. It is implied by the type **_Bool** being an unsigned integer type (for signed types a single bit bit-field can only hold the values 0 and -1). These are also the only two values that are guaranteed to be represented by the type **_Bool**.

standard unsigned integer 487

_Bool large enough to store 0 and 1 476

C90

Support for the type **_Bool** is new in C99.

---

bit-field addressable storage unit

An implementation may allocate any addressable storage unit large enough to hold a bit-field. 1409

Commentary

There is no requirement on implementations to allocate the smallest possible storage unit. They may even allocate more bytes than `sizeof(int)`.

Other Languages

Languages that support some form of object layout specification often require developers to specify the storage unit and the bit offset, within that unit, where the storage for an object starts.

1390 struct/union syntax

Common Implementations

Many implementations allocate the same storage unit for bit-fields as they do for the type **`int`**. The only difference being that they will often allocate storage for more than one bit-field in such storage units. Implementations that support bit-field types having a rank different from **`int`** usually base the properties of the storage unit used (e.g., alignment and size) on those of the type specifier used.

1410 bit-field packed into
1395 bit-field shall have type

Coding Guidelines

Like other integer types, the storage unit used to hold bit-field types is decided by the implementation. The applicable guidelines are the same.

1395 bit-field shall have type
569.1 representation information using

Example

```
#include <stdio.h>

struct {
        char m_1;
        signed int m_2 :3;
        char m_3;
       } x;

void f(void)
{
if ((&x.m_3 - &x.m_1) == sizeof(int))
   printf("bit-fields probably use the same storage unit as int\n");
if ((&x.m_3 - &x.m_1) == 2*sizeof(int))
   printf("bit-fields probably use the same storage unit and alignment as int\n");
}
```

1410 If enough space remains, a bit-field that immediately follows another bit-field in a structure shall be packed into adjacent bits of the same unit.

bit-field packed into

Commentary

This is a requirement on the implementation. However, any program written to verify what the implementation has done, has to make use of other implementation-defined behavior. This requirement does not guarantee that all adjacent bit-fields will be packed in any way. An implementation could choose its addressable storage unit to be a byte, limiting the number of bit-fields that it is required to pack. However, if the storage unit used by an implementation is a byte, this requirement means that all members in the following declaration must allocated storage in the same byte.

```
struct {
        int mem_1 : 5;
        int mem_2 : 1;
        int mem_3 : 2;
       } x;
```

C++

This requirement is not specified in the C++ Standard.

9.6p1 *Allocation of bit-fields within a class object is implementation-defined.*

---

bit-field overlaps storage unit

If insufficient space remains, whether a bit-field that does not fit is put into the next unit or overlaps adjacent units is implementation-defined. 1411

Commentary

spirit of C 14

One of the principles that the C committee derived from the spirit of C was that an operation should not expand to a surprisingly large amount of machine code. Reading a bit-field value is potentially three operations; load value, shift right, and zero any unnecessary significant bits. If implementations were required to allocate bit-fields across overlapping storage units, then accessing such bit-fields is likely to require at least twice as many instructions on processors having alignment restrictions. In this case it would be necessary to load values from the two storage units into two registers, followed by a sequence of shift, bitwise-AND, and bitwise-OR operations. This wording allows implementation vendors to chose whether they want to support this usage, or leave bits in the storage unit unused.

alignment 39

Other Languages

Even languages that contain explicit mechanisms for specifying storage layout sometimes allow implementations to place restrictions on how objects straddle storage unit boundaries.

Common Implementations

Implementations that do not have alignment restrictions can access the appropriate bytes in a single load or store instruction and do not usually include a special case to handle overlapping storage units. Some processors include instructions[968] that can load/store a particular sequence of bits from/to storage.

representation information using 569.1

Coding Guidelines

The guideline recommendation dealing with the use of representation information are applicable here.

Example

The extent to which any of the following members are put in the same storage unit is implementation-defined.

```
struct T {
           signed int m_1 :5;
           signed int m_2 :5; /* Straddles an 8-bit boundary. */
           signed int m_3 :5;
           signed int m_4 :5; /* Straddles a 16-bit boundary. */
           signed int m_5 :5;
           signed int m_6 :5;
           signed int m_7 :5; /* Straddles a 32-bit boundary. */
         };
```

The order of allocation of bit-fields within a unit (high-order to low-order or low-order to high-order) is implementation-defined. 1412

Commentary

byte 53 addressable unit
object 570 contiguous sequence of bytes
member 1422 address increasing
unary & 1088 operand constraints

An implementation is required to chose one of these two orderings The standard does not define an order for bits within a byte, or for bytes within multibyte objects. Either of these orderings is consistent with the relative order of members required by the Standard.

It is not possible to take the address of an object having a bit-field type, and so bit-field member ordering cannot be deduced using pointer comparisons. However, the ordering can be deduced using a union type.

Common Implementations

While there is no requirement that the ordering be the same for each sequence of bit-field declarations (within a structure type), it would be surprising if an implementation used a different ordering for different declarations. Many implementations use the allocation order implied by the order in which bytes are allocated within multibyte objects.

Coding Guidelines

The guideline recommendation dealing with the use of representation information is applicable here.

569.1 representation information using

Example

```
/*
 * The member bf.m_1 might overlap the same storage as m_4[0] or m_4[1]
 * (using a 16-bit storage unit).  It might also be the most significant
 * or least significant byte of m_3 (using int as the storage unit).
 */
union {
       struct {
                signed int m_1 :8;
                signed int m_2 :8;
               } bf;
       int m_3;
       char m_4[2];
      } x;
```

1413 The alignment of the addressable storage unit is unspecified.

alignment addressable storage unit

Commentary

This behavior differs from that of the non-bit-field members, which is implementation-defined.

1421 member alignment

C++

The wording in the C++ Standard refers to the bit-field, not the addressable allocation unit in which it resides. Does this wording refer to the alignment within the addressable allocation unit?

Alignment of bit-fields is implementation-defined. Bit-fields are packed into some addressable allocation unit. 9.6p1

Common Implementations

Implementations that support bit-field types having a rank different from **int** usually base the properties of the alignment used on those of the type specifier used.

1395 bit-field shall have type

Coding Guidelines

The guideline recommendation dealing with the use of representation information is applicable here.

569.1 representation information using

1414 A bit-field declaration with no declarator, but only a colon and a width, indicates an unnamed bit-field.[106)]

bit-field unnamed

Commentary

Memory mapped devices and packed data sometimes contains sequences of bits that have no meaning assigned to them (sometimes called *holes*). When creating a sequence of bit-fields that map onto the meaningful values any holes also need to be taken into account. Unnamed bit-fields remove the need to create an *anonymous* name (sometimes called a *dummy* name) to denote the bit sequences occupied by the holes. In some cases the design of a data structure might involve having some spare bits, between certain members, for future expansion.

Other Languages

Languages that support some form of layout specification usually use a more direct method of specifying where to place objects (using bit offset and width). It is not usually necessary to specify where the holes go.

Coding Guidelines

Any value denoted by the sequence of bits specified by an unnamed bit-field is not accessible to a conforming program. The usage is purely associated with specifying representation details. There is no minimization of storage usage justification and the guideline recommendation dealing with the use of representation information is applicable here.

representation information using 569.1

---

bit-field zero width

As a special case, a bit-field structure member with a width of 0 indicates that no further bit-field is to be packed into the unit in which the previous bit-field, if any, was placed. 1415

Commentary

This special case provides an additional, developer accessible, mechanism for controlling the layout of bit-fields in structure types (it has no meaningful semantics for members of union types). It might be thought that this special case is redundant, a developer either working out exactly what layout to use for a particular implementation or having no real control over what layout gets used in general. However, if an implementation supports the allocation of bit-fields across adjacent units a developer may be willing to trade less efficient use of storage for more efficient access to a bit-field. Use of a zero width bit-field allows this choice to be made.

bit-field overlaps storage unit 1411

---

footnote 103

103) A structure or union can not contain a member with a variably modified type because member names are not ordinary identifiers as defined in 6.2.3. 1416

Commentary

It would have been possible for the C committee to specify that members could have a variably modified type. The reasons for not requiring such functionality are discussed elsewhere.

variable modified only scope 1569

C90

Support for variably modified types is new in C99.

C++

Variably modified types are new in C99 and are not available in C++.

---

footnote 104

104) The unary & (address-of) operator cannot be applied to a bit-field object; 1417

Commentary

Such an occurrence would be a constraint violation.

unary & operand constraints 1088

---

thus, there are no pointers to or arrays of bit-field objects. 1418

Commentary

The syntax permits the declaration of such bit-fields and they are permitted as implementation-defined extensions. The syntax for declarations implies that the declaration:

bit-field shall have type 1395

```
1  struct {
2          signed int abits[32] : 1;
3          signed int *pbits : 3;
4          } vector;
```

declares `abits` to have type array of bit-field, rather than being a bit-field of an array type (which would also violate a constraint). Similarly `pbits` has type pointer to bit-field.

bit-field shall have type 1395

One of the principles that the C committee derived from the spirit of C was that an operation should not

spirit of C 14

expand to a surprisingly large amount of machine code. Arrays of bit-fields potentially require the generation of machine code to perform relatively complex calculations, compared to non-bit-field element accesses, to calculate out the offset of an element from the array index, and to extract the necessary bits.

The C pointer model is based on the byte as the smallest addressable storage unit. As such it is not possible to express the address of individual bits within a byte.

53 byte addressable unit

Other Languages

Some languages (e.g., Ada, CHILL, and Pascal) support arrays of objects that only occupy some of the bits of a storage unit. When translating such languages, calling a library routine that extracts the bits corresponding to the appropriate element is often a cost effective implementation technique. Not only does the offset need to be calculated from the index, but the relative position of the bit sequence within a storage unit will depend on the value of the index (unless its width is an exact division of the width of the storage unit). Pointers to objects that do not occupy a complete storage unit are rarely supported in any language.

1419 105) As specified in 6.7.2 above, if the actual type specifier used is **int** or a typedef-name defined as **int**, then it is implementation-defined whether the bit-field is signed or unsigned.

footnote 105

Commentary

This issue is discussed elsewhere.

1387 bit-field int

C90

This footnote is new in C99.

1420 106) An unnamed bit-field structure member is useful for padding to conform to externally imposed layouts.

footnote 106

Commentary

Bit-fields, named or otherwise, in general are useful for padding to conform to externally imposed layouts (however, giving names to the padding bits can provide useful source code information).

1421 Each non-bit-field member of a structure or union object is aligned in an implementation-defined manner appropriate to its type.

member alignment

Commentary

The standard does not require the alignment of other kinds of objects to be documented. Developers sometimes need to be able to calculate the offsets of members of structure types (the `offsetof` macro was introduced into C90 to provide a portable method of obtaining this information). Knowing the size of each member, the relative order of members, and their alignment requirements is invariably sufficient information (because implementations insert the minimum padding between members necessary to produce the required alignment).

1422 member address increasing

While all members of the same union object have the same address, the alignment requirements on that address may depend on the types of the members (because of the requirement that a pointer to an object behave the same as a pointer to the first element of an array having the same object type).

1207 pointer to union members compare equal
1165 additive operators pointer to object

C++

The C++ Standard specifies (3.9p5) that the alignment of all object types is implementation-defined.

Other Languages

Most languages do not call out a special case for the alignment of members.

Common Implementations

Most implementations use the same alignment requirements for members as they do for objects having automatic storage duration. It is possible for the offset of a member having an array type to depend on the number of elements it contains. For instance, the Motorola 56000 supports pointer operations on circular buffers, but requires that the alignment of the buffer be a power of 2 greater than or equal to the buffer size.

39 alignment
39 Motorola 56000

Coding Guidelines

storage 1354 layout

The discussion on making use of storage layout information is applicable here.

---

member address increasing

Within a structure object, the non-bit-field members and the units in which bit-fields reside have addresses that increase in the order in which they are declared. 1422

Commentary

structure 1206 members later compare later

Although not worded as such, this is effectively a requirement on the implementation. It is consistent with a requirement on the result of comparisons of pointers to members of the same structure object. Prior to the publication of the C Standard there were several existing practices that depended on making use of information on the relative order of members in storage; including:

- Accessing individual members of structure objects via pointers whose value had been calculated by performing arithmetic on the address of other members (the `offsetof` macro was invented by the committee to address this need).
- Making use of information on the layout of members to overlay the storage they occupy with other objects.

member 1421 alignment

By specifying this ordering requirement the committee prevented implementations from using a different ordering (for optimization reasons), increasing the chances that existing practices would continue to work as expected (these practices also rely on other implementation-defined behaviors). The cost of breaking existing code and reducing the possibility of being able to predict member storage layout was considered to outweigh any performance advantages that might be obtained from allowing implementations to choose the relative order of members.

C++

The C++ Standard does not say anything explicit about bit-fields (9.2p12).

Other Languages

Few other languages guarantee the ordering of structure members. In practice, most implementations for most languages order members in storage in the same sequences as they were declared in the source code. The **packed** keyword in Pascal is a hint to the compiler that the storage used by a particular record is to be minimized. A few Pascal (and Ada) implementations reorder members to reduce the storage they use, or to change alignments to either reduce the total storage requirements or to reduce access costs for some frequently used members.

Common Implementations

The quantity and quality of analysis needed to deduce when it is possible to reorder members of structures has deterred implementors from attempting to make savings, for the general case, in this area. Some impressive savings have been made by optimizers[741] for languages that do not make this pointer to member guarantee.

Palem and Rabbah[1043] looked at the special case of dynamically allocated objects used to create tree structures. Building a tree structure usually requires the creation of many objects having the same type. A common characteristic of some operations on tree structures is that an access to an object, using a particular member name, is likely to be closely followed by another access to an object using the same member name. Rather than simply reordering members, they separated out each member into its own array, based on dynamic profiles of member accesses (the Trimaran[46] and `gcc` compilers were modified to handle this translation internally; it was invisible to the developer). For instance:

```
1  struct T {
2             int m_1;
3             struct T *next;
4            };
5  /*
```

```
6    * Internally treated as if written
7    */
8   int m_1[4];
9   struct T *(next[4]);
```

dynamically allocating storage for an object having type `struct T` resulted in storage for the two arrays being allocated. A second dynamic allocation request requires no storage to be allocated, the second array element from the first allocation could be used. If tree structures are subsequently walked in an order that is close to the order in which they are built, there is an increased probability that members having the same name will be in the same cache line. Using a modified `gcc` to process seven data intensive benchmarks resulted in an average performance improvement of 24% on Intel Pentium II and III, and 9% on Sun Ultra-Sparc-II.

Franz and Kistler[444] describe an optimization that splits objects across non-contiguous storage areas to improve cache performance. However, their algorithm only applies to strongly typed languages where developers cannot make assumptions about member layout, such as Java.

pointer compressing members

Zhang and Gupta[1511] developed what they called the *common-prefix* and *narrow-data* transformations. These compress 32-bit integer values and 32-bit address pointers into 15 bits. This transformation is dynamically applied (the runtime system checks to see if the transformation can be performed) to the members of dynamically allocated structure objects, enabling two adjacent members to be packed into a 32-bit word (a bit is used to indicate a compressed member). The storage optimization comes from the commonly seem behavior: (1) integer values tend to be small (the runtime system checks whether the top 18 bits are all 1's or all 0's), and (2) that the addresses of the links, in a linked data structure, are often close to the address of the object they refer to (the runtime system checks whether the two address have the same top 17 bits). Extra machine code has to be generated to compress and uncompress members, which increases code size (average of 21% on the user code, excluding linked libraries) and lowers runtime performance (average 30%). A reduction in heap usage of approximate 25% was achieved (the Olden benchmarks were used).

0 Olden benchmark

Coding Guidelines

The order of storage layout of the members in a structure type is representation information that is effectively guaranteed. It would be possible to use this information, in conjunction with the `offsetof` macro to write code to access specific members of a structure, using pointers to other members. However, use of information on the relative ordering of structure members tends not to be code based, but data based (the same object is interpreted using different types). The coding guideline issues associated with the layout of types are discussed elsewhere.

1354 storage layout

1423 A pointer to a structure object, suitably converted, points to its initial member (or if that member is a bit-field, then to the unit in which it resides), and vice versa.

pointer to structure points at initial member

Commentary

Although not worded as such, this is effectively a requirement on the implementation. The only reason for preventing implementations inserting padding at the start of a structure type is existing practice (and the resulting existing code that treats the address of a structure object as being equal to the address of the first member of that structure).

Other Languages

Most languages do not go into this level of representation detail.

Coding Guidelines

The guideline recommendation dealing with the use of representation information is applicable here.

569.1 representation information using

1424 There may be unnamed padding within a structure object, but not at its beginning.

structure unnamed padding

Commentary

Unnamed padding is needed when the next available free storage, for a member of a structure type, does not have the alignment required by the member type. Another reason for using unnamed padding is to mirror the layout algorithm used by another language, or even that used by another execution environment.

alignment 39
member 1421
alignment

The standard does not guarantee that two structure type having exactly the same member types have exactly the same storage layout, unless they are part of a common initial sequence.

structural 1585
compatibility
common initial sequence 1038

C90

There may therefore be unnamed padding within a structure object, but not at its beginning, as necessary to achieve the appropriate alignment.

C++

This commentary applies to POD-struct types (9.2p17) in C++. Such types correspond to the structure types available in C.

Other Languages

No language requires implementations to pad members so that there is no padding between them. Few language specifications call out the fact that there may be padding within structure objects.

Common Implementations

Implementations usually only insert the minimum amount of unnamed padding needed to obtain the correct storage alignment for a member.

Coding Guidelines

The presence of unnamed padding increases the size of a structure object. Developers sometimes order members to minimize the amount of padding that is likely to be inserted by a translator. Ordering the members by size (either smallest to largest, or largest to smallest) is a common minimization technique. This is making use of layout information and a program may depend on the size of structure objects being less than a certain value (perhaps there may be insufficient available storage to be able to run a program if this limit is exceeded). However, it is not possible to tell the difference between members that have been intentionally ordered to minimize padding, rather than happening to have an ordering that minimizes (or gets close to minimizing) padding. Consequently these coding guidelines are silent on this issue.

Unnamed padding occupies storage bytes within an object. The pattern of bits set, or unset, within these bytes can be accessed explicitly by a conforming program (using `memcpy` or `memset` library functions). They may also accessed implicitly during assignment of structure objects. It is the values of these bytes that is a potential cause of unexpected behavior when the `memcmp` (amongst others) library function is used to compare two objects having structure type.

footnote 602
43

Example

```
#include <stdlib.h>

/*
 * In an implementation that requires objects to have an address that is a
 * multiple of their size, padding is likely to occur as commented.
 */
struct S_1 {
            char mem_1; /* Likely to be internal padding following this member. */
            long mem_2; /* Unlikely to be external padding following this member. */
           };
struct S_2 {
            long mem_1; /* Unlikely to be internal padding following this member. */
```

```
13              char mem_2; /* Likely to be external padding following this member. */
14             };
15
16  void f(void)
17  {
18  struct S_1 *p_s1 = malloc(4*sizeof(struct S_1));
19  struct S_2 *p_s2 = malloc(4*sizeof(struct S_2));
20  }
```

1425 The size of a union is sufficient to contain the largest of its members.

Commentary

A union may also contain unnamed padding.

1428 structure trailing padding

1426 The value of at most one of the members can be stored in a union object at any time.

union member at most one stored

Commentary

This statement is a consequence of the members all occupying overlapping storage and having their first byte start at the same address. The value of any bytes of the object representation that are not part of the value representation, of the member last assigned to, are unspecified.

531 union type overlapping members
1427 union members start same address
589 union member when written to

Other Languages

Pascal supports a construct, called a *variant tag*, that can be used by implementations to check that the member being read from was the last member assigned to. However, use of this construct does require that developers explicitly declare such a tag within the type definition. A few implementations perform the check suggested by the language standard. Ada supports a similar construct and implementations are required to perform execution time checks, when a member is accessed, on what it calls the *discriminant* (which holds information on the last member assigned to).

Common Implementations

The RTC tool[866] performs runtime type checking and is capable of detecting some accesses (it does not distinguish between different pointer types and different integer types having the same size) where the member read is different from the last member stored in.

1427 A pointer to a union object, suitably converted, points to each of its members (or if a member is a bit-field, then to the unit in which it resides), and vice versa.

union members start same address

Commentary

Although not worded as such, this is effectively a requirement on the implementation. A consequence of this requirement is that all members of a union type have the same offset from the start of the union, zero. A previous requirement dealt with pointer equality between different members of the same union object. This C sentence deals with pointer equality between a pointer to an object having the union type and a pointer to one of the members of such an object.

1207 pointer to union members compare equal

C++

This requirement can be deduced from:

> *Each data member is allocated as if it were the sole member of a* ***struct****.* 9.5p1

Other Languages

Strongly typed languages do not usually (Algol 68 does) provide a mechanism that returns the addresses of members of union (or structure) objects. The result of this C requirement (that all members have the same

address) are not always specified, or implemented, in other languages. It may be more efficient on some processors, for instance, for members to be aligned differently (given that in many languages unions may only be contained within structure declarations and so could follow other members of a structure).

Common Implementations

The fact that pointers to different types can refer to the same storage location, without the need for any form of explicit type conversion, is something that optimizers performing points-to analysis need to take into account.

Coding Guidelines

The issues involved in having pointers to different types pointing to the same storage locations is discussed elsewhere.

pointer 1299 qualified/unqualified versions

---

structure trailing padding

There may be unnamed padding at the end of a structure or union. 1428

Commentary

The reasons why an implementation may need to add this padding are the same as those for adding padding between members. When an array of structure or union types is declared, the first member of the second and subsequent elements needs to have the same alignment as that of the first element. In:

structure 1424 unnamed padding

```
union T {
          long m_1;
          char m_2[11];
         };
```

it is the alignment requirements of the member types, rather than their size, that determines whether there is any unnamed padding at the end of the union type. When one member has a type that often requires alignment on an even address and another member contains an odd number of bytes, it is likely that some unnamed padding will be used.

C++

The only time this possibility is mentioned in the C++ Standard is under the **`sizeof`** operator:

5.3.3p2 *When applied to a class, the result is the number of bytes in an object of that class including any padding required for placing objects of that type in an array.*

Other Languages

The algorithms used to assign offsets to structure members are common to implementations of many languages, including the rationale for unnamed padding at the end. Few language definitions explicitly call out the fact that structure or union types may have unnamed padding at their end.

Common Implementations

Most implementations use the same algorithm for assigning member offsets and creating unnamed padding for all structure and union types in a program, even when these types are anonymous (performing the analysis to deduce whether the padding is actually required is not straight-forward). Such an implementation strategy is likely to waste a few bytes in some cases. But it has the advantage that, for a given implementation and set of translator options, the same structure declarations always have the same size (there may not be any standard's requirement for this statement to be true, but there is sometimes a developer expectation that it is true).

Coding Guidelines

Unnamed padding is a representation detail associated with storage layout. That this padding may occur after the last declared member is simply another surprise awaiting developers who try to make use of storage layout details. The guideline recommendation dealing with the use of representation information is applicable here.

storage 1354 layout representation information using 569.1

1429 As a special case, the last element of a structure with more than one named member may have an incomplete array type;

Commentary

The Committee introduced this special case, in C99, to provide a standard defined method of using what has become known as the *struct hack*. Developers sometimes want a structure object to contain an array object whose number of elements is decided during program execution. A standard, C90, well defined, technique is to have a member point at dynamically allocated storage. However, some developers, making use of representation information, caught onto the idea of simply declaring the last member be an array of one element. Storage for the entire structure object being dynamically allocated, with the storage allocation request including sufficient additional storage for the necessary extra array elements. Because array elements are contiguous and implementations are not required to perform runtime checks on array indexes, the additional storage could simply be treated as being additional array elements. This C90 usage causes problems for translators that perform sophisticated flow analysis, because the size of the object being accessed does not correspond to the size of the type used to perform the access. Should such translators play safe and treat all structure types containing a single element array as their last member as if they will be used in a *struct hack* manner?

The introduction of flexible array members, in C99, provides an explicit mechanism for developers to indicate to the translator that objects having such a type are likely to have been allocated storage to make use of the *struct hack*.

The presence of a member having an incomplete type does not cause the structure type that contains it to have an incomplete type.

C90

The issues involved in making use of the *struct hack* were raised in DR #051. The response pointed out declaring the member to be an array containing fewer elements and then allocating storage extra storage for additional elements was not strictly conforming. However, declaring the array to have a large number of elements and allocating storage for fewer elements was strictly conforming.

```
#include <stdlib.h>
#define HUGE_ARR 10000 /* Largest desired array. */

struct A {
          char x[HUGE_ARR];
         };

int main(void)
{
struct A *p = (struct A *)malloc(sizeof(struct A)
                                  - HUGE_ARR + 100); /* Want x[100] this time. */
p->x[5] = '?'; /* Is strictly conforming. */
return 0;
}
```

Support for the last member having an incomplete array type is new in C99.

C++

Support for the last member having an incomplete array type is new in C99 and is not available in C++.

Common Implementations

All known C90 implementations exhibit the expected behavior for uses of the *struct hack*. However, some static analysis tools issue a diagnostic on calls to `malloc` that request an amount of storage that is not consistent (e.g., smaller or not an exact multiple) with the size of the type pointed to by any explicit cast of its return value.

Coding Guidelines

Is the use of flexible arrays members more or less error prone than using any of the alternatives?

The *struct hack* is not widely used, or even widely known about by developers (although there may be some development communities that are familiar with it). It is likely that many developer will not be expecting this usage. Use of a member having a pointer type, with the pointed-to object being allocated during program execution, is a more common idiom (although more statements are needed to allocate and deallocate storage; and experience suggests that developers sometimes forget to free up the additional pointed-to storage, leading to storage leakage).

From the point of view of static analysis the appearance of a member having an incomplete type provides explicit notification of likely usage. While the appearance of a member having a completed array type is likely to be taken at face value. Without more information on developer usage, expectations, and kinds of mistakes made it is not possible to say anything more on these possible usages.

---

flexible array member

this is called a *flexible array member*. 1430

Commentary

This defines the term *flexible array member*.

C++

There is no equivalent construct in C++.

---

flexible array member ignored

~~With two exceptions~~ In most situations, the flexible array member is ignored. 1431

Commentary

The following are some situations where the member is ignored:

- forming part of a common initial sequence, even if it is the last member,
- compatibility checking across translation units, and
- if an initializer is given in a declaration (this is consistent with the idea that the usage for this type is to allocate variably sized objects via `malloc`).

---

structure size with flexible member

~~First, the size of the structure shall be equal to the offset of the last element of an otherwise identical structure that replaces the flexible array member with an array of unspecified length.[106)]~~ In particular, the size of the structure is as if the flexible array member were omitted except that it may have more trailing padding than the omission would imply. 1432

Commentary

The C99 specification required implementations to put any padding before the flexible array member. However, several existing implementations (e.g., GNU C, Compaq C, and Sun C) put the padding after the flexible array member. Because of the efficiency gains that might be achieved by allowing implementations to put the padding after the flexible array member the committee decided to sanction this form of layout.

The wording was changed by the response to DR #282.

~~Second~~However, when a `.` (or `->`) operator has a left operand that is (a pointer to) a structure with a flexible array member and the right operand names that member, it behaves as if that member were replaced with the longest array (with the same element type) that would not make the structure larger than the object being accessed; 1433

Commentary

The structure object acts as if it effectively grows to fill the available space (but it cannot shrink to smaller than the storage required to hold all the other members).

1434 the offset of the array shall remain that of the flexible array member, even if this would differ from that of the replacement array.

Commentary

This is a requirement on the implementation. It effectively prevents an implementation inserting additional padding before the flexible array member, dependent on the size of the array. Fixing the offset of the flexible array member makes it possible for developers to calculate the amount of additional storage required to accommodate a given number of array elements.

1435 If this array would have no elements, it behaves as if it had one element but the behavior is undefined if any attempt is made to access that element or to generate a pointer one past it.

Commentary

In the following example:

```
1  struct T {
2             int mem_1;
3             float mem_2[];
4            } *glob;
5
6  glob=malloc(sizeof(struct T) + 1);
```

insufficient storage has been allocated (assuming `sizeof(float) != 1`) for there to be more than zero elements in the array type of the member `mem_2`. However, the requirements in the C Standard are written on the assumption that it is not possible to create a zero sized object, hence this *as-if* specification.

Other Languages

Few languages support the declaration of object types requiring zero bytes of storage.

1436 EXAMPLE ~~Assuming that all array members are aligned the same, after the declarations:~~

EXAMPLE
flexible member

```
struct s { int n; double d[]; };
struct ss { int n; double d[1]; };
```

~~the three expressions:~~

```
sizeof (struct s)
offsetof(struct s, d)
offsetof(struct ss, d)
```

~~have the same value. The structure **structs** has a flexible array member **d**.~~
If **sizeof (double)** is 8, then after the following code is executed:

```
struct s *s1;
struct s *s2;
s1 = malloc(sizeof (struct s) + 64);
s2 = malloc(sizeof (struct s) + 46);
```

and assuming that the calls to **malloc** succeed, the objects pointed to by **s1** and **s2** behave, for most purposes, as if the identifiers had been declared as:

```
struct { int n; double d[8]; } *s1;
struct { int n; double d[5]; } *s2;
```

Following the further successful assignments:

```
s1 = malloc(sizeof (struct s) + 10);
s2 = malloc(sizeof (struct s) +  6);
```

they then behave as if the declarations were:

```
struct { int n; double d[1]; } *s1, *s2;
```

and:

```
double *dp;
dp = &(s1->d[0]);        // valid
*dp = 42;                // valid
dp = &(s2->d[0]);        // valid
*dp = 42;                // undefined behavior
```

The assignment:

```
*s1 = *s2;
```

only copies the member **n** ; if any of the array elements are within the first **sizeof(structs)** bytes of the structure, these might be copied or simply overwritten with indeterminate values. ~~and not any of the array elements. Similarly:~~

```
struct s  t1 = { 0 };            // valid
struct s  t2 = { 2 };            // valid
struct ss tt = { 1, { 4.2 }};    // valid
struct s  t3 = { 1, { 4.2 }};    // invalid: there is nothing for the 4.2 to initialize

t1.n = 4;                        // valid
t1.d[0] = 4.2;                   // undefined behavior
```

Commentary

Flexible array members are a new concept for many developers and this extensive example provides a mini-tutorial on their use.

The wording was changed by the response to DR #282.

footnote 106

~~106) The length is unspecified to allow for the fact that implementations may give array members different alignments according to their lengths.~~ 1437

Commentary

One reason for an implementation to use different alignments for array members of different lengths is to take advantage of processor instructions that require arrays to be aligned on multiples of their length.

Motorola 39 56000

The wording was changed by the response to DR #282.

6.7.2.2 Enumeration specifiers

enumeration specifier syntax

1439

enum-specifier:
enum *identifier*$_{opt}$ **{** *enumerator-list* **}**
enum *identifier*$_{opt}$ **{** *enumerator-list* **, }**
enum *identifier*
enumerator-list:
enumerator
enumerator-list **,** *enumerator*
enumerator:
enumeration-constant
enumeration-constant **=** *constant-expression*

Commentary

Support for a trailing comma is intended to simplify the job of automatically generating C source.

C90

Support for a trailing comma at the end of an *enumerator-list* is new in C99.

C++

The form that omits the brace enclosed list of members is known as an elaborated type specifier, 7.1.5.3, in C++.

The C++ syntax, 7.2p1, does not permit a trailing comma.

Other Languages

Many languages do not use a keyword to denote an enumerated type, the type is implicit in the general declaration syntax. Those languages that support enumeration constants do not always allow an explicit value to be given to an enumeration constant. The value is specified by the language specification (invariably using the same algorithm as C, when no explicit values are provided).

Common Implementations

Support for enumeration constants was not included in the original K&R specification (support for this functionality was added during the early evolution of C[1180]). Many existing C90 implementations support a trailing comma at the end of an *enumerator-list*.

Coding Guidelines

A general discussion on enumeration types is given elsewhere. 517 enumeration set of named constants

The order in which enumeration constants are listed in an enumeration type declaration often follows some rule, for instance:

- *Application conventions* (e.g., colors of rainbow, kings of England, etc.).
- *Human conventions* (e.g., increasing size, direction— such as left-to-right, or clockwise, alphabetic order, etc.).
- *Numeric values* (e.g., baud rate, Roman numerals, numeric value of enumeration constant, etc.).

While ordering the enumeration constant definitions according to some rule may have advantages (directly mapping to a reader's existing knowledge or ordering expectations may reduce the effort needed for them to organize information for later recall), there may be more than one possible ordering, or it may not be possible to create a meaningful ordering. For this reason no guideline recommendation is made here. 0 developer expectations

Do the visual layout factors that apply to the declaration of objects also apply to enumeration constants? The following are some of the differences between the declarations of enumeration constants and objects: 1348.1 init-declarator one per source line

- There are generally significantly fewer declarations of enumerator constants than objects, in a program (which might rule out a guideline recommendation on the grounds of applying to a construct that rarely occurs in source).
- Enumeration constants are usually declared amongst other declarations at file scope (i.e., they are not visually close to statements). One consequence of this is that, based on declarations being read on as as-needed basis, the benefits of maximizing the amount of surrounding code that appears on the display at the same time are likely to be small. 770 reading kinds of

The following guideline recommendation is given for consistency with other layout recommendations.

Cg 1439.1 No more than one enumeration constant definition shall occur on each visible source code line.

The issue of enumeration constant naming conventions is discussed elsewhere. 792 enumeration constant naming conventions

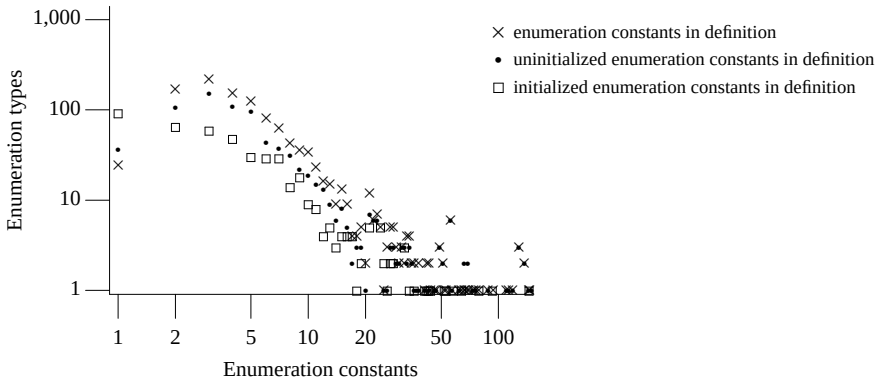

Figure 1439.1: Number of enumeration constants in an enumeration type and number whose value is explicitly or implicitly specified. Based on the translated form of this book's benchmark programs (also see Figure 298.1).

Usage

A study by Neamtiu, Foster, and Hicks[998] of the release history of a number of large C programs, over 3-4 years (and a total of 43 updated releases), found that in 40% of releases one or more enumeration constants were added to an existing enumeration type while enumeration constants were deleted in 5% of releases and had one or more of their names changed in 16% of releases.[997]

Table 1439.1: Some properties of the set of values (the phrase *all values* refers to all the values in a particular enumeration definition) assigned to the enumeration constants in enumeration definitions. Based on the translated form of this book's benchmark programs.

Property	%
All value assigned implicitly	60.1
All values are bitwise distinct and zero is not used	8.6
One or more constants share the same value	2.9
All values are continuous , i.e. , number of enumeration constants equals maximum value minus minimum value plus 1	80.4

Constraints

enumeration constant representable in int

The expression that defines the value of an enumeration constant shall be an integer constant expression that has a value representable as an **int**. 1440

Commentary

constant 823 representable in its type
enumeration 864 constant type

This constraint is consistent with the requirement that the value of a constant be in the range of representable values for its type. Enumeration constants are defined to have type **int**.

C++

7.2p1 *The* `constant-expression` *shall be of integral or enumeration type.*

7.2p4 *If an initializer is specified for an enumerator, the initializing value has the same type as the expression.*

Source developed using a C++ translator may contain enumeration initialization values that would be a constraint violation if processed by a C translator.

```
#include <limits.h>

enum { umax_int = UINT_MAX}; /* constraint violation */
                             // has type unsigned int
```

Common Implementations

Some implementations support enumeration constants having values that are only representable in the types **unsigned int**, **long**, or **unsigned long**.

Coding Guidelines

The requirement is that the constant expression have a value that is representable as an **int**. The only requirement on its type is that it be an integer type. The constant expression may have a type other than **int** because of the use of a macro name that happens to have some other type, or because one of its operands happens to have a different type. If the constant expression consists, in the visible source, of an integer constant containing a suffix, it is possible that the original author or subsequent readers may assume some additional semantics are implied. However, such occurrences are rare and for this reason no guideline covering this case is given here.

There may be relationships between different enumeration constants in the same enumeration type. The issue of explicitly showing this relationship in the definition, using the names of those constants rather than purely numeric values, is a software engineering one and is not discussed further in these coding guidelines.

```
enum { E1 = 33, E2 = 36, E3 = 3 };

/* does not specify any relationship, and is not as resistant to modification as: */

enum { e1 = 33, e2 = e1+3, e3 = e2-e1 };
```

The enumeration constants defined in by an enumerated type are a set of identifiers that provide a method of naming members having a particular property. These properties are usually distinct and in many cases the values used to represent them are irrelevant.

Semantics

1441 The identifiers in an enumerator list are declared as constants that have type **int** and may appear wherever such are permitted.[107)]

enumerators type int

Commentary

The issues associated with enumeration constants having type **int** are discussed elsewhere, as are the issues of it appearing wherever such a type is permitted.

864 enumeration constant type
670 expression wherever an int may be used

C++

Following the closing brace of an `enum-specifier`*, each enumerator has the type of its enumeration. Prior to the closing brace, the type of each enumerator is the type of its initializing value.* 7.2p4

In C the type of an enumeration constant is always **int**, independently of the integer type that is compatible with its enumeration type.

```
#include <limits.h>

int might_be_cpp_translator(void)
{
enum { a = -1, b = UINT_MAX }; // each enumerator fits in int or unsigned int
```

```
6
7   return (sizeof(a) != sizeof(int));
8   }
9
10  void CPP_DR_172_OPEN(void) // Open C++ DR
11  {
12  enum { zero };
13
14  if (-1 < zero) /* always true */
15                 // might be false (because zero has an unsigned type)
16     ;
17  }
```

Other Languages

Most languages that contain enumerator types treat the associated enumerated constants as belonging to a unique type that is not compatible with type **int**. In these languages an enumeration constant must be explicitly cast (Pascal provides a built-in function, **ord**) before they can appear where a constant having type **int** may appear.

Coding Guidelines

object 1352 role
bit-set role 945

The values given to the enumeration constants in a particular enumeration type determine their role and the role of an object declared to have that type. To fulfil a bit-set role the values of the enumeration constants need to be bitwise distinct. All other cases create a type that has a symbolic role.

Example

```
1   enum T { attr_a = 0x01, attr_b = 0x02, attr_c = 0x04, attr_d = 0x10, attr_e = 0x20};
```

An enumerator with = defines its enumeration constant as the value of the constant expression. 1442

Commentary

This specifies the semantics associated with a token sequence permitted by the syntax (like the semantics of simple assignment, the identifier on the left of the **=** has as its value the constant expression on the right).

Other Languages

Not all languages that support enumeration constants allow the value, used to represent them during program execution, to be specified in their definition.

Coding Guidelines

macro 1931 object-like

Some guideline documents recommend against assigning an explicit value to an enumeration constant. Such recommendations limit enumeration types to having a symbolic role only. It has the effect of giving developers no choice but to use object-like macros to create sets of identifiers having bit-set roles. Using macros instead of enumerations makes it much more difficult for static analysis tools to deduce an association between identifiers (it may still be made apparent to human readers by grouping of macro definitions and appropriate commenting), which in turn will reduce their ability to flag suspicious use of such identifiers.

If the first enumerator has no =, the value of its enumeration constant is 0. 1443

Commentary

limit 298 enumeration constants

This choice is motivated by common usage and implementation details. Most enumeration types contain relatively few enumeration constants and many do not explicitly assign a value to any of them. Implicitly starting at zero means that it is possible to represent the values of all enumeration constants in an enumeration type within a byte of storage.

Other Languages

This is the common convention specified by other languages, or by implementations of other languages that do not specify the initial value.

1444 Each subsequent enumerator with no = defines its enumeration constant as the value of the constant expression obtained by adding 1 to the value of the previous enumeration constant.

Commentary

If the previous enumeration constant had the value MAX_INT, adding one will produce a value that cannot be represented in an **int**, violating a constraint.

1440 enumeration constant representable in int

Other Languages

This is the common convention specified by other languages, or by implementations of other languages that do not specify the initial value.

1445 (The use of enumerators with = may produce enumeration constants with values that duplicate other values in the same enumeration.)

Commentary

When such enumeration constants are tested for equality with each other the result will be 1 (true), because it is their values not their spellings that are compared.

C++

The C++ Standard does not explicitly mention this possibility, although it does give an example, 7.2p2, of an enumeration type containing more than one enumeration constant having the same value.

Other Languages

No languages known to your author, that support the explicit definition of enumeration constant values, prohibits the appearance of duplicate values in the same enumeration.

Coding Guidelines

There are two ways in which more than one enumeration constant, in the same enumerated type, can have the same value. Either the values were explicitly assigned, or the at least one of the values was implicitly assigned its value. This usage may be an oversight, or it may be intentional (i.e., fixing the names of the first and last enumeration constant when it is known that new members may be added at a later date). These guideline recommendations are not intended to recommend against the creation of faults in code. What of the intended usage?

0 guidelines not faults

```
1   enum ET {FIRST_YEAR, Y_1898=FIRST_YEAR, Y_1899, Y_1900, LAST_KNOWN_YEAR=Y1900};
```

Do readers of the source assume there are no duplicate values among different enumeration constants, from the same enumerated type? Unfortunately use of enumerations constants are not sufficiently common among developers to provide the experience needed to answer this question.

1446 The enumerators of an enumeration are also known as its members.

Commentary

Developers often refer to the enumerators as *enumeration constants*, rather than *members*.

C++

The C++ Standard does not define this additional terminology for enumerators; probably because it is strongly associated with a different meaning for members of a class.

7.2p1

. . . the associated `enumerator` *the value indicated by the* `constant-expression`.

---

enumeration type compatible with

Each enumerated type shall be compatible with **`char`**, a signed integer type, or an unsigned integer type. 1447

Commentary

This is a requirement on the implementation. The term *integer types* cannot be used because enumerated types are included in its definition. There is no guarantee that when the **`sizeof`** operator is applied to an enumerator the value will equal that returned when **`sizeof`** is applied to an object declared to have the corresponding enumerator type.

integer types 519

C90

Each enumerated type shall be compatible with an integer type;

The integer types include the enumeration types. The change of wording in the C99 Standard removes a circularity in the specification.

integer types 519

C++

An enumeration is a distinct type (3.9.1) with named constants.

7.2p1

The underlying type of an enumeration may be an integral type that can represent all the enumerator values defined in the enumeration (7.2p5). But from the point of view of type compatibility it is a distinct type.

enumeration 864 constant type
enumeration 518 different type

It is implementation-defined which integral type is used as the underlying type for an enumeration except that the underlying type shall not be larger than ***`int`*** *unless the value of an enumerator cannot fit in an* ***`int`*** *or* ***`unsigned int`***.

7.2p5

While it is possible that source developed using a C++ translator may select a different integer type than a particular C translator, there is no effective difference in behavior because different C translators may also select different types.

Other Languages

Most languages that support enumerated types treat such types as being unique types, that is not compatible with any other type.

Coding Guidelines

Experience shows that developers are often surprised by some behaviors that occur when a translator selects a type other than **`int`** for the compatible type. The two attributes that developers appear to assume an enumerated type to have are promoting to a signed type (rather than unsigned) and being able to represent all the values that type **`int`** can (if values other than those in the enumeration definition are assigned to the object).

If the following guideline recommendation on enumerated types being treated as not being compatible with any integer type is followed, these assumptions are harmless.

Experience with enumerated types in more strongly typed languages has shown that the diagnostics issued when objects having these types, or their members, are mismatched in operations with other types, are a very effective method locating faults. Also a number of static analysis tools[493, 683, 1157] perform checks on the use of objects having an enumerated type and their associated enumeration constants[1447.1] .

[1447.1] However, this is not necessarily evidence of a worthwhile benefit. Vendors do sometimes add features to a product because of a perceived rather actual benefit.

Cg 1447.1 Objects having an enumerated type shall not be treated as being compatible with any integer type.

Example

```
#include <stdio.h>

void f(void)
{
enum T {X};

if ((enum T)-1 < 0)
   printf("The type of enum {X} is signed\n");

if (sizeof(enum T) == sizeof(X))
   printf("The type of enum {X} occupies the same number of bytes as int\n");
}
```

1448 The choice of type is implementation-defined,[108)] but shall be capable of representing the values of all the members of the enumeration.

Commentary

This is a requirement on the implementation.

C90

The requirement that the type be capable of representing the values of all the members of the enumeration was added by the response to DR #071.

Other Languages

Languages that support enumeration types do not usually specify low level implementation details, such as the underlying representation.

Common Implementations

Most implementations chose the type **int**. A few implementations attempt to minimize the amount of storage occupied by each enumerated type. They do this by selecting the compatible type to be the integer type with the lowest rank, that can represent all constant values used in the definition of the contained enumeration constants.

Coding Guidelines

An implementation's choice of type will affect the amount of storage allocated to objects defined to have the enumerated type. The alignment of structure members having such types may also be affected. One reason why some developers do not use enumerated types is that they do not always have control over the amount of storage allocated. While this is a very minor consideration in most environments, in resource constrained environments it may be of greater importance.

A definition of an enumeration type may not include (most don't) enumeration constants for each of the possible values that can be represented in the underlying value representation (invariably some integer type). The guideline recommendation that both operands of a binary operator have the same enumerated type limits, but does not prevent, the possibility that a value not represented in the list of enumeration constants will be created.

517.3 enumeration constant as operand

Whether or not the creation of a value that is not represented in the list of enumeration constants is considered to be acceptable depends on the interpretation given to what *value* means. The approach taken by these coding guideline subsections is to address the issue from the point of view of the operators that might be expected to apply to the given enumeration type (these are discussed in the C sentence for the respective operators). The following example shows two possibilities:

```
enum roman_rep {
                 I = 1,
                 V = 5,
                 X = V+V,
                 L = V*X,
                 C = L+L,
                 D = C*V,
                 M = X*C
               } x;
enum termios_c_iflag {              /* A list of bitwise distinct values. */
                       BRKINT = 0x01,
                       ICRNL  = 0x02,
                       IGNBRK = 0x04,
                       IGNCR  = 0x10,
                       IGNPAR = 0x20,
                       INLCR  = 0x40
                      } y;

void f(void)
{
x= V+V;             /* Create a value whose arithmetic value is     represented. */
x= X+L;             /* Create a value whose arithmetic value is not represented. */
y= ICRNL | IGNPAR;  /* Create a value whose bit-set is     represented. */
y= ICRNL << 8;      /* Create a value whose bit-set is not represented. */
}
```

---

enumerated type incomplete until

The enumerated type is incomplete until after the `}` that terminates the list of enumerator declarations. 1449

Commentary

tag 1458 incomplete until

This sentence is a special case of one given elsewhere.

C90

The C90 Standard did not specify when an enumerated type was completed.

C++

The C++ Standard neither specifies that the enumerated type is incomplete at any point or that it becomes complete at any point.

7.2p4 *Following the closing brace of an* `enum-specifier`*, each enumerator has the type of its enumeration*

Example

The definition:

```
enum e_tag { e1 = sizeof(enum e_tag)};
```

is not permitted (it is not possible to take the size of an incomplete type). But:

```
enum e_tag { e1, e2} e_obj[sizeof(enum e_tag)];
```

is conforming.

EXAMPLE The following fragment: 1450

```
enum hue { chartreuse, burgundy, claret=20, winedark };
enum hue col, *cp;
col = claret;
cp = & col;
if (*cp != burgundy)
        /* ... */
```

makes **hue** the tag of an enumeration, and then declares **col** as an object that has that type and **cp** as a pointer to an object that has that type. The enumerated values are in the set { 0, 1, 20, 21 }.

C++

The equivalent example in the C++ Standard uses the enumeration names red, yellow, green and blue.

Other Languages

In Pascal this example could be written as (no explicit assignment of values is supported):

```
1  type
2       hue : ( chartreuse, burgundy, claret, winedark );
```

and in Ada as:

```
1  type
2       hue is ( chartreuse, burgundy, claret, winedark );
3  for hue use (chartreuse => 0, burgundy => 1, claret => 20, winedark => 21);
```

1451 **Forward references:** tags (6.7.2.3).

1452 107) Thus, the identifiers of enumeration constants declared in the same scope shall all be distinct from each other and from other identifiers declared in ordinary declarators. footnote 107

Commentary

This requirement can be deduced from the fact that enumeration constants are in the same name space as ordinary identifiers, they have no linkage, and that only one identifier with these attributes shall (a constraint) be declared in the same scope.

444 name space ordinary identifiers
432 identifier no linkage
1350 declaration only one if no linkage

C++

The C++ Standard does not explicitly make this observation.

Other Languages

Ada permits the same identifier to be defined as an enumeration constant in different enumerated type in the same scope. References to such identifiers have to be explicitly disambiguated.

1453 108) An implementation may delay the choice of which integer type until all enumeration constants have been seen. footnote 108

Commentary

This footnote is discussing the behavior of a translator that processes the source in a single pass. Many translators operate in a single pass and this behavior enables this form of implementation to continue to be used.

10 implementation single pass
10 implementation single pass

An enumerated type is incomplete until after the closing **}**, and there are restrictions on where an incomplete type can be used, based on the size of an object of that type. One situation where the size may be needed is in determining the representation used by an implementation for a pointer to a scalar type (there is no flexibility for pointers to structure and union types). An implementation does not know the minimum storage requirements needed to represent an object having an enumerated type until all of the members of that type had been processed. In the example below, a single pass implementation, that minimizes the storage allocated, and uses different representations for pointers to different scalar types, would not be able to evaluate `sizeof(enum e_T *)` at the point its value is needed to give a value to e2.

1449 enumerated type incomplete until
1465 footnote 109
559 pointer to qualified/unqualified types
560 alignment pointer to structures

```
1  struct s_T;
2  enum e_T {
```

```
3             e1=sizeof(struct s_T *),
4             e2=sizeof(enum e_T *),
5            };
6
```

C90

The C90 Standard did not make this observation about implementation behavior.

C++

This behavior is required of a C++ implementation because:

7.2p5 *The underlying type of an enumeration is an integral type that can represent all the enumerator values defined in the enumeration.*

Common Implementations

Some implementations unconditionally assign the type **int** to all enumerated types. Others assign the integer type with the lowest rank that can represent the values of all of the enumeration constants.

6.7.2.3 Tags

---

type contents defined once

A specific type shall have its content defined at most once. 1454

Commentary

declaration 1350 only one if no linkage

content 1462 list defines

The general requirement that an identifier with no linkage not be declared more than once does not apply to tags. An identifier denoting the same tag can be declared zero or more times if no content is defined. Among these declarations can be one that defines the content. What constitutes *content* is specified elsewhere.

C90

This requirement was not explicitly specified in the C90 Standard (although it might be inferred from the wording), but was added by the response to DR #165.

C++

The C++ Standard does not classify the identifiers that occur after the **enum**, **struct**, or **union** keywords as tags. There is no tag namespace. The identifiers exist in the same namespace as object and typedef identifiers. This namespace does not support multiple definitions of the same name in the same scope (3.3p4). It is this C++ requirement that enforces the C one given above.

---

tag name same struct, union or enum

Where two declarations that use the same tag declare the same type, they shall both use the same choice of **struct**, **union**, or **enum**. 1455

Commentary

This sentence was added by the response to DR #251. The following code violates this constraint:

```
1  struct T {
2             int mem;
3            };
4  union T x; /* Constraint violation. */
```

C90

The C90 Standard did not explicitly specify this constraint. While the behavior was therefore undefined, it is unlikely that the behavior of any existing code will change when processed by a C99 translator (and no difference is flagged here).

C++

7.1.5.3p3

The `class-key` *or* **`enum`** *keyword present in the* `elaborated-type-specifier` *shall agree in kind with the declaration to which the name in the* `elaborated-type-specifier` *refers.*

Common Implementations

Early translators allowed the **`struct`** and **`union`** keywords to be intermixed (i.e., the above example was considered to be valid).

1456 A type specifier of the form

```
enum identifier
```

without an enumerator list shall only appear after the type it specifies is complete.

Commentary

Incomplete types are needed to support the declaration of mutually recursive structure and union types. It is not possible to create a mutually recursive enumerated type and a declaration making use of self-referencing recursion is an edge case that does not appear to be of practical use.

C90

This C99 requirement was not specified in C90, which did not containing any wording that ruled out the declaration of an incomplete enumerated type (and confirmed by the response to DR #118). Adding this constraint brings the behavior of enumeration types in line with that for structure and union types. 1118 sizeof constraints
Source code containing declarations of incomplete enumerator types will cause C99 translators to issue a diagnostic, where a C90 translator was not required to issue one.

```
1  enum E1 { ec_1 = sizeof (enum E1) };   /* Constraint violation in C99. */
2  enum E2 { ec_2 = sizeof (enum E2 *) }; /* Constraint violation in C99. */
```

C++

[Note: if the `elaborated-type-specifier` *designates an enumeration, the* `identifier` *must refer to an already declared* `enum-name`*.* 3.3.1p5

If the `elaborated-type-specifier` *refers to an* `enum-name` *and this lookup does not find a previously declared* `enum-name`*, the* `elaborated-type-specifier` *is ill-formed.* 3.4.4p2

```
1  enum incomplete_tag *x; /* constraint violation */
2                          // undefined behavior
3
4  enum also_incomplete; /* constraint violation */
5                        // ill-formed
```

Semantics

1457 All declarations of structure, union, or enumerated types that have the same scope and use the same tag declare the same type. tag declarations same scope

Commentary

What constitutes a declaration of structure, union, or enumerated type? The answer depends on whether a prior declaration, using the same identifier as a tag, is visible. If such an identifier is visible at the point of another declaration, no new type is declared (and there may also be a constraint violation).

struct-or-union identifier visible 1472
type contents defined once 1454

```
1  struct T_1 {   /* A declaration (1) of tag T_1. */
2              int mem_1;
3             };
4
5  void f(void)
6  {
7  struct T_1 *p; /* Prior declaration (1) is visible, not a declaration of T_1. */
8  struct T_1 {   /* A declaration (2) of tag T_1. */
9              float mem_2;
10            };
11 struct T_1 *q; /* Prior declaration (2) is visible and used. */
12 struct U_1 *r; /* No prior declaration of U_1 visible, a declaration of U_1. */
13 struct U_1 {   /* Defines the content of prior declaration of U_1. */
14             void *mem_3;
15            };
16
17 sizeof(p->mem_1);
18 sizeof(q->mem_2);
19 sizeof(r->mem_3);
20 }
```

struct-or-union identifier visible 1472

The wording that covers tags denoting the same type, but declared in different scopes occurs elsewhere.

C90

This requirement was not explicitly specified in the C90 Standard (although it might be inferred from the wording), but was added by the response to DR #165.

C++

The C++ Standard specifies this behavior for class types (9.1p2). While this behavior is not specified for enumerated types, it is not possible to have multiple declarations of such types.

Coding Guidelines

identifier declared in one file 422.1

If the guideline recommendation specifying a single point of declaration is followed, the only situation where a tag, denoting the same type, is declared more than once is when its type refers to another type in some mutually recursive way.

---

tag incomplete until

The type is incomplete[109)] until the closing brace of the list defining the content, and complete thereafter. 1458

Commentary

The closing brace that defines its content may occur in a separate declaration. Incomplete types are one of the three kinds of types defined in C. The only other incomplete type is **void**, which can never be completed.

incomplete types 475
void is incomplete type 523

C++

The C++ Standard specifies this behavior for class types (9.2p2), but is silent on the topic for enumerated types.

---

tag declarations different scope

Two declarations of structure, union, or enumerated types which are in different scopes or use different tags declare distinct types. 1459

Commentary

tag declarations same scope 1457

The discussion on what constitutes a declaration is also applicable here.

```
1  struct T_1 {           /* A declaration (1) of tag T_1. */
2              int mem_1;
3             };
4
5  void f(void)
6  {
7  struct T_1 *p; /* Prior declaration (1) is visible, not a declaration of T_1. */
8  struct T_1;    /* This is always a declaration, it is a different type from (1). */
9  struct T_1 *q; /* q points at a different type than p. */
10 }
11
12 void g(struct T_1 *); /* Prior declaration visible, not a declaration of T_1. */
13 void h(struct U_1 *); /* No prior declaration visible, a declaration of U_1.  */
```

C90

The C99 Standard more clearly specifies the intended behavior, which had to be inferred in the C90 Standard. 1457 tag declarations same scope

C++

The C++ Standard specifies this behavior for class definitions (9.1p1), but does not explicitly specify this behavior for declarations in different scope.

Coding Guidelines

If the guideline recommendation dealing with the reuse of identifier names is followed there will never be two distinct types with the same name. The case of distinct tags being declared with function prototype scope does not need a guideline recommendation. Such a declaration will render the function uncallable, as no type can be declared to be compatible with its parameter type. A translator will issue a diagnostic if a call to it occurs in the source. 792.3 identifier reusing names

---

1460 Each declaration of a structure, union, or enumerated type which does not include a tag declares a distinct type. struct/union declaration no tag

Commentary

A declaration of a structure or union type that includes a tag may declare a distinct type, or it may refer to a previously declared distinct type.

If one of the identifiers declared is a typedef name, it will be possible to refer to the type in other contexts. If the identifier being declared is an object there is no standard defined way of referring to its type. Such types are sometimes known as *anonymous* types. 1468 footnote 110

Two types have compatible type if they are the same. Types that are distinct are not the same. 631 compatible type if

C90

The C90 Standard refers to a " . . . a new structure, union, or enumerated type," without specifying the distinctness of new types. The C99 Standard clarified the meaning.

C++

The C++ Standard specifies that a class definition introduces a new type, 9.1p1 (which by implication is distinct). However, it does not explicitly specify the status of the type that is created when the tag (a C term) is omitted in a declaration.

Other Languages

A small number of languages (e.g., CHILL) use structural equivalence for their type compatibility rules, rather than name equivalence. In such cases it is possible for many different type declarations to be treated as being compatible. 650 structural equivalence

Common Implementations

Some implementations (`gcc`) include the **`typeof`** operator. This returns the type of its operand. With the availability of such an operator no types can be said to be anonymous.

A type specifier of the form 1461

struct-or-union *identifier*$_{opt}$ **{** *struct-declaration-list* **}**

or

enum *identifier* **{** *enumerator-list* **}**

or

enum *identifier* **{** *enumerator-list* **,** **}**

declares a structure, union, or enumerated type.

Commentary

type specifier 1378 syntax struct tag; 1464

This specification provides semantics for a subset of the possible token sequences supported by the syntax of *type-specifier*. The difference between this brace delimited form and the semicolon terminated form is similar to the difference between the brace delimited and semicolon terminated form of function declarations (i.e., one specifies content and the other doesn't).

C90

Support for the comma terminated form of enumerated type declaration is new in C99.

C++

The C++ Standard does not explicitly specify this semantics (although 9p4 comes close).

content list defines

The list defines the *structure content*, *union content*, or *enumeration content*. 1462

Commentary

type 1454 contents defined once identifier 406 scope determined by declaration placement name space 438

This defines the terms *structure content*, *union content*, or *enumeration content*, which is the *content* referred to by the constraint requirement. The content is the members of the type declared, plus any type declarations contained within the declaration. Any identifiers declared by the list has the same scope as that of the tag, that might be defined, and may be in several name spaces.

Other Languages

Object-oriented languages allow additional members to be added to a class (structure) through the mechanism of inheritance.

tag declare

If an identifier is provided,[110)] the type specifier also declares the identifier to be the tag of that type. 1463

Commentary

This provides the semantic association for the identifier that appears at this point in the syntax.

C++

The term *tag* is not used in C++, which calls the equivalent construct a *class name*.

Table 1463.1: Occurrence of types declared with tag names (as a percentage of all occurrences of each keyword). Based on the visible form of the `.c` and `.h` files.

	`.c` files	`.h` files
union identifier	65.5	75.8
struct identifier	99.0	88.4
enum identifier	86.6	53.6

1464 A declaration of the form

struct tag;

```
struct-or-union identifier ;
```

specifies a structure or union type and declares the identifier as a tag of that type.[111]

Commentary

This form of declaration either declares, or redeclares, the identifier, as a tag, in the current scope. The following are some of the uses for this form of declaration:

- To support mutually referring declarations when there is the possibility that a declaration of one of the tags is already visible.
- To provide a mechanism for information hiding. Developers can declare a tag in an interface without specifying the details of a types implementation,
- In automatically generated code, where the generator does not yet have sufficient information to fully define the content of the type, but still needs to refer to it.

1474 EXAMPLE mutually referential structures

1465 109) An incomplete type may only by used when the size of an object of that type is not needed.

footnote 109 size needed

Commentary

When is the size of an object not needed? Who, or what needs the size and when do they need it?

The implementation needs the size of objects to allocate storage for them. When does storage need to be allocated for an object? In theory, not until the object is encountered during program execution (and in practice for a few languages). However, delaying storage allocation until program execution incurs a high-performance penalty. Knowing the size during translation enables much more efficient machine code to be generated. Also, knowing the size when the type is first encountered (if the size has to be known by the implementation) can simplify the job of writing a translator (many existing translators operated in a single pass).

1354 object reserve storage

10 implementation single pass

The size of an object having an incomplete array type is not needed to access an element of that array.

728 incomplete array indexing

The Committee responses to defect reports (e.g., DR #017) asking where the size of an object is needed do not provide a list of places. Now the wording has been moved to a footnote, perhaps this discussion will subside.

C90

It declares a tag that specifies a type that may be used only when the size of an object of the specified type is not needed.

The above sentence appears in the main body of the standard, not a footnote.

The C99 wording is more general in that it includes all incomplete types. This is not a difference in behavior because these types are already allowed to occur in the same context as an incomplete structure/union type.

475 incomplete types

C++

The C++ Standard contains no such rule, but enumerates the cases:

3.9p8

[Note: the rules for declarations and expressions describe in which contexts incomplete types are prohibited.]

Other Languages

Knowing the size of objects is an issue in all computer languages. When the size needs to be known is sometimes decided by high-level issues of language design (some languages require their translators to effectively perform more than one pass over the source code), other times it is decided by implementation techniques.

Common Implementations

implementation 10 single pass

Most C translators perform a single pass over the source code, from the point of view of syntactic and semantic processing. An optimizer may perform multiple passes over the internal representation of statements in a function, deciding how best to generate machine code for them.

---

size not needed examples

It is not needed, for example, when a typedef name is declared to be a specifier for a structure or union, or when a pointer to or a function returning a structure or union is being declared. (See incomplete types in 6.2.5.) 1466

Commentary

typedef 1633 is synonym

alignment 560 pointer to structures

alignment 561 pointer to unions

A typedef name is simply a synonym for the type declared. All pointers to structure types and all pointers to union types have the same alignment requirements. No information on their content is required. The size may not be needed when a function returning a structure or union is declared, but it is needed when such a function is defined.

Other Languages

Many languages support some form of pointer to generic type, where little information (including size) is known about the pointed-to type. Support for type declarations where the size is unknown, in other contexts, varies between languages. In Java the number of elements in an array type is specified during program execution.

Common Implementations

This is one area where vendors are often silent on how their language extensions operate. For instance, the `gcc` **`typeof`** operator returns the type of its operand. However, the associated documentation says nothing about the case of the operand type being incomplete and having a tag that is identical to another definition occurring within the scope that the **`typeof`** occurred. One interpretation (unsupported by any specification from the vendor) of the following:

```
1  extern struct fred f;
2
3  int main (void)
4  {
5  typeof (f) *x;
6  struct fred { int x; } s;
7  typeof (f) *y;
8  y=&s;                  /* Types not compatible? */
9  }
10
11 struct fred {
12              int mem;
13             };
```

is that both `x` and `y` are being declared as being pointers to the type of `f`, that is an incomplete type, and that the declaration of the tag `fred`, in a nested scope, has no effect on the declaration of `y`.

Example

```
1  typedef struct foo T;
2
3  struct foo *ptr;
4  struct foo f(void);
5
6  void g(void *p)
7  {
8  (struct foo *)p;
9  }
```

1467 The specification has to be complete before such a function is called or defined.

Commentary

In these contexts the commonly used methods for mapping source code to machine code need to know the number of bytes in a types object representation.

C90

The specification shall be complete before such a function is called or defined.

The form of wording has been changed from appearing to be a requirement (which would not be normative in a footnote) to being commentary.

1468 110) If there is no identifier, the type can, within the translation unit, only be referred to by the declaration of which it is a part.

footnote 110

Commentary

The requirements for referring to objects declared using such types are discussed elsewhere. Such types are distinct and are said to be *anonymous*. They cannot be referred to elsewhere in the translation unit. Although their associated objects can be accessed. In:

633 compatible separate translation units
1460 struct/union declaration no tag

```
1  struct {
2           int m1;
3          } x, y;
4  struct {
5           int m1;
6          } z;
```

x and y are compatible with each other. They both have the same anonymous type, but the object z has a different anonymous type. Note that the types of the objects x, y, and z would be considered to be compatible if they occurred in different translation units.

633 compatible separate translation units

C90

This observation was is new in the C90 Standard.

C++

The C++ Standard does not make this observation.

Other Languages

Some languages include a **`typeof`** operator, which returns the type of its operand.

Common Implementations

Some implementations include a **typeof** operator. This returns the type of its operand. The availability of such an operator means that no types never need be truely anonymous.

Of course, when the declaration is of a typedef name, subsequent declarations can make use of that typedef name to declare objects having the specified structure, union, or enumerated type. 1469

Commentary

Use of a typedef name does not alter the requirements on the type not being an incomplete type in some contexts. size needed 1465

```
1  struct S;
2  typedef struct S t_1;
3  extern t_1 f(void);
4
5  struct S {
6            int mem;
7           };
8  typedef struct S t_2;
9  t_2 glob;
10
11 t_1 f(void)
12 {
13 return glob;
14 }
```

C90

This observation is new in the C90 Standard.

C++

The C++ Standard does not make this observation.

Example

In the following both a and b have the same type. The typedef name T_S provides a method of referring to the anonymous structure type.

```
1  typedef struct {
2                 int m2;
3                 } T_S;
4  T_S a;
5  T_S b;
```

---

111) A similar construction with **enum** does not exist. footnote 111 1470

Commentary

The need for mutual recursion between different enumerated types is almost unheard of. One possible use of such a construct might be to support the hiding of enumeration values. For instance, an object of such an enumeration type might be passed as a parameter which only ever appeared as an argument to function calls. However, C99 considers the following usage to contain a number of constraint violations.

```
1  enum SOME_STATUS_SET; /* First constraint violation. */
2
3  extern enum SOME_STATUS_SET get_status(void);
4  extern void use_status(enum SOME_STATUS_SET *);
```

C++

If an `elaborated-type-specifier` *is the sole constituent of a declaration, the declaration is ill-formed unless . . .* 7.1.5.3p1

The C++ Standard does not list `enum identifier ;` among the list of exceptions and a conforming C++ translator is required to issue a diagnostic for any instances of this usage.

The C++ Standard agrees with this footnote for its second reference in the C90 Standard.

1471 struct-or-union identifier not visible

1471 If a type specifier of the form

struct-or-union identifier not visible

struct-or-union identifier

occurs other than as part of one of the above forms, and no other declaration of the identifier as a tag is visible, then it declares an incomplete structure or union type, and declares the identifier as the tag of that type.[111]

Commentary

The forms of *struct-or-union identifier*, excluded by this wording, are the identifier being followed by a semicolon or a left brace. The remaining possible occurrences of this form are described elsewhere and include:

1466 size not needed examples

```
1  struct secret_info *point_but_not_look;
```

C++

The C++ Standard does not explicitly discuss this kind of construction/occurrence, although 3.9p6 and 3.9p7 discuss this form of incomplete type.

Coding Guidelines

When no other declaration is visible at the point this type specifier occurs, should this usage be permitted? Perhaps it was intended that a tag be visible at the point in the source where this type specifier occurs. However, not having a prior declaration visible is either harmless (intended or otherwise), or will cause a diagnostic to be issued by a translator.

A pointer to an incomplete structure or union type is a more strongly typed form of generic pointer than a pointer to **void**. Whether this use of pointer to incomplete types, for information hiding purposes, is worthwhile can only be decided by the developer.

1472 If a type specifier of the form

struct-or-union identifier visible

struct-or-union identifier

or

enum *identifier*

occurs other than as part of one of the above forms, and a declaration of the identifier as a tag is visible, then it specifies the same type as that other declaration, and does not redeclare the tag.

Commentary

The forms of *struct-or-union identifier*, excluded by this wording, are the identifier being followed by a semicolon or a left brace. This is the one form that is not a declaration.

Coding Guidelines

type 1454 contents defined once

culture of C 0

Technically the only reason for using tags is to define mutually recursive structure or union types. However, in practice this is the most common form used to declare objects having structure, union, or enumerated types. In general these coding guidelines recommend that developers continue to following common existing practices. Given that most existing code contains declarations that use this form of type specifier, is there a worthwhile benefit in recommending use of an alternative form? The following are some of the issues involved in the obvious alternative form, the use of typedef names:

- While the use of a typedef name may appear to reduce future maintenance costs (e.g., if the underlying type changes from a structure to an array type, a single edit to the definition of a typedef name is sufficient to change to any associated object declarations). In practice the bulk of the costs associated with such a change are created by the need to modify the operators used to access the object (i.e., from a member selection operator to a subscript operator). Also experience suggests that this kind of change in type is not common.
- Changes in an objects structure type may occur as a program evolves. For instance, the object `x` may have structure type `t_1` because it needs to represent information denoted by a few of the members of that type. At a later time the type `t_1` may be subdivided into several structure types, with the members referenced by `x` being declared in the type `t_1_3`. Developers then have the choice of changing the declaration of `x` to be `t_1_3`, or leaving it alone. However, the prior use of a typedef name, rather than a tag, is unlikely to result in any cost savings, when changing the declaration of `x` (i.e., developers are likely to have declared `x` to have type `t_1`, rather than a synonym of that type, so the declaration of `x` will either have to be edited).
- What are the cognitive costs and benefits associated with the presence, or absence of a keyword in the source of a declaration? There is a cost to readers in having to process an extra token (i.e., the keyword) in the visible source, or any benefits, to readers of the visible source. However, the visual presence of this keyword may reduce the cognitive effort needed to deduce the kind of declaration being made. There does not appear to be a significant cost/benefit difference between any of these cognitive issues.

EXAMPLE 1 This mechanism allows declaration of a self-referential structure. 1473

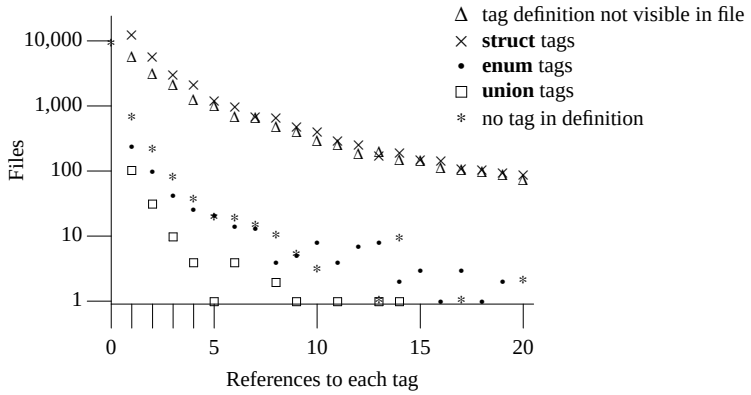

Figure 1472.1: Number of files containing a given number of references to each tag previously defined in the visible source of that file (times, bullet, square; the definition itself is not included in the count), tags with no definition visible in the `.c` file (triangle; i.e., it is defined in a header) and anonymous structure/union/enumeration definitions (star). Based on the visible form of the `.c` files.

```
struct tnode {
        int count;
        struct tnode *left, *right;
};
```

specifies a structure that contains an integer and two pointers to objects of the same type. Once this declaration has been given, the declaration

```
struct tnode s, *sp;
```

declares **s** to be an object of the given type and **sp** to be a pointer to an object of the given type. With these declarations, the expression **sp->left** refers to the left **struct tnode** pointer of the object to which **sp** points; the expression **s.right->count** designates the **count** member of the right **struct tnode** pointed to from **s**. The following alternative formulation uses the **typedef** mechanism:

```
typedef struct tnode TNODE;
struct tnode {
        int count;
        TNODE *left, *right;
};
TNODE s, *sp;
```

Commentary

Both of these formulations of commonly seen in source code.

Other Languages

Creating a self-referential type in Pascal requires the definition of two type names.

```
1  type
2     TNODE_PTR = ^TNODE; (* special rules covers this forward reference case *)
3     TNODE = record
4             count : integer;
5             left,
6             right : TNODE_PTR
7             end;
```

1474 EXAMPLE 2 To illustrate the use of prior declaration of a tag to specify a pair of mutually referential structures, the declarations

EXAMPLE mutually referential structures

```
struct s1 { struct s2 *s2p; /* ... */ }; // D1
struct s2 { struct s1 *s1p; /* ... */ }; // D2
```

specify a pair of structures that contain pointers to each other. Note, however, that if **s2** were already declared as a tag in an enclosing scope, the declaration **D1** would refer to *it*, not to the tag **s2** declared in **D2**. To eliminate this context sensitivity, the declaration

```
struct s2;
```

may be inserted ahead of **D1**. This declares a new tag **s2** in the inner scope; the declaration **D2** then completes the specification of the new type.

Commentary

```
1  struct s2 { int mem1; };
2
3  void f(void)
4  {
5  struct s2;
6  struct s1 { struct s2 *s2p; /* ... */ };
7  struct s2 { struct s1 *s1p; /* ... */ };
8  }
```

without the declaration of the tag s2 in the body of f, the declaration at file scope would be visible and the member s2p would refer to it, rather than the subsequence definition in the same scope,

C++

This form of declaration would not have the desired affect in C++ because the braces form a scope. The declaration of s2 would need to be completed within that scope, unless there was a prior visible declaration it could refer to.

Forward references: declarators (6.7.5), array declarators (6.7.5.2), type definitions (6.7.7). 1475

6.7.3 Type qualifiers

type qualifier syntax

1476

type-qualifier:
const
restrict
volatile

Commentary

Rationale

Type qualifiers were introduced in part to provide greater control over optimization. Several important optimization techniques are based on the principle of "cacheing": under certain circumstances the compiler can remember the last value accessed (read or written) from a location, and use this retained value the next time that location is read. (The memory, or "cache", is typically a hardware register.) If this memory is a machine register, for instance, the code can be smaller and faster using the register rather than accessing external memory.

C90

Support for **restrict** is new in C99.

C++

Support for **restrict** is new in C99 and is not specified in the C++ Standard.

Other Languages

Some languages use the keyword **read**, or **readonly** as a type qualifier to indicate that an object can only be read from. BCPL uses **MANIFEST**.

Common Implementations

The keyword **noalias** was included in some drafts of the C90 Standard. It provided functionality whose intended use was similar to that provided by the keyword **restrict** in C99.

Coding Guidelines

declaration specifier ordering 1357.1

A guideline on the relative order of type qualifiers within a declaration specifier is given elsewhere.

Usage

Developers do not always make full use of the **const** qualifier. An automated analysis[437] of programs whose declarations contained a relatively high percentage (29%) of **const** qualifiers found that it would have been possible to declare 70% of the declarations using this qualifier. Engblom[389] reported that for real-time embedded C code 17% of object declarations contained the **const** type qualifier.

Table 1476.1: Common token sequences containing *type-qualifier*s (as a percentage of each *type-qualifier*). Based on the visible form of the `.c` files.

Token Sequence	% Occurrence First Token	% Occurrence of Second Token	Token Sequence	% Occurrence First Token	% Occurrence of Second Token
; volatile	0.1	36.1	**{ const**	0.2	5.6
, **const**	0.2	32.8	**const unsigned**	6.2	1.4
(const	0.2	28.1	**const struct**	11.1	1.3
(volatile	0.0	26.2	**volatile unsigned**	25.6	1.1
; const	0.1	14.1	**const void**	5.3	0.8
identifier **volatile**	0.0	11.4	**volatile struct**	15.5	0.4
{ volatile	0.1	11.0	**volatile int**	7.4	0.1
const char	54.1	10.4	**volatile** identifier	36.2	0.0
static const	1.5	10.0	**volatile (**	8.9	0.0
static volatile	0.3	8.6	**const** identifier	17.6	0.0

Constraints

1477 Types other than pointer types derived from object or incomplete types shall not be restrict-qualified.

restrict constraint

Commentary

The specification of the **restrict** qualifier only defines the behavior for pointers that refer to objects (because it is only intended to deal with such quantities). In the case of function parameters having array type (e.g., `void f(float a[restrict][100]);`) the implicit conversion to pointer type occurs before this constraint is applied (this intent is expressed in WG14/N521, an example in the standard, and the rationale).

1502 restrict formal definition
729 array converted to pointer
1622 EXAMPLE compatible function prototypes
1599 function declarator static

Semantics

1478 The properties associated with qualified types are meaningful only for expressions that are lvalues.[112)]

qualifier meaningful for lvalues

Commentary

Although type qualifiers are specified in terms of creating new type, they really act as modifiers of the declarator. Use of these keywords gives a type additional properties. However, they do not change its representation or alignment requirements. These properties are associated with the declared object, not its value (although they all specify something about the possible attributes of the values by the objects declared using them). A qualified type can be applied to a non-lvalue through the use of a cast operator (e.g., `(const long)1`).

556 qualifiers representation and alignment

C++

The C++ Standard also associates properties of qualified types with rvalues (3.10p3). Such cases apply to constructs that are C++ specific and not available in C.

Common Implementations

Some implementations support directives that allow the developer to specify which areas of storage objects or literals are to be held in.

Coding Guidelines

The fact that type qualifiers are only meaningful for lvalue expressions does not prevent developers using them in other contexts. Such usage is redundant and does not affect how a translator should interpret the behavior of a program (the issue of redundant code is discussed elsewhere). Is there a worthwhile benefit recommending against the use of type qualifiers in contexts where they have no meaning? The usage, in the visible source and not via a typedef name, suggests that the author may believe it has some affect on the behavior of the program. In practice such usage is very rare and the developer misconception harmless.

190 redundant code

1479 If the same qualifier appears more than once in the same *specifier-qualifier-list*, either directly or via one or more **typedef**s, the behavior is the same as if it appeared only once.

qualifier appears more than once

Commentary

Having the same qualifier appear more than once in the same *specifier-qualifier-list* may be redundant, but it is harmless. Support for such usage can simplify the automatic generation of C source code and reduce the amount of coordination needed between different development groups (e.g., over who is responsible for ensuring a given qualifier appears in a chain of typedef names; qualifiers can appear on in typedef name defined by a group, independent of any references it makes to typedef names defined by other development groups). It can also reduce maintenance costs for existing source (e.g., a change to the definition of a typedef name does not have any cascading affects on any existing declarations it appears in with qualifiers). The same permission is given for function specifiers.

function specifier appears more than once 1527

C90

The following occurs within a Constraints clause.

> *The same type qualifier shall not appear more than once in the same specifier list or qualifier list, either directly or via one or more* **typedef***s.*

Source code containing a declaration with the same qualifier appearing more than once in the same *specifier-qualifier-list* will cause a C90 translator to issue a diagnostic.

C++

7.1.5p1 > *However, redundant cv-qualifiers are prohibited except when introduced through the use of typedefs (7.1.3) or template type arguments (14.3), in which case the redundant cv-qualifiers are ignored.*

The C++ Standard does not define the term *prohibited*. Applying common usage to this term suggests that it is to be interpreted as a violation of a diagnosable (because "no diagnostic is required", 1.4p1, has not been specified) rule.

The C++ specification is intermediate between that of C90 and C99.

```
1  const const int cci; /* does not change the conformance status of program */
2                       // in violation of a diagnosable rule
```

Coding Guidelines

Is there a worthwhile benefit recommending against having the same qualifier appears more than once in the same *specifier-qualifier-list*?

There is an obvious organizational and maintenance benefit in allowing the same qualifier to occur more than once via typedefs. Having the same qualifier appear more than once in the visible source of a *specifier-qualifier-list* suggests that insufficient attention was invested by the original author. This usage also requires subsequent readers to invest more cognitive effort in comprehending the declaration. However, support for this usage is new in C99 and measurements of source show an underuse of the most common qualifier (i.e., **const**). Overuse of qualifiers does not look like it will be an issue that needs addressing via a guideline. Such usage is redundant and does not affect the behavior of a program (the issue of redundant code is discussed elsewhere).

redundant code 190

Example

```
1  const const int glob_1;
2  const int const long const extern const signed const glob_2;
3
4  typedef const int C_I;
5  typedef const C_I const_C_I;
```

1480 If an attempt is made to modify an object defined with a const-qualified type through use of an lvalue with non-const-qualified type, the behavior is undefined.

const qualified attempt modify

Commentary

Modifying a const-qualified object requires the use of a pointer to it (plus an appropriate cast operation; attempting to modify the object using its declared type is a constraint violation). The undecidability of detecting all such pointer usages at translation time and the overhead of performing the check during program execution resulted in the committee specifying the behavior as undefined, rather than a constraint violation.

1289 assignment operator modifiable lvalue

1502 restrict formal definition

The author of the source may intend a use of the **const** qualifier to imply a read-only object, and a translator may treat it as such. However, a translator is not required to perform any checks at translation or execution time to ensure that the object is not modified (via some pointer to it).

C++

An lvalue for an object is necessary in order to modify the object except that an rvalue of class type can also be used to modify its referent under certain circumstances. [Example: a member function called for an object (9.3) can modify the object.]

3.10p10

The C++ Standard specifies a different linkage for some objects declared using a const-qualified type.

425 static internal linkage

Other Languages

Languages that contain some form of readonly qualifier usually specify that so qualified objects cannot be modified and attempts to perform such modifications are treated as errors. There is usually some indirect mechanism that will have the effect of modifying such objects, and few implementations are required to detect such modifications during program execution.

Common Implementations

Some freestanding implementations place static storage duration, const-qualified, objects in read-only memory. While it might be possible to write to this memory, the value of objects held there are not modified by such operations. Some hosted implementations place static storage duration, const-qualified, objects in a region of storage marked as read-only (some processor memory management units support such types of memory and automatically perform checks on accesses to it).

Many implementations place const-qualified objects in the same kind of storage as other objects. However, this does not mean that if these qualified objects are modified, the modified value is actually used by a program. A translator may reduce optimization overhead by assuming const-qualified objects are never modified. This could result in values held in registers being reused, after the object held in storage had been modified.

Coding Guidelines

There are many different ways of attempting to modify a const-qualified object. Enumerating all such cases would create an unnecessarily large number of guidelines, and is not guaranteed to catch all cases. To be able to attempt to modify a const-qualified object, without a translator issuing a diagnostic, it is necessary to use an explicit cast. A single guideline covering this case is discussed elsewhere and deals with the issue at the point potential for problems starts.

1135 pointer conversion constraints

Example

```
1  extern const int g_1 = 3;
2  extern int g_2;
3
4  void f(const int *pi);
5  /*
```

```
 * The declaration of pi implies that the statements within f will
 * not modify its value.  However, an optimizer cannot assume that
 * the value *pi will remain unchanged throughout the execution of
 * f.  For instance the function f may modify g_2; whose address
 * is passed as an argument in the second call below.
 */

void g(void)
{
const int *loc_1 = &g_1;
int *loc_2 = &g_2;

f(loc_1);
f((const int *)loc_2);
}
```

EXAMPLE 1309 const pointer

Also see an example elsewhere.

---

volatile qualified attempt modify

If an attempt is made to refer to an object defined with a volatile-qualified type through use of an lvalue with non-volatile-qualified type, the behavior is undefined.[113)] 1481

Commentary

const 1480 qualified attempt modify

The issues are the same as for the const-qualified case.

Common Implementations

The extent to which the behavior, in this case, differs from that intended will depend on the optimizations performed by an implementation. If an implementation has reused a value, held in a register because it was accessed via a non-volatile-qualified type, there will be no access to the volatile-qualified object. Presumably the object was declared to have volatile-qualified type because accesses to it caused some external affect. The difference on the behavior of a program, because of less accesses to such a qualified object can only be guessed at.

Coding Guidelines

pointer conversion 1135 constraints

Like the const-qualified case, the appropriate guideline recommendation is discussed elsewhere.

Example

```
extern volatile int glob_1;

void f(int *p_1)
{
(*p_1)++;
(*p_1)++;
}

void g(void)
{
f((int *)glob_1);
}
```

---

volatile last-stored value

An object that has volatile-qualified type may be modified in ways unknown to the implementation or have other unknown side effects. 1482

Commentary

The **volatile** qualifier informs the implementation that it would be unsafe to optimize accesses to objects declared using it.

Other Languages

The **volatile** field modifier in Java is used to provide a method of ensuring that accesses to objects whose values may be modified by different threads are reconciled with the master copy in shared memory.

Common Implementations

The **volatile** qualifier is mainly seen in freestanding implementations and hosted implementations where storage is shared between multiple programs. The following are some of the behaviors often seen for objects declared using this qualifier:

- Updating an object on a periodic basis (e.g., a realtime clock).
- Modifying an object after every read from it (e.g., instance, an input device sending characters down a serial line).
- An object may not contain the value last written to it (e.g., an output port, where reading from that location returns the status of the write operation).

The only meaningful volatile-qualified objects are often declared by the implementation, as part of a vendor supplied API. This is because having an object modified in ways unknown to the implementation usually involves associating it with some external device. Such associations usually require making use of some implementation provided language extension, or by passing the address of the object to a vendor supplied library function.

Coding Guidelines

Qualifying an object declaration with **volatile** may inform the translator that it may be modified in ways unknown, but how well will developers understand the implications of the changing value? For instance, in:

```
1  extern volatile long seconds_since_midnight;
2
3  void f(void)
4  {
5  int now_hours = (seconds_since_midnight / 3600);
6  int now_minutes = (seconds_since_midnight / 60);
7  int now_seconds = (seconds_since_midnight % 60);
8  }
```

the time at the start of the evaluation of the expression assigned to `now_hours` may have been 9:59:59 and at the start of the evaluation of the expression assigned to `now_minutes` 10:00:00. The values of the three objects would then be identical to the time obtained at 9:00:00.

Rev 1482.1 A sequence of related expressions that accesses the value of the same volatile-qualified object shall be checked to ensure the changeability of the volatile nature of the objects value has been taken into account.

1483 Therefore any expression referring to such an object shall be evaluated strictly according to the rules of the abstract machine, as described in 5.1.2.3.

Commentary

This is a requirement on the implementation. The possibility of a third-party library configuring a hardware device to update the contents of an object, whose address was passed as a parameter, means that implementations cannot assume that volatile-qualified objects contain known values, just because the implementation provides no mechanism for associating them with a hardware device.

C++

There is no equivalent statement in the C++ Standard. But it can be deduced from the following two paragraphs:

1.9p5 *A conforming implementation executing a well-formed program shall produce the same observable behavior as one of the possible execution sequences of the corresponding instance of the abstract machine with the same program and the same input.*

1.9p6 *The observable behavior of the abstract machine is its sequence of reads and writes to* **`volatile`** *data and calls to library I/O functions.*[6)]

Furthermore, at every sequence point the value last stored in the object shall agree with that prescribed by the abstract machine, except as modified by the unknown factors mentioned previously.[114)] 1484

Commentary

This is a requirement on the implementation. As well as performing the same number of accesses required by the abstract machine, updates to the stored value must have occurred in the order in which sequence points are reached (multiple accesses to the same volatile-qualified object between successive sequence points results in undefined behavior). The extent to which this requirement gives developers the ability to predict the value last stored in an object will depend on the uniqueness of the ordering of sequence points. These issues are also discussed in a C Standard example given elsewhere.

object 941 modified once between sequence points
sequence 187 points

example

---

footnote 112

112) The implementation may place a **`const`** object that is not **`volatile`** in a read-only region of storage. 1485

Commentary

The following are some of possible benefits of using read-only storage:

- the cost of ROM is significantly lower than that of RAM,
- the contents of ROM are not lost when power to the computer is switched off, and
- it may be possible to cause write accesses to regions of storage that an operating system has marked as being read-only to raise an exception that can be caught by a program debugging tool.

const volatile 1496 EXAMPLE

In some cases a **`const`** object that is **`volatile`** can be in a read-only region of storage.

C++

The C++ Standard does not make this observation.

Common Implementations

Sometimes the storage is physically read-only, as in ROM hardware. Sometimes implementations make use of a host operating system's ability to configure regions of storage as read-only, after the program image has been loaded, and enforcing that requirement (invariably through hardware assisted, memory management support).

Moreover, the implementation need not allocate storage for such an object if its address is never used. 1486

Commentary

An implementation need not allocate storage for any object whose address is never used. The difference with const-qualified objects is that a translator often knows in advance what their value is going to be, through out the execution of a program (it appears in the initialization of the objects definition). If this value is a constant expression the translator can substitute it wherever the identifier denoting the const-qualified object occurs. A translator could treat members of a const-qualified structure object in a similar fashion. If such substitutions were made, the undefined behavior associated with any attempts to modify the value being to have no effect.

1480 const qualified attempt modify

C++

The C++ Standard does not make this observation. However, given C++ supports zero sized objects, 1.8p5, there may be other cases where implementations need not allocate storage.

Common Implementations

Replacing references to objects by their known values, at a given point in a program, is not limited to const-qualified objects. However, significantly more analysis is needed for translators to perform this kind of substitution on references to non-const-qualified objects.

1487 113) This applies to those objects that behave as if they were defined with qualified types, even if they are never actually defined as objects in the program (such as an object at a memory-mapped input/output address).

footnote 113

Commentary

Such objects may exist in the addressable storage of a program and accessed by casting an integer value, representing that address, to a pointer type. The properties associated with the qualification of a pointed-to type always apply, no matter what location in storage is pointed at.

C++

The C++ Standard does not make this observation.

1488 What constitutes an access to an object that has volatile-qualified type is implementation-defined.

Commentary

This implementation-defined behavior is caused by the different possible ways an implementation can access an objects having bit-field types.

```
1   extern volatile int glob;
2
3   struct {
4           volatile unsigned int m_1 :5;
5                    unsigned int m_2 :5;
6           volatile unsigned int m_3 :5;
7          } x;
8
9   void f(void)
10  {
11  glob = glob + 1;
12  glob++;
13
14  x.m_1 = 2;
15  x.m_2 = 3;
16  int loc = x.m_2 + x.m_2;
17  }
```

The first increment of `glob` would generally be considered to involve two accesses. The second increment of `glob` could be performed in one access on some processors (those whose having an increment memory instruction), but two accesses on other processors (the majority, which effectively perform the sequence load/increment/store).

In the second set of assignments the access methods are likely to be fundamentally different. One or more bit-fields might be packed into the same storage unit. The assignment to `m_1` may need to read from the storage unit that holds its value, to obtain the value of the bits representing the member `m_2` (so they can be bitwise-AND'ed with the new value, unless the processor supports some form of bit-field access instruction). Assignments to non-bit-field objects do not normally involve a read of their value. An even more surprising access could occur through the assignment to `m_2`, which could also cause the members `m_1` or `m_3` to be accessed, even although they are not explicitly mentioned in the assignment.

bit-field 1410 packed into

bit-field 672 in expression

Volatile-qualified objects can also be affected by translator optimizations. The evaluation of the expression assigned to `loc` could cause the value of `x.m_2` to be held in a register, so it would not need to be loaded for the second access. This optimization would potentially result in one fewer accesses to `x.m_1`.

C++

The C++ Standard does not explicitly specify any behavior.

7.1.5.1p8 *[Note: . . . In general, the semantics of* **`volatile`** *are intended to be the same in C++ as they are in C.]*

Common Implementations

In those implementations that support volatile-qualified objects whose value is modified in ways unknown to the implementation, the objects have non-bit-field scalar types.

Coding Guidelines

This implementation-defined behavior has the ability to generate many surprises for developers. However, implementations that support volatile-qualified objects whose value is modified in ways unknown to the implementation and whose object representation only occupies part of a storage unit are very rare. For this reason no guideline recommendations are made here.

An object that is accessed through a restrict-qualified pointer has a special association with that pointer. 1489

Commentary

The emerging common terminology usage is the term *restricted pointer* (which is also used in the standard) rather than *restrict-qualified pointer*.

It is not possible to declare a restrict-qualified object, so all restrict-qualified pointers are created by the conversion of a non-restrict-qualified address. The equivalent association for objects accessed via their declared name can be obtained by using the **`register`** storage class in the objects declaration. Because it is not possible to take the address of such an object it cannot have any aliases.

restrict 1477 constraint

unary & 1088 operand constraints

As the specification of what an object is composed of, and an example given in the standard show, the object accessed through a restrict-qualified pointer could be part of a larger object.

object 570 contiguous sequence of bytes

restrict 1519 example 2

C90

Support for the **`restrict`** qualifier is new in C99.

C++

Support for the **`restrict`** qualifier is new in C99 and is not available in C++.

Other Languages

Optimizing the performance of identical operations on array objects is one of the intended uses of restrict-qualified pointers. Some languages (Fortran 90, Ada) achieve the same result by supporting operations that can be applied to every element in an array, or slice of an array.

This association, defined in 6.7.3.1 below, requires that all accesses to that object use, directly or indirectly, the value of that particular pointer.[115)] 1490

restrict requires all accesses

Commentary

This association only applies within the lifetime of the restricted pointer object, which may be a subset of the lifetime of the pointed-to object. It enables optimizations to be localized to accesses of an object within a particular scope (e.g., a function definition or loop). The optimization being driven by the method used to access the object, rather than the object itself.

451 lifetime of object
1503 restrict pointer lifetime

There is no requirement on translators to check that a particular restricted pointer is the only method used to access the pointed-to object. Such a requirement would be counter productive, since the purpose of this qualifier is to overcome the technical difficulties associated with deducing the information it denotes automatically (although algorithms for automatically deducing some cases are known[10]). If this requirement is not met the behavior is undefined. A translator that relies on the presence of the **restrict** qualifier, to perform optimizations, may produce different results in this case, than if the qualifier did not appear in the pointer declaration.

1513 restrict undefined behavior

This association only applies if the access is through a restricted pointer. Assigning the value of a restricted pointer to a non-restricted pointer does not cause the special association to also be assigned. For instance, in the following example, accesses through the pointers p and q are not restrict-qualified.

```
void f(float * restrict r,
       float * restrict s,
       int len)
{
float *p = r,
      *q = s;

while(len-- > 0)
   *p++ = *q++;
}
```

Common Implementations

The **restrict** qualifier specifies behavior that involves a relationship between one pointer and all other pointers. An alternative approach is to specify relationships between sets of pointers (which may only be a relationship between two pointers). Such an approach enables aliasing behaviors to be specified that would not be possible using the **restrict** qualifier. Koes, Budiu, Venkataramani and Goldstein[758] produced a tool which analyses source for sets of pointers which were likely, but not guaranteed, to be independent of each other and an estimated optimization benefit if a compiler could assume they were independent. They found that in many cases developers needed only a few minutes to verify whether the pointers were actually independent and that worthwhile increases in program speed were possible (they modified gcc to accept and use pointer information provided by a new pragma).

Coding Guidelines

Use of the **restrict** qualifier relies on the original use meeting, and subsequent developers maintaining, the guarantee required by the standard. While it may be possible to use static analysis tools to verify the requirement in some cases (where the analysis does not consume huge amounts of resources), the availability of such tools is open to question. Without a guaranteed method of enforcement, and no established practices for avoiding the problem, no guideline is given here.

Example

When defining a macro to take the place of a function, it is not necessary to be concerned with the scope of the argument passed, provided the lifetime of the pointer used is that of the body of the macro. In the following example, the claim being made by the restricted pointer only needs to exist within the block created by the macro body.

```
float *c;

#define WG14_N448(N, A, B)      \
```

```
    {                           \
    int n = (N);                \
    float *restrict a = (A);    \
    float *const b = (B);       \
    int i;                      \
    for (i = 0; i < n; i++)     \
       a[i] = b[i] + c[i];      \
    }
```

In the following two examples the objects accessed by the restricted pointers are subobjects of a larger whole. There can be so called *edge effects* where the two subobject storage areas meet. At this edge point it is
cache 0 possible that accesses to elements from both subobjects will be loaded into the same cache line. The affect may be that assumptions about cache line interaction, made when deciding what machine code to generate, are no longer true. The performance impact of optimizer assumptions about the cache not being met will be processor and optimizer specific.

```
void WG14_N866_D(int n, int * restrict x, int * restrict y)
{
/*
 * Let the number of elements in the pointed-to object be 3n.  The following
 * modifies the lower-n elements through x, and modifies the upper-n
 * elements through y.  The middle n elements are read through x and y.
 */
for(int i=0; i<n; i++)
   {
   x[i]     += x[i+n];
   y[i+2*n] += y[i+n];
   }
}

void f(void)
{
int z[300];

WG14_N866_D(100, z, z);
}
```

In the following example the individual array elements pointed to by each of the restricted pointers are disjoint.

```
void WG14_N886_K(int n, char * restrict p, char * restrict q)
{
for(int i=0; i<n; i+=2)
   {
   ++p[i];
   ++q[i];
   }
}

void all_edge_affects(void)
{

WG14_N886_K(100, r, r+1);
}
```

restrict intended use

The intended use of the **restrict** qualifier (like the **register** storage class) is to promote optimization, and deleting all instances of the qualifier from all preprocessing translation units composing a conforming program does not change its meaning (i.e., observable behavior). 1491

Commentary

The **restrict** type qualifier allows programs to be written so that translators can produce significantly faster executables. Anyone for whom this is not a concern can safely ignore this feature of the language. Rationale

A proof by Landi[804] brought the search for an optimal alias detection algorithm (determining whether two different identifiers refer to the same storage location at a particular point in a program) to an abrupt end (at least for programs containing **if** statements, loops, dynamic storage allocation, and manipulating at least a singly linked list). He showed that in general: (1) determining whether an alias occurs during some execution of a program is undecidable, and (2) determining whether an alias occurs during all executions of a program is uncomputable (simplifying the problem to (1) intraprocedural analysis where no use is made of dynamic storage allocation is NP-hard,[805] and (2) flow-insensitive, intraprocedural, may-alias analysis is NP-hard[596]). alias analysis

The **restrict** qualifier promotes optimization by reducing some costs (to vendors in producing the optimizer and the developer in terms of resources needed to run the translator), at the expense of increasing another cost (developer time needed to deduce where the qualifier can be added).

It is possible that deleting all instances of the **restrict** qualifier will change the observable behavior of a program (because the requirement on accesses was not being met). 1490 restrict requires all accesses

Other Languages

The implementations of some languages support pragmas that enable developers to communicate optimization information to the translator.

Common Implementations

Whenever a value is stored indirectly through a pointer, a translator has to assume that potentially all objects now hold a different values. A little analysis allows the set of potentially out-of-date object values to be reduced to those whose address is ever assigned to a pointer. Successively more sophisticated analyses can be used to reduce the size of this set. A store through a restricted pointer can be assumed to not affect the value of any other value accessed in the lifetime of that pointer object. This information helps other optimization techniques to do a better job, by making it possible for them to hold on longer to the information they have built up about the values and properties of objects.

The use of restricted pointers (rather than pointers without this qualification) is not itself an optimization technique. Use of a restricted pointer provides alias information that, for non-restricted pointer accesses, would otherwise have to be obtained through complete program analysis.

A number of algorithms for deducing the set of objects that a pointer could be pointing to, at any point in a program, have been proposed.[31, 870, 1510] Unfortunately, for all but the smallest programs, they require large amounts of memory and processor time. An empirical evaluation[577] of the different algorithms used programs of under 7.1 KLOC for its comparisons (this figure is an over estimate since it is based on a line count of the entire source, not just the executable statements), with a single program of 29.6 KLOC exceeding available memory (200 M byte) for some of the measurements. Researchers have started to make use of the common cases seen in production code to design alternative algorithms that require fewer resources. Making use of such information enabled an analysis of Microsoft Word 97,[318] 1.4 MLOC of C++, to produce results close to those obtained by Andersen's algorithm.[31]

Hind[576] discusses pointer analysis issues that still remain open.

Coding Guidelines

The **restrict** qualifier also has uses outside of optimization. The use of this qualifier could be treated as an assertion that could to be checked by static analysis tools. The C99 Standard is still too new to know if this kind of usage will occur.

Example

processor 940
SIMD

The SIMD approach uses a fine grained model of executing portions of a program in parallel. Being able to automatically break a program into components that execute on different processors (i.e., executing different functions on different processors) has proved to be extremely difficult. However, at the time of this writing there are no commercial translators offering such functionality. Automatically deducing that calls to `walk_tree`, in the following example, can be distributed to different processors remains a very difficult problem.

```
#include <stddef.h>

struct data {
             long important_value;
            };
struct t_rec {
              struct data information;
              struct t_rec * restrict left,
                           * restrict right;
             };
typedef struct t_ref * restrict TREE;

extern void process_data(struct data);

void walk_tree(TREE root)
{
if (root->left != NULL)
   walk_tree(root->left);
if (root->right != NULL)
   walk_tree(root->right);

process_data(root->information);
}
```

---

qualified array type

If the specification of an array type includes any type qualifiers, the element type is so-qualified, not the array type. 1492

Commentary

The implications of this specification become apparent when arrays are converted to pointers to their first element. The declaration `const int arr[10];` declares `arr` to have type array of **`const int`**. If an occurrence of this object is implicitly converted to a pointer type, the resulting type is pointer to **`const int`**. If the qualifier had been associated with the array type, the converted pointer type would have been **`const`** pointer to **`int`**. The following example requires a more complicated chain of reasoning (based on a discussion by McDonald):

```
struct T {
          int *mem_1[2];
          int **mem_2;
         };

const struct T s;  /* Members inherit const. */

void f(void)
{
TYPE_1 loc_1;
TYPE_2 loc_2;

loc_1 = &s.mem_1; /* Statement 1. */
```

```
14  loc_2 =  s.mem_1; /* Statement 2. */
15  }
```

What should the types TYPE_1 and TYPE_2 look like? The result of the dot selection operator includes any qualifiers in the type of its left operand. The two types needed are:

1033 struct qualified result qualified

1. an expression having array type is not converted to *pointer to . . .* when it is the operand of the unary **&** operator. Thus, `&s.mem_1` has type pointer to array of const pointer to int, and the declaration of `loc_1` needs to be `int * const (*loc_1)[2];`.

729 array converted to pointer

2. in the second case `s.mem_1` is implicitly converted to a pointer type. However, does the conversion to pointer type occur before the above C rule on qualifiers is applied? The two possibilities are:

729 array converted to pointer

```
1  int *  const *  /* Type if qualified before conversion. */
2  int ** const    /* Type if qualified after conversion.  */
```

   Applying the qualifier before conversion is considered to be the preferred interpretation (it is also the behavior of the implementations tested by your author; also see elsewhere) because it prevents the elements of the array, `mem_1`, being modified (whereas the member `mem_2` is treated as having type `int ** const`).

1497 EXAMPLE const aggregate

A method of specifying qualifiers, in an array declaration, so they are associated with the array type was introduced in C99 and is discussed elsewhere.

1571 qualified array of

Other Languages

Few, in any, languages implicitly convert arrays into pointers to their first element. So the distinction that occurs in C, because of this implicit conversion, does not arise.

Coding Guidelines

Because of the implicit conversion that occurs for parameters declared to have an array type, it is possible for them to be assigned to (because qualifiers applies to the element type). Assigning to an object defined, in the source, using an array type might be considered suspicious with or without a qualifier. However, the usage is rare and these coding guidelines are silent on the issue.

729 array converted to pointer

Example

```
1  void f(const int arr_1[10], const int arr_2[20])
2  {
3  arr_1 = arr_2;
4  }
```

1493 If the specification of a function type includes any type qualifiers, the behavior is undefined.[116)]

Commentary

A function type describes a function with specified return type. It would be meaningless to say that a function returned a volatile-qualified type. It only gets to return a single value. A function type having a const-qualified return type could be interpreted to mean that the value returned was always the same. The C committee choose not to give this interpretation to such a construct.

532 function type

C++

8.3.5p4

In fact, if at any time in the determination of a type a cv-qualified function type is formed, the program is ill-formed.

A C++ translator will issue a diagnostic for the appearance of a qualifier in a function type, while a C translator may silently ignore it.

The C++ Standard allows *cv-qualifiers* to appear in a function declarator. The syntax is:

8.3.5p1 *D1 (parameter-declaration-clause) cv-qualifier-seq$_{opt}$ exception-specification$_{opt}$*

the *cv-qualifier* occurs after what C would consider to be the function type.

Common Implementations

The most commonly seen behavior is to ignore the type qualifiers.

Coding Guidelines

Function types whose return type includes a qualifier can occur through the use of typedef names. It would be consistent for a functions return type to use the same typedef name as the objects appearing in its **return** statement. While it might be unusual for a const-qualified object to appear in a **return** statement, the usage appears harmless and is not common.

Example

footnote 137 1820 A footnote in the standard also provides some examples.

```
1  typedef const int C_I;
2
3  C_I f(int p_1)
4  {
5  return p_1 + 1;
6  }
```

---

qualified type to be compatible

For two qualified types to be compatible, both shall have the identically qualified version of a compatible type; 1494

Commentary

simple assignment constraints 1296 The requirements on the types of the operands of the assignment operators ignore any qualifiers on the type of the right operand.

C++

compatible type if 631 The C++ Standard does not define the term *compatible type*. However, the C++ Standard does define the terms *layout-compatible* (3.9p11) and *reference-compatible* (8.5.3p4). However, *cv-qualifiers* are not included in the definition of these terms.

---

the order of type qualifiers within a list of specifiers or qualifiers does not affect the specified type. 1495

Commentary

type qualifier syntax 1476 Measurements of qualifier ordering are discussed elsewhere.

C++

The C++ Standard does not specify any ordering dependency on *cv-qualifiers* within a *decl-specifier*.

Coding Guidelines

declaration specifier ordering 1357.1 The guideline recommendation dealing with the ordering of keywords within type specifiers is discussed elsewhere.

1496 EXAMPLE 1 An object declared

const volatile EXAMPLE

```
extern const volatile int real_time_clock;
```

may be modifiable by hardware, but cannot be assigned to, incremented, or decremented.

Commentary

Such an object may be in a memory mapped region of storage that is effectively read-only, from the programs perspective (in the sense that any writes to objects in that area of storage do not modify the values held there).

1497 EXAMPLE 2 The following declarations and expressions illustrate the behavior when type qualifiers modify an aggregate type:

EXAMPLE const aggregate

```
const struct s { int mem; } cs = { 1 };
struct s ncs;  // the object ncs is modifiable
typedef int A[2][3];
const A a = {{4, 5, 6}, {7, 8, 9}}; // array of array of const int
int *pi;
const int *pci;

ncs = cs;      // valid
cs = ncs;      // violates modifiable lvalue constraint for =
pi = &ncs.mem; // valid
pi = &cs.mem;  // violates type constraints for =
pci = &cs.mem; // valid
pi = a[0];     // invalid: a[0] has type "const int *"
```

Commentary

The terms *valid* and *invalid* are commonly used by developers. However, the C Standard does not define them. As used in this example, the term *valid* might be interpreted as "does not affect the conformance status of the program". And the term *invalid* might be interpreted as "will cause a translator to issue a diagnostic message".

Coding Guidelines

Some developers might be surprised that in the following declarations:

```
1  const struct s { int mem; } cs = { 1 };
2  struct s ncs;  // the object ncs is modifiable
```

the **`const`** qualifier in the first declaration only applies to the type of `cs` (i.e., the tag `s` is not defined to refer to a const-qualified type). Type qualifiers are not part of any of the syntactic constructs used to define tags.

1464 struct tag; 1471 struct-or-union identifier not visible

1498 114) A **`volatile`** declaration may be used to describe an object corresponding to a memory-mapped input/output port or an object accessed by an asynchronously interrupting function.

footnote 114

Commentary

These are probably the two most common uses of the **`volatile`** qualifier.

C++

The C++ Standard does not make this observation.

1499 Actions on objects so declared shall not be "optimized out" by an implementation or reordered except as permitted by the rules for evaluating expressions.

Commentary

This is a requirement on the implementation. Accessing an object declared with a volatile-qualified type is a side effect. The result of this side effect is likely to be unknown to the implementation, which is likely to play safe.

185 side effect

C++

7.1.5.1p8 *[Note: **volatile** is a hint to the implementation to avoid aggressive optimization involving the object because the value of the object might be changed by means undetectable by an implementation. See 1.9 for detailed semantics. In general, the semantics of **volatile** are intended to be the same in C++ as they are in C.]*

Example

In the function f below, a translator may optimize the evaluation of the expression appearing in the first return statement. The value 0 can be unconditionally returned after a read access to glob_2 (no multiplication operation is performed). The expression in the second **return** statement may exhibit undefined behavior. It depends on whether accessing glob_2 causes its value to be modified. An implementation could choose to unconditionally return the value 0 after two read accesses to glob_2 (no subtraction operation is performed). The undefined behavior, if an access does modify glob_2, being that the new values do not affect the value returned.

object 941 modified once between sequence points

```
1  extern int glob_1;
2  extern volatile int glob_2;
3
4  int f(void)
5  {
6  if (glob_1 == 1)
7     return glob_2 * 0;        /* First return.  */
8  else
9     return (glob_2 - glob_2); /* Second return. */
10 }
```

---

footnote 115

115) For example, a statement that assigns a value returned by **malloc** to a single pointer establishes this association between the allocated object and the pointer. 1500

Commentary

lvalue 725 converted to value

Taking the address of an object with static or automatic storage duration is not an access to that object. Such an address may also be assigned to a restricted pointer to establish this association.

---

footnote 116

116) Both of these can occur through the use of **typedef**s. 1501

Commentary

```
1  typedef char A[10];
2
3  volatile A v_a;
4
5  typedef int F(void);
6
7  const F *cp_f;
```

C++

The C++ Standard does not make this observation, but it does include the following example:

8.3.5p4 *[Example:*

```
typedef void F();
struct S {
const F f;     // ill-formed:
               // not equivalent to: void f() const;
};
```

—end example]

6.7.3.1 Formal definition of restrict

1502 Let **D** be a declaration of an ordinary identifier that provides a means of designating an object **P** as a restrict-qualified pointer to type **T**.

restrict formal definition

Commentary

A typedef name, function, and enumeration constant are also ordinary identifiers. However, they do not declare objects.

C++

Support for the **restrict** qualifier is new in C99 and is not available in C++.

Example

```
1  #include <stdlib.h>
2
3  typedef int T;
4
5  T * restrict D;
6
7  void f(void)
8  {
9  D = (T * restrict)malloc(sizeof(T)); /* Allocate object P. */
10 }
```

1503 If **D** appears inside a block and does not have storage class **extern**, let **B** denote the block.

restrict pointer lifetime

Commentary

This and the following two sentences define a region of program text, denoted by **B** (and **B2** elsewhere). This formal definition of **restrict** refers to events that occur before, during, or after the execution of this block.

1512 restrict B2
1514 restrict execution of block means

Example

```
1  typedef int T;
2
3  void f(void)
4  {               /* Started D's associated block B.  */
5  T * restrict D  /* D is now visible in the block B. */
6                  ;
7  }               /* Ended D's associated block B.    */
```

1504 If **D** appears in the list of parameter declarations of a function definition, let **B** denote the associated block.

Commentary

```
typedef int T;

void f(T * restrict D /* D is now visible, outside of its associated block B. */
                      )
{                      /* Started D's associated block B. */
/* ... */
}                      /* Ended D's associated block B.   */
```

Otherwise, let **B** denote the block of **main** (or the block of whatever function is called at program startup in a freestanding environment). 1505

Commentary

The cases covered by this *otherwise* include all objects having static storage duration and file scope, and all objects having allocated storage duration.

---

restrict pointer based on

In what follows, a pointer expression **E** is said to be *based* on object **P** if (at some sequence point in the execution of **B** prior to the evaluation of **E**) modifying **P** to point to a copy of the array object into which it formerly pointed would change the value of **E**.[117] 1506

Commentary

additive operators 1165 pointer to object

This defines the term *based*. The use of the term *array object* here refers to a prior specification about a pointer to a non-array object behaving like a pointer to an array containing a single element (although technically that wording limits itself to "for the purposes of these operators").

That is, the value of **E** depends on the value of **P**, not the value pointed to by **P**. It is possible that the former value of **P** is indeterminate, so the involvement of copies of formerly pointed-to array-objects is a conceptual one.

Example

```
#include <stdint.h>
#include <stdlib.h>
#include <string.h>

struct t {
          int *q;
          int i;
         } a[2] = { 0, /* ... */ };

void WG14_N448(struct t *restrict P,
               _Bool c_flag)
{                                /* Block B, associated with P, has started here. */
struct t *q;
intptr_t n;
/*
 * Adjust P to point at copy of original object?
 */
if (c_flag)
   {
   struct t *r;
   r = malloc(2*sizeof(*P));
   memcpy(r, P, 2*sizeof(*P));
   P = r;
   }
```

```
q = P;
n = (intptr_t)P;
/*
 * Lists of pointer expressions that are, and are not,
 * based on object P, in the execution of block B.
 *
 *      expression E           expression E
 *    based on object P     not based on object P
 *
 *        P                     P->q
 *        P+1                   P[1].q
 *        &P[1]                 &P
 *        &P[1].i
 *        &P->q
 *        q                     q->q
 *        ++q
 *        (char *)P             (char *)(P->i)
 *        (struct t *)n         ((struct t *)n)->q
 */
}                                /* Block B has ended here. */

void f(void)
{
WG14_N448(a, 0);
WG14_N448(a, 1);
}
```

1507 Note that "based" is defined only for expressions with pointer types.

Commentary

For instance, in the example function, `WG14_N448`, given in the Example subclause of the previous C sentence, *based* is defined for `q->q`, but not for `q->i`.

1508 During each execution of **B**, let **L** be any lvalue that has **&L** based on **P**.

restrict
&L based on L

Commentary

This defines the term **L**. Starting with the address of **L**, that is based on **P**, we can use it to walk back through any chain of pointers.

Example

In the following we have `&(p->v[i])` (equivalent to `(p->v)+i`) based on the restricted pointer `p->v`. Walking up the pointer chain, `&(p->v)` is based on the restricted pointer `p`,

```
typedef struct {
                 int n;
                 double * restrict v;
                } vector;

void f(vector * restrict p)
{
p->v[i];
}
```

1509 If **L** is used to access the value of the object **X** that it designates, and **X** is also modified (by any means), then the following requirements apply: **T** shall not be const-qualified.

Commentary

This requirement means that, if **T** is const-qualified then this qualification cannot be cast away and the object **X** modified via some non-const-qualified lvalue **L** (if this sequence of operations occurred the behavior would be undefined).

Example

The use of **const** (via the typedef name T) and **restrict** in the definition of WG14_N866_F implies that g only accesses the value of *p, and does not modify it. On some processor architectures a translator could use this information to generate code to initiate the load from *p before the call to g, making the value available sooner both within execution of g and for the **return** statement. The size of the performance benefit will depend on the size of the type T.

```
1  typedef const int T; /* Some type T. */
2  extern void g();
3
4  T WG14_N866_F(T * restrict p)
5  {
6  g(p);
7  return *p;
8  }
```

Every other lvalue used to access the value of **X** shall also have its address based on **P**. 1510

Commentary

Automatically deducing, during program translation, the set of lvalues used to access X is potentially very expensive, computationally. Being able to assume that such lvalues are based on P (otherwise the behavior is undefined) considerably reduces an optimizer's computational overhead (when performing optimizations that rely on points-to information).

Every access that modifies **X** shall be considered also to modify **P**, for the purposes of this subclause. 1511

Commentary

There are a number of ways wording in the standard can promote optimization. Possibilities include: (1) bounding the behavior for common cases (such as limits on how objects referenced by restricted pointers are accessed), and (2) ensuring that edge cases have undefined behavior (a translator does not have to bother taking them into account, the behavior can be whatever happens to occur). The purpose of this C sentence is to render some awkward edge cases undefined behavior.

Example

When the one or more parameters of a function definition have a restricted pointer type a translator needs to be able to optimize the function body, independent of the actual arguments passed. Passing the address of an object as the value of two separate arguments, in a function call, occurs reasonably frequently. The following examples are based on a discussion in document WG14/N866 written by Homer.

restrict 1519 example 2

```
1  typedef struct {
2                  int n;
3                  double * restrict v;
4                 } vector;
5
6  void WG14_N866_C(vector * restrict p, vector * restrict q)
7  {
8  int i;
9  for(i=1; i < p->n; i++)
10     p->v[i] += q->v[i-1];
11 }
```

What behavior does this C clause give to the calls `WG14_N866_C(&x, &y)` and `WG14_N866_C(&x, &x)` (when `x.n>1`)?

1. **B** is the block formed by the body of the definition of `WG14_N866_C`,
2. Let **L** be the lvalue `p->v[i]`, and **X** the object which it designates,
3. Let **X** be `p->v[i]`,
4. `&(p->v[i])` (equivalent to `(p->v)+i`) is based on the restricted pointer `p->v`, 1508 restrict &L based on L
5. a modification of **X** is considered also to modify the object designated by `p->v` (current C sentence),
6. recursively, `&(p->v)` is based on the restricted pointer `p`,
7. when the arguments passed are `(&x, &y)` `p` and `q` refer to different objects, and no other pointer is based on `p`,
8. when the arguments are `(&x, &x)` the same object is also accessed through the lvalue `q->v`, but `&(q->v)` is not based on `p` and therefore behavior is undefined. 1513 restrict undefined behavior

A translator is thus able to unconditionally optimize the body of the function `WG14_N866_C` (either the **`restrict`** semantics does hold, or the undefined behavior can be that it does :-).

In the following function definition, even if `*a` and `*b` happen to refer to the same object, the members `a->p` and `b->q` will be distinct restricted pointers. A translator can infer that `*(a->p)` and `*(b->q)` are distinct objects, and so there is no potential aliasing to inhibit optimization of the body of `f`.

```
1  typedef struct {
2                   int * restrict p;
3                   int * restrict q;
4                  } T;
5
6  int WG14_N866_E(T * restrict a, T * restrict b)
7  {
8  *(a->p) += 1;
9  return *(b->q);
10 }
```

During an execution of `f`, the only object that is actually modified is `(*a)->p`. Now `&((*a)->p)` is `a->p`, a restricted pointer, so `a->p` is also considered to be modified. Recursively, `&(a->p)` is based on `a`, another restricted pointer. Because no other lvalues are used to access either `(*a)->p` or `a->p`, all the requirements of the specification are met (and they do not involve `b`).

1512 If **`P`** is assigned the value of a pointer expression **`E`** that is based on another restricted pointer object **`P2`**, associated with block **`B2`**, then either the execution of **`B2`** shall begin before the execution of **`B`**, or the execution of **`B2`** shall end prior to the assignment. restrict B2

Commentary

This requirement allows restricted pointers to be passed as arguments to function calls, and a restricted pointer within a nested scope to be assigned the value of a restricted pointer from an outer scope. If the value of a restricted pointer is assigned to another restricted pointer, e.g., **P_nest**, in a nested scope, the requirement applies only within the scope of **P_nest** and only to objects modified within that scope that are referenced through expressions based on **P_nest** at least once.

The case where execution of **B2** ends prior to the assignment covers the situation where a value, based on the restricted pointer object **P2**, returned from a function call is assigned to **P**. 1521 restrict example 4

Coding Guidelines

Parallels can be drawn between the coding guideline discussion on the assignment of object addresses to pointers and the assignment of restricted pointers to other restricted pointer objects. 454 pointer indeterminate

Example

```
#define INLINE(P_1, P_2, N) {                          \
                            int * restrict q_1 = P_1;  \
                            int * restrict q_2 = P_2;  \
                            for (int i = 0; i < N; i++)  \
                               {                       \
                               q_1[i] += q_2[i];       \
                               }                       \
                            }
```

---

restrict undefined behavior

If these requirements are not met, then the behavior is undefined. 1513

Commentary

In particular, an implementation is free to make the general assumption that the requirements are met and to perform the optimizations that are performed when they are met.

---

restrict execution of block means

Here an execution of **B** means that portion of the execution of the program that would correspond to the lifetime of an object with scalar type and automatic storage duration associated with **B**. 1514

Commentary

lifetime 451 of object

This sentence clarifies the meaning by using an existing, well defined, term, lifetime.

A translator is free to ignore any or all aliasing implications of uses of **restrict**. 1515

Commentary

A developer may be able to deduce translator behavior from the performance of the program image, or by examining the undefined behavior that occurs for certain constructs.

restrict 1513 undefined behavior

Coding Guidelines

Uses of **restrict** provide information on source code properties believed to be true by developers. Something that static analysis tools can check and make use of.[10]

EXAMPLE 1 The file scope declarations 1516

```
int * restrict a;
int * restrict b;
extern int c[];
```

assert that if an object is accessed using one of **a**, **b**, or **c**, and that object is modified anywhere in the program, then it is never accessed using either of the other two.

Commentary

The declaration of c does not explicitly assert anything about **restrict** related semantics. It just so happens that all of the other declarations are restrict-qualified, which implies additional semantics on accesses to c. If another declaration, say `extern int *d;`, appeared in the list, then the same object could be accessed using either c or d, but the stated relationship between a, b, and c would remain true (and so would an equivalent one between a, b, and d).

---

footnote 117

117) In other words, **E** depends on the value of **P** itself rather than on the value of an object referenced indirectly through **P**. 1517

Commentary

The specification of **restrict** provides a mechanism for developers to give guarantees about the set of objects a pointer may point at. Translators may use these guarantees to deduce information about the value of an object referenced indirectly though so qualified pointers.

1518 For example, if identifier **p** has type **(int **restrict)**, then the pointer expressions **p** and **p+1** are based on the restricted pointer object designated by **p**, but the pointer expressions ***p** and **p[1]** are not.

Commentary

If p had type (int * restrict * restrict then both *p and p[1] would be based on the restricted pointer *p.

1519 EXAMPLE 2 The function parameter declarations in the following example

restrict example 2

```
void f(int n, int * restrict p, int * restrict q)
{
        while (n-- > 0)
                *p++ = *q++;
}
```

assert that, during each execution of the function, if an object is accessed through one of the pointer parameters, then it is not also accessed through the other.

The benefit of the **restrict** qualifiers is that they enable a translator to make an effective dependence analysis of function **f** without examining any of the calls of **f** in the program. The cost is that the programmer has to examine all of those calls to ensure that none give undefined behavior. For example, the second call of **f** in **g** has undefined behavior because each of **d[1]** through **d[49]** is accessed through both **p** and **q**.

```
void g(void)
{
        extern int d[100];
        f(50, d + 50, d); // valid
        f(50, d +  1, d); // undefined behavior
}
```

Commentary

As this example states, the burden of correctness lies with the programmer. A translator is entitled to act as if what the programmer said (through the use of **restrict**) is correct.

Other Languages

Some languages (e.g., Fortran and Ada) copying operations such as these can be performed through the use of array slicing operators.

Coding Guidelines

The technical difficulties involved in proving that a developer's use of **restrict** has defined behavior are discussed elsewhere.

1491 alias analysis

1520 EXAMPLE 3 The function parameter declarations

```
void h(int n, int * restrict p, int * restrict q, int * restrict r)
{
        int i;
        for (i = 0; i < n; i++)
                p[i] = q[i] + r[i];
}
```

illustrate how an unmodified object can be aliased through two restricted pointers. In particular, if **a** and **b** are disjoint arrays, a call of the form **h(100, a, b, b)** has defined behavior, because array **b** is not modified within function **h**.

Commentary

Information on when objects may, or may not, be modified is of primary importance to the optimization process. Lack of information on when two read accesses refer to the same object may result in suboptimal code, but it does not prevent some optimizations being made. The committee did not consider it worth addressing this "reads via two apparently independent pointers" issue in C99.

restrict example 4

EXAMPLE 4 The rule limiting assignments between restricted pointers does not distinguish between a function call and an equivalent nested block. With one exception, only "outer-to-inner" assignments between restricted pointers declared in nested blocks have defined behavior. 1521

```
{
        int * restrict p1;
        int * restrict q1;
        p1 = q1; // undefined behavior
        {
                int * restrict p2 = p1; // valid
                int * restrict q2 = q1; // valid
                p1 = q2;                // undefined behavior
                p2 = q2;                // undefined behavior
        }
}
```

The one exception allows the value of a restricted pointer to be carried out of the block in which it (or, more precisely, the ordinary identifier used to designate it) is declared when that block finishes execution. For example, this permits **new_vector** to return a **vector**.

```
typedef struct { int n; float * restrict v; } vector;
vector new_vector(int n)
{
        vector t;
        t.n = n;
        t.v = malloc(n * sizeof (float));
        return t;
}
```

Commentary

restrict B2 1512 These exceptions are discussed elsewhere.

6.7.4 Function specifiers

function specifier syntax

1522

function-specifier:
inline

Commentary

Rationale The **inline** keyword, adapted from C++ . . .

The keyword **inline** is invariably used by languages to specify functions that are to be considered for inlining by a translator.

C90

Support for *function-specifier* is new in C99.

C++

The C++ Standard also includes, 7.1.2p1, the *function-specifier*s **virtual** and **explicit**.

Other Languages

Few languages specify support for function inlining, although their implementations may provide it as an extension (e.g., some Fortran implementations support some form of `inline` command line option). Some implementations support automatic inlining as an optimization phrase. CHILL supports the **`inline`** keyword. Ada defines a pragma directive that may be used to pass inlining information to the translator, e.g., `pragma inline(fahr)`.

Common Implementations

`gcc` supported **`inline`** as an extension to C90.

Constraints

1523 Function specifiers shall be used only in the declaration of an identifier for a function.

Commentary

The concept denoted by the only available function specifier has no interpretation for object or incomplete types.

1529 inline suggests fast calls

Coding Guidelines

Those coding guideline documents that argue against the use of the **`register`** storage-class specifier may well argue against the use of function specifiers for the same reasons. These coding guidelines do not recommend against this usage for the same reason they did not recommend against the use of the **`register`** storage-class specifier.

1370 register extent effective

1524 An inline definition of a function with external linkage shall not contain a definition of a modifiable object with static storage duration, and shall not contain a reference to an identifier with internal linkage.

inline static storage duration

Commentary

Note: this constraint applies to an *inline definition*. Having a function declared using the **`inline`** specifier is not enough for this constraint to apply.

1540 inline definition

1541 inline definition not an external definition

Functions declared with external linkage and the inline specifier can have more than one definition. Two function definitions containing any of the identifiers described by this constraint could not be called interchangeably. For instance, given the translation unit:

file_1.c

```
1  #include "f.h"
2
3  void g_1(void)
4  {
5  f();
6  }
```

and another translation unit:

file_2.c

```
1  #include "f.h"
2
3  void g_2(void)
4  {
5  f();
6  }
```

and the header file:

f.h

```
1  inline void f(void)
2  {
```

```
3  static int total;
4
5  total++;
6  }
```

the call to the function `f` within `file_1.c` could result in the inline function defined in that source file being invoked, while the call in `file_2.c` could result in the inline function defined in that source file being invoked. C has a very loose model for handling translation of separate source files, a translator is not required to have knowledge of the contents of `file_1.c` when it is translating `file_2.c` and vice versa. In the above case storage for two copies of `total` will be created and independently referenced. This is likely to be surprising to developers who carefully ensure that only one definition of `f` exists.

linkage 420

The requirements in this constraint prevent developers being surprised by this case and do not require any separate source file translation techniques beyond those currently required of a translator.

An object defined to be a const-qualified type is not modifiable and hence the following is permitted:

modifiable 724
lvalue

f.h

```
1  inline void f(void)
2  {
3  static const int magic = 42;
4  }
```

Rationale

Therefore, the following example might not behave as expected.

```
inline const char *saddr(void)
{
    static const char name[] = "saddr";
    return name;
}

int compare_name(void)
{
    return saddr() == saddr();  // unspecified behavior
}
```

Since the implementation might use the inline definition for one of the calls to `saddr` and use the external definition for the other, the equality operation is not guaranteed to evaluate to 1 (true). This shows that static objects defined within the inline definition are distinct from their corresponding object in the external definition. This motivated the constraint against even defining a non-**`const`** object of this type.

C++

The C++ Standard does not contain an equivalent prohibition.

7.1.2p4 *A **`static`** local variable in an **`extern inline`** function always refers to the same object.*

The C++ Standard does not specify any requirements involving a static local variable in a static inline function. Source developed using a C++ translator may contain inline function definitions that would cause a constraint violation if processed by a C translator.

Coding Guidelines

The guideline recommendation dealing with identifiers at file scope that are referenced in more than one source file is applicable here.

identifier declared in one file 422.1

In a hosted environment, the **`inline`** function specifier shall not appear in a declaration of **`main`**. 1525

Commentary

An implementation may associate special properties with the function called on program startup. In a hosted environment the name of the function called at program startup is known (i.e., `main`). While in a freestanding environment the name of this function is not known (it is implementation-defined).

162 hosted environment startup
155 freestanding environment startup

C++

A program that declares `main` *to be* **`inline`** *or* **`static`** *is ill-formed.* 3.6.1p3

A program, in a freestanding environment, which includes a declaration of the function `main` (which need not exist in such an environment) using the **`inline`** function specifier will result in a diagnostic being issued by a C++ translator.

Semantics

1526 A function declared with an **`inline`** function specifier is an *inline function*. inline function

Commentary

This defines the term *inline function*, which is a commonly used term, by developers, in many languages.

1527 The function specifier may appear more than once; function specifier appears more than once

Commentary

This permission is consistent with that given for type qualifiers.

1479 qualifier appears more than once

C++

The C++ Standard does not explicitly specify this case (which is supported by its syntax).

Coding Guidelines

The coding guideline issues for function specifiers occurring more than once are different from those for type qualifiers. There is a single function specifier and the context in which it occurs creates few rationales for the need of more than one to appear. However, while multiple function specifiers might be considered unusual there does not appear to be any significant benefit in a guideline recommendation against this usage.

1479 qualifier appears more than once

1528 the behavior is the same as if it appeared only once.

Commentary

This is consistent with type qualifiers.

1529 Making a function an inline function suggests that calls to the function be as fast as possible.[118)] inline suggests fast calls

Commentary

The **`inline`** specifier is a hint from the developer to the translator. The 1970s gave us the **`register`** keyword and the 1990s have given us the **`inline`** keyword. In both eras commercially usable translation technology was not up to automating the necessary functionality and assistance from developers was the solution adopted. Published figures on translators that automatically decide which functions to inline[216, 323, 348] show total program execution time reductions of around 2% to 8%. The latest research on inlining[1449] has not significantly improved on these program execution time reductions, but it does not seem to cause the large increase in executable program size seen in earlier work, and the translation overhead associated with deducing what to inline has been reduced.

The complexity of selecting which functions to inline, to minimize a program's execution time while keeping the size of the program image below some maximum limit and the size of individual functions below some maximum limit, is known to be at least NP-complete.[1199]

141 program image

Developers often believe that function calls take a long time to execute (relative to other instructions). While this might have been true 20 years ago, it is rarely true today. Processor designers have invested significant resources in speeding up the calling of functions (call instructions have been simplified, no complicated VAX type instructions,[284] and branch prediction is applied to the call/return instructions, helping to minimize stalls of the instruction pipeline). See Davidson[323] for a performance comparison of the effect of **inline** across four different processors.

processor 0 pipeline

On modern processors the time taken to execute a call or return instruction is usually less than that required to execute a multiply (although it may slow the execution of other instructions because of a stalled pipeline or failed branch prediction), it can even be as fast as an add instruction. The relative unimportance of call/return instruction performance is shown both by situations where a dramatic decrease in execution time has little impact on overall program performance[1435] and the fact that putting duplicate sections of code in a translator created function is treated as a potentially worthwhile speed optimization.[786] The impact of using separate functions, rather than inlined code, is in areas other than the call/return instruction execution overhead. They include the instruction cache, register usage, and the characteristics of memory (locals on the stack) accesses.

branch prediction 1739

It often comes as a surprise to developers that use of the **register** storage class can slow a program down. The same is also true of the **inline** function specifier; its use can slow a program down (although the situations where this occurs appear to be less frequent than for the **register** storage class). Degradations in performance due to an increase in page swapping (on hosts with limited storage) or an increase in program size causing a decrease in the number of cache hits are the most commonly seen reasons. One published report[275] (Fortran source) found that a lack of sophisticated dependency analysis in the translator meant that it had to make worst-case assumptions in a critical loop that did not apply in the non-inlined source. Even when **inline** is used intelligently (based on execution counts of function calls) improvements in performance can vary significantly, depending on the characteristics of the source code and on the architecture of the host processor.[323, 348]

register 1369 storage-class

C++

The C++ Standard gives an implementation technique, not a suggestion of intent:

7.1.2p2 *The **inline** specifier indicates to the implementation that inline substitution of the function body at the point of call is to be preferred to the usual function call mechanism.*

Such wording does not prevent C++ implementors interpreting the function specifier in the C Standard sense (by, for instance, giving instructions to the hardware memory manager to preferentially keep a function's translated machine code in cache).

Common Implementations

A parallel can be drawn with the hint provided by the **register** storage class. To what extent will an implementation unconditionally follow the suggestion provided by the appearance of the **inline** function specifier on a function definition, ignore it completely (performing its own analysis of program behavior to deduce which function calls should be inlined[216]), or implement some half-way point? Support for this keyword is new in C99 and there are still too few implementations supporting it to be able to spot any trends.

register 1369 storage-class

Although inlining is thought of in terms of speeding up the call itself, removing the machine instruction that performs the call is often the smallest saving made. Other savings are obtained from the removal of the interfacing machine code that saves and restores registers across the call, and the code for creating a new stack frame and restoring the old one on return (Davidson[323] gives equations for making various cost/benefit decisions and compares predicted behavior against results obtained from four different processors).

Inlining can also have effects beyond the immediate point of call. Many translators treat a single function as the unit of optimization, making worst-case assumptions about the effects of any function calls. Inlining a function allows the statements it contains to be optimized in the context of the call site (arguments are often constant expressions and their values can often replace parameter object accesses in the function body) and also allows information that previously had to be thrown away, because of the call, to be kept and used (a

recent innovation, known as *cloning*, changes calls to a function with a call to a copy of that function that has been optimized, based on knowledge of the arguments passed;[67, 1449] when two or more calls to a function share some argument values this technique can provide almost the same performance improvement without the overhead of excessive code expansion).

Inlining a function at the point of call can have disadvantages (and potentially no advantages), including the following:

- The quantity of generated code can increase significantly. Storage to hold generated code is rarely a problem on hosted implementation, but in freestanding implementations it can be a major issue. The increase in size of a program image can also affect the performance of processors instruction cache; the possible effects are complex, depending on size and configuration of the cache.[221, 916] The Texas Instruments TMS320C compiler[623] supports the `-io size` option. The optimizer multiplies the number of times a function is called by its size (an internal, somewhat arbitrary, measure is used) and only inlines the function if the result is less than the developer specified value of `size`.
- The maximum amount of stack storage required by a program can increase. When a function is inlined its stack storage requirements are added to those of the function into which it is merged. Optimizers choose not to inline functions at some call sites if the increase in stack storage requirements exceeds some predefined limit.[216]

```
inline void f(void)
{
int af[100];
/* ... */
}

void g(void)
{
int ag[100];
/* ... */
}

void h(void)
{
/*
 * When f is not inlined the storage it uses is freed before
 * the call to g, and so can be reused.
 * When f is inlined into h the storage it uses becomes part of
 * the storage allocated to h, and additional storage is required
 * by the call to g.
 */
f();
g();
}
```

Inlining not only offers opportunities for reducing the mount of generated code, but also reducing the total amount of stack storage required by nested function calls. Objects with automatic storage duration need to be allocated storage whether the function that defines them is inlined or not. When the function is inlined the storage is allocated in the stack frame of the function into which they are inlined. Inlining thus changes the stack usage profile of a program. Storage requirements can either increase or decrease, depending on what functions are inlined, the housekeeping overhead of a function call and the extent to which it is possible for objects to share storage locations.

Ratliff[1146] modified `vpcc`[326] to attempt to minimize the amount of stack frame storage required for locally defined objects (by using the same storage for different objects, based on the regions of code over which those objects were accessed; the SPARC architecture was used, which has alignment requirements). Table 1529.1 shows the affect of inlining on the amount of storage that is saved.

Table 1529.1: Number of bytes of stack space needed by various programs before and after inlining (automatically performed by vpcc). *Bytes saved* refers to the amount of storage saved by optimizing the allocation of locally defined objects. Adapted from Ratliff.[1146]

Program	Stack Size	Bytes Saved (%)	Inlined Stack Size	Inlined Bytes Saved (%)	Program	Stack Size	Bytes Saved (%)	Inlined Stack Size	Inlined Bytes Saved (%)
ackerman	312	8 (2.56)	232	8 (3.45)	linpack	1,504	48 (3.19)	3,312	112 (3.38)

Automatically inlining all functions can lead to very large program images. While heuristics based on number of calls and function size can reduce code expansion, information on which functions are frequently called during program execution enables a more targeted approach to inlining to be made (see Arnold, Fink, Sarkar, and Sweeney[59] for a comparison of inlining performance based on using static and dynamic information, Java based).

The translator for the HP–was DEC– Tru68 platform supports the **__forceinline** storage-class modifier.[600] Functions declared using this modifier are unconditionally inlined by the translator.

Coding Guidelines

The term *type safe macro* (because the types of the arguments are checked) or simply *safe macro* (because the arguments are only evaluated once) are sometimes applied to the use of inline functions.

The extent to which such suggestions are effective is implementation-defined.[119)] 1530

Commentary

There is no requirement on an implementation to handle calls to a function defined with the **inline** function specifier any differently than calls to a function defined without one. This behavior parallels that for the **register** storage-class specifier.

register 1370 extent effective

C++

7.1.2p2 *An implementation is not required to perform this inline substitution at the point of call;*

A C++ implementation is not required to document its behavior.

Coding Guidelines

register 1370 extent effective

Drawing parallels with the implementation-defined behavior of the **register** storage class would suggest that although this behavior is implementation-defined, no recommendation against its use be given. However, there is an argument for recommending the use of **inline** in some circumstances. Developers sometimes use macros because of a perceived performance advantage. Suggesting that an inline function be used instead may satisfy the perceived need for performance (whether or not the translator used performs any inlining is often not relevant), gaining the actual benefit of argument type checking and a nested scope for any object definitions.

Any function with internal linkage can be an inline function. 1531

Commentary

The C Standard explicitly gives this permission because it goes on to list restrictions on inline functions with external linkage.

C++

The C++ Standard does not explicitly give this permission (any function declaration can include the **inline** specifier, but this need not have any effect).

1532 For a function with external linkage, the following restrictions apply:

Commentary

The following restrictions define a model that has differences from the one used by C++.

Rationale

Inlining was added to the Standard in such a way that it can be implemented with existing linker technology, and a subset of C99 inlining is compatible with C++.

C++

The C++ Standard also has restrictions on inline functions having external linkage. But it does not list them in one paragraph.

A program built from the following source files is conforming C, but is ill-formed C++ (3.2p5).

File a.c

```
inline int f(void)
{
return 0+0;
}
```

File b.c

```
int f(void)
{
return 0;
}
```

Building a program from sources files that have been translated by different C translators requires that various external interface issues, at the object code level, be compatible. The situation is more complicated when the translated output comes from both a C and a C++ translator. The following is an example of a technique that might be used to handle some inline functions (calling functions across source files translated using C and C++ translators is more complex).

x.h

```
inline int my_abs(int p)
{
return (p < 0) ? -p : p;
}
```

x.c

```
#include "x.h"

extern inline int my_abs(int);
```

The handling of the second declaration of the function `my_abs` in `x.c` differs between C and C++. In C the presence of the **extern** storage-class specifier causes the definition to serve as a non-inline definition. While in C++ the presence of this storage-class specifier is redundant. The final result is to satisfy the requirement for exactly one non-inline definition in C, and to satisfy C++'s one definition rule.

1350 C++ one definition rule

If a function is declared with an **inline** function specifier, then it shall also be defined in the same translation unit. 1533

Commentary

This is a requirement on the program. It removes the need for linker technology that obtains a definition from some place other than the same translation unit.

C++

7.1.2p4 *An inline function shall be defined in every translation unit in which it is used and shall have exactly the same definition in every case (3.2).*

The C++ Standard only requires the definition to be given if the function is used. A declaration of an inline function with no associated use does not require a definition. This difference permits a program, written using only C constructs, to be acceptable to a conforming C++ implementation but not be acceptable to a C implementation.

Coding Guidelines

identifier declared in one file 422.1

The guideline recommendation dealing with placing the textual declaration of identifiers, having external linkage, in a single source file is applicable here.

footnote 118

118) By using, for example, an alternative to the usual function call mechanism, such as "inline substitution". 1534

Commentary

Another possibility would be to load the machine code generated from a function body into faster memory, for instance cache memory.

Other Languages

Most language specifications do not discuss inline function implementation details.

Common Implementations

Most translators perform inlining using some internal representation (which is rarely viewable). The output of a function inliner implemented by Davidson and Holler[322] was C source code (with functions having been inlined at the point of call).

Inline substitution is not textual substitution, nor does it create a new function. 1535

Commentary

A number of interpretations of the term *inline substitution* are possible. This wording clarifies that the two listed interpretations (with their associated semantics) are not intended to apply. From the developers point of view the semantic of a function call are the abstract one specified by the standard. The only measurable external changes, caused by the addition of a *function-specifier* to the definition of a function, in a program image should be in its size and execution time performance.

operator () 1000

An inline function is processed through the eight phases of translation at their point of definition. The sequence of machine code instructions used to implement a call to that function is an internal detail that is not visible to the developer. A few changes have to be made to the machine code when it is inlined. A **return** statement that contains a value has to be changed so that the value is simply treated like any other expression that occurred at the point of the function call. Any invocation of the `va_*` macros still have to refer to the arguments of the function that originally contained them (which may mean creating a dummy function call stack).

C++

The C++ Standard does not make this observation.

Coding Guidelines

Inline functions are too new to know whether developers make either of these incorrect assumptions.

1536 Therefore, for example, the expansion of a macro used within the body of the function uses the definition it had at the point the function body appears, and not where the function is called;

Commentary

Any other specification of behavior has the potential to cause a change in the appearance of the **inline** function specifier, in a function definition, to change the semantics of a program. Also the existing translation model uses phases of translation. Macro expansion is performed in translation phase 4, prior to any identifiers being converted to keywords.

129 translation phase 4

C++

The C++ Standard does not make this observation.

1537 and identifiers refer to the declarations in scope where the body occurs.

Commentary

The identifiers that may be in scope where the body occurs, but not where the call to the function occurs all have file scope. They include typedef names and tag names, as well as objects and other functions.

1538 Likewise, the function has a single address, regardless of the number of inline definitions that occur in addition to the external definition.

Commentary

It is a requirement on the implementation that the address of every function, during program execution, be unique (also see the response to DR #079). It is also a requirement on the implementation that pointers to different functions do not compare equal.

422 function external linkage denotes same
423 identifier same if internal linkage
1233 pointers compare equal

C++

*An **inline** function with external linkage shall have the same address in all translation units.* 7.1.2p4

There is no equivalent statement, in the C++ Standard, for inline functions having internal linkage.

1539 119) For example, an implementation might never perform inline substitution, or might only perform inline substitutions to calls in the scope of an **inline** declaration.

footnote 119

Commentary

A translator that operates in a single pass over the source, which the majority do, does not have access to the body of an inline function until its definition is encountered. Consequently it may decide that any calls prior to the definition are not inlined. Other complications that might cause a translator to not perform inline substitution include the following:

10 implementation single pass

- When one or more functions forms a recursive chain it may be difficult to fully inline one function into any of the others.
- The `va_*` macros make assumptions about how the parameters they refer to are laid out in storage. The overhead of ensuring that these layout requirements are met, in any inline function that contains uses of these macros, may be sufficient to prevent inline substitution providing any benefit.

inline definition

If all of the file scope declarations for a function in a translation unit include the **inline** function specifier without **extern**, then the definition in that translation unit is an *inline definition*. 1540

Commentary

EXAMPLE 1544
inline
implementation 10
single pass
as-if rule 122
inline 1524
static storage duration

This defines the term *inline definition*. This specification violates the general principle that it be possible to translate C in a single pass. The presence of the word *all* means that a translator has to have seen all declarations of an identifier before it knows whether it is an inline definition. While an implementation still may choose to perform inline substitution before it has processed all of the source (subject to the as-if rule), some constraint requirements only apply to inline definitions, not external definitions, (an implementation is not prohibited from generating spurious diagnostic messages, but it must still correctly translate the source file).

C++

This term, or an equivalent one, is not defined in the C++ Standard.

The C++ Standard supports the appearance of more than one inline function definition, in a program, having a declaration with **extern**. This difference permits a program, written using only C constructs, to be acceptable to a conforming C++ implementation but not be acceptable to a C implementation.

Coding Guidelines

identifier 422.1
declared in one file

If the guideline recommendation specifying a single textual definition of an identifier is followed there will never be more than one declaration for a function, in a translation unit, that include the **inline** function specifier.

Example

```
1  inline int f_1(void)         /* May be an inline definition. */
2  {}
3  inline int f_2(void)         /* May be an inline definition. */
4  {}
5  extern inline int f_3(void)  /* Not an inline definition. */
6  {}
7  extern inline int f_1(void); /* No, f_1 is not an inline definition. */
8
9                               /* End-of-File, f_2 is an inline definition. */
```

inline definition not an external definition

An inline definition does not provide an external definition for the function, and does not forbid an external definition in another translation unit. 1541

Commentary

external 1817
definition

An inline definition is explicitly specified as not being an external definition. The status of an inline function as an inline definition or an external definition does not affect the suggest it provides to a translator.

external 1818
linkage
exactly one external definition

An inline definition is intended for use only within the translation unit in which it occurs. Because it is not an external definition, the constraint requirement that only one external definition for an identifier occur in a program does not apply. However, if a function is used within an expression an external definition for it must exist somewhere in the entire program. The absence, in a function declaration, of **inline** or the inclusion of **extern** in a declaration creates such an external definition. Also, because an inline definition does not provide an external definition, another translation unit may have to contain an external definition (to satisfy references from other translation units).

An inline definition provides an alternative to an external definition, which a translator may use to implement any call to the function in the same translation unit. 1542

Commentary

The inline definition provides all the information (return type and parameter information) needed to call the external definition. Its body can also be used to perform inline substitution. An inline function might be said to have *ghostly linkage*. It exists if the translator believes in it. Otherwise it does not exist and the external definition is referenced.

C++

In C++ there are no alternatives, all inline functions are required to be the same.

> *If a function with external linkage is declared inline in one translation unit, it shall be declared inline in all translation units in which it appears; no diagnostic is required.* 7.1.2p4

A C program may contain a function, with external linkage, that is declared inline in one translation unit but not be declared inline in another translation unit. When such a program is translated using a C++ translator a diagnostic may be issued.

Coding Guidelines

The guideline recommendation specifying a single textual definition is applicable here. 422.1 identifier declared in one file

---

1543 It is unspecified whether a call to the function uses the inline definition or the external definition.[120)]

Commentary

The C Standard does not require that the sequence of tokens representing an inline definition or external definition, of the same function, be the same. However, the intended implication, to be drawn from the unspecified nature of the choice of the definition used, is that a programs external output shall be the same in both cases (apart from execution time performance). If the definitions of the two functions are such that the external program outputs would not be the same, the behavior is undefined. 49 unspecified behavior

C++

In the C++ Standard there are no alternatives. An inline definition is always available and has the same definition:

> *An inline function shall be defined in every translation unit in which it is used and shall have exactly the same definition in every case (3.2).* 7.1.2p4

Rationale

> Second, the requirement that all definitions of an inline function be "exactly the same" is replaced by the requirement that the behavior of the program should not depend on whether a call is implemented with a visible inline definition, or the external definition, of a function. This allows an inline definition to be specialized for its use within a particular translation unit. For example, the external definition of a library function might include some argument validation that is not needed for calls made from other functions in the same library. These extensions do offer some advantages; and programmers who are concerned about compatibility can simply abide by the stricter C++ rules.

Common Implementations

The context in which a call occurs can have as much influence over whether a function is inlined as the definition of the function itself. For instance, are there any non-inlined calls nearby (which would have already prevented any flow analysis from building up much information that could be used at the inlined call), does the size of the function exceed some specified, internal translator, limit (there can be other limits such as the amount of storage required by the declarations in a function)?

Coding Guidelines

identifier declared in one file 422.1

If the guideline recommendation specifying a single textual definition of an identifier is followed the output of a program will not depend on the function chosen.

Example

In the following example the two definitions of the function `f` are different. The developer has used the fact that the call in `g` occurs in a context where the test performed in the external definition is known to be true. A simplified version of the definition of `f`, applicable to the call made in `g`, has been created and it is hoped that this will result in inline substitution.

file_1.c

```
1  void f(void)
2  {
3  if (complicated_test) /* A time consuming test. */
4     do_something;
5  else
6     do_something_else;
7  }
```

file_2.c

```
1  inline void f(void)
2  {
3  do_something;
4  }
5
6  void g(void)
7  {
8  if (part_of_complicated_test)
9     {
10    some_code;
11    if (rest_of_complicated_test)
12       f();
13    }
14 }
```

EXAMPLE inline

EXAMPLE The declaration of an inline function with external linkage can result in either an external definition, or a definition available for use only within the translation unit. A file scope declaration with **extern** creates an external definition. The following example shows an entire translation unit. 1544

```
inline double fahr(double t)
{
        return (9.0 * t) / 5.0 + 32.0;
}

inline double cels(double t)
{
        return (5.0 * (t - 32.0)) / 9.0;
}

extern double fahr(double);        // creates an external definition

double convert(int is_fahr, double temp)
{
        /* A translator may perform inline substitutions */
        return is_fahr ? cels(temp) : fahr(temp);
}
```

Note that the definition of **fahr** is an external definition because **fahr** is also declared with **extern**, but the definition of **cels** is an inline definition. Because **cels** has external linkage and is referenced, an external

definition has to appear in another translation unit (see 6.9); the inline definition and the external definition are distinct and either may be used for the call.

Commentary

Although `fahr` is an external definition, an implementation may still choose to inline calls to it, from within the definition of `convert`.

C++

The declaration:

```
extern double fahr(double);     // creates an external definition
```

does not create a reference to an external definition in C++.

1545 **Forward references:** function definitions (6.9.1).

1546 120) Since an inline definition is distinct from the corresponding external definition and from any other corresponding inline definitions in other translation units, all corresponding objects with static storage duration are also distinct in each of the definitions.

footnote 120

Commentary

The only objects that can have static storage duration are those that have no linkage and are not modifiable lvalues.

1524 inline static storage duration

C++

A ***static*** *local variable in an extern inline function always refers to the same object. A string literal in an* ***extern inline*** *function is the same object in different translation units.* 7.1.2p4

The C++ Standard is silent about the case where the **extern** keyword does not appear in the declaration.

```
inline const char *saddr(void)
{
static const char name[] = "saddr";
return name;
}

int compare_name(void)
{
return saddr() == saddr(); /* may use extern definition in one case and inline in the other */
                           // They are either the same or the program is
                           // in violation of 7.1.2p2 (no diagnostic required)
}
```

6.7.5 Declarators

declarator syntax

1547

declarator:
pointer$_{opt}$ *direct-declarator*
direct-declarator:
identifier
(*declarator* **)**
direct-declarator **[** *type-qualifier-list*$_{opt}$ *assignment-expression*$_{opt}$ **]**
direct-declarator **[** **static** *type-qualifier-list*$_{opt}$ *assignment-expression* **]**

```
                direct-declarator [ type-qualifier-list static assignment-expression ]
                direct-declarator [ type-qualifier-list_opt * ]
                direct-declarator ( parameter-type-list )
                direct-declarator ( identifier-list_opt )

pointer:
                * type-qualifier-list_opt
                * type-qualifier-list_opt pointer
type-qualifier-list:
                type-qualifier
                type-qualifier-list type-qualifier
parameter-type-list:
                parameter-list
                parameter-list , ...
parameter-list:
                parameter-declaration
                parameter-list , parameter-declaration
parameter-declaration:
                declaration-specifiers declarator
                declaration-specifiers abstract-declarator_opt
identifier-list:
                identifier
                identifier-list , identifier
```

Commentary

Parentheses can be used to change the way tokens in declarators are grouped in a similar way to the grouping of operands in an expression.

parameter 1603
declaration
typedef name
in parentheses

The declaration of function parameters does not have the flexibility available to declarations that are not parameters. For instance, it is not possible to write `void f(double a, b, c)` instead of `void f(double a, int b, int c)`.

C90

Support for the syntax:

```
direct-declarator [ type-qualifier-list_opt assignment-expression_opt ]
direct-declarator [ static type-qualifier-list_opt assignment-expression ]
direct-declarator [ type-qualifier-list static assignment-expression ]
direct-declarator [ type-qualifier-list_opt * ]
```

is new in C99. Also the C90 Standard only supported the form:

```
direct-declarator [ constant-expression_opt ]
```

C++

The syntax:

direct-declarator **[** *type-qualifier-list*$_{opt}$ *assignment-expression*$_{opt}$ **]**
direct-declarator **[** **static** *type-qualifier-list*$_{opt}$ *assignment-expression* **]**
direct-declarator **[** *type-qualifier-list* **static** *assignment-expression* **]**
direct-declarator **[** *type-qualifier-list*$_{opt}$ * **]**
direct-declarator **(** *identifier-list*$_{opt}$ **)**

is not supported in C++ (although the form *direct-declarator* **[** *constant-expression*$_{opt}$ **]** is supported).

The C++ Standard also supports (among other constructions) the form:

8p4

direct-declarator **(** *parameter-declaration-clause* **)** *cv-qualifier-seq*$_{opt}$ *exception-specification*$_{opt}$

The C++ Standard also permits the comma before an ellipsis to be omitted, e.g., `int f(int a ...);`.

Other Languages

The extent to which the identifier being declared is visually separate from its associated type information varies between languages. At one extreme languages in the Pascal family completely separate the two (both Pascal and Ada require that a colon, **:**, appear between an identifier and its type information). C (and C++) are at the other extreme, integrating the identifier being declared into the syntax of the type declaration. Fortran might be considered intermediate, with the identifier being syntactically integrated with the type in some cases (e.g., array declarations `REAL A(10)`).

Common Implementations

The type qualifiers **near**, **far**, **pascal**, **tiny**, and **huge** (sometimes prefixed with one or more underscores) are ubiquitous extensions for implementations targeting the Intel x86 processor family (these qualifiers are also found in other implementations where the target processor supports a variety of pointer sizes). `gcc` supports a variety of kinds of declaration containing the keyword **__attribute__** that specify a variety of different kinds of semantic information about the identifier being declared. The HP C/iX translator[1039] supports a short pointer (32-bit) and long pointer (64-bit). The declaration of a type denoting a long pointer uses the punctuator `^`. For instance, `int ^long_ptr`.

Coding Guidelines

A very common mistake made by beginners is to treat the following two declarations of `arr` as being compatible:

1588 EXAMPLE array not pointer

```
int arr[];
```

and

```
int *arr;
```

being unaware that the duality between arrays and pointers only holds in expressions. However, this is a developer education rather than a coding guideline issue.

A more subtle mistake that even experienced developers make is to treat the star, `*`, token as belonging to the type information. For instance, in:

```
char * pc_1,
       pc_2;  /* Has type char, not char * */
char (* pc_3),
        pc_4; /* Same type as pc_2.        */
```

it is only p_1 and p_3 that have pointer types. One possible reason for the categorizations mistake is the proximity of the type specifier and the * token. Developers do not seem to make the same mistake with array bounds declarators, where an identifier appears between the type and the **[ ]** tokens. The following guideline recommendation is a simple method of avoiding this kind of mistake.

Cg 1547.1 The number of star, *, tokens appearing on each declarator of the same declarator list of a declaration shall be the same.

Redundant parentheses do not commonly appear in declarators and this issue is not discussed further.

Example

```
1  int (x); /* Redundant () */
2
3  int (((aa[1])[1])[1]); /* Harder to follow than without ()? */
4  int ab[1][1][1];
5
6  int (*ap1)[10]; /* Pointer to array of 10 ints. */
7  int *(ap2[10]); /* Array of pointers to int. */
8  int *ap3[10];   /* Which is this? */
9
10 typedef int * p_i;
11
12 p_i * p_1,
13       p_2;
```

Semantics

Each declarator declares one identifier, and asserts that when an operand of the same form as the declarator appears in an expression, it designates a function or object with the scope, storage duration, and type indicated by the declaration specifiers. 1548

Commentary

The form of an identifier in an expression is likely to be the same as that in the declarator. For instance, the declarator * x will have this form in an expression when the value pointed to by x is required and the declarator y[2] will have this form in an expression when an element of the array y is referred to. It is the declarator portion of a declaration that declares the identifier. There is a special kind of declarator, an *abstract-declarator*, which does not declare an identifier.

abstract declarator syntax 1624

full declarator A *full declarator* is a declarator that is not part of another declarator. 1549

Commentary

full expression 1712

This defines the term *full declarator* (which mimics that for full expression). A declarator appearing as an operand of a cast operator, that is not part of an initializer, is a full declarator. The declarators for the parameters in a function declaration are part of another declarator.

C90

Although this term was used in the C90 Standard, in translation limits, it was not explicitly defined.

C++

This term, or an equivalent one, is not defined by the C++ Standard.

full declarator sequence point The end of a full declarator is a sequence point. 1550

Commentary

It is possible for a nonconstant expression to occur within a declarator (for instance, the expression denoting the number of array elements) and its may cause side effects. In: 185 side effect

```
extern int glob;

void f(char a_1[glob++], char a_2[glob++]])
{ /* ... */ }
```

941 object modified once between sequence points

`glob` is modified twice between two adjacent sequence points and the behavior is undefined. While in:

```
int g(void)
{
static int val;
return ++val;
}

void f(char a_1[g()], char a_2[g()])
{ /* ... */ }
```

the behavior is unspecified.

C90

The ability to use an expression causing side effects in an array declarator is new in C99. Without this construct there is no need to specify a sequence point at the end of a full declarator.

C++

The C++ Standard does not specify that the end of ant declarator is a sequence point. This does not appear to result in any difference of behavior.

Other Languages

Those languages supporting some form of execution time array bounds selection invariably have the same behavior (i.e., an evaluation order is not defined).

Coding Guidelines

This ability for declarators to cause side effects is new in C99, although declarations could cause side effects in C90 through the use of an initializer. This issue of side effects is discussed elsewhere 941 object modified once between sequence points

Example

```
extern int glob;

void f(void)
{
int arr_1[glob++],
    arr_2[glob++];
}
```

1551 If in the nested sequence of declarators in a full declarator ~~contains~~ there is a declarator specifying a variable length array type, the type specified by the full declarator is said to be *variably modified*. variably modified

Commentary

This defines the term *variably modified*. The parameter types or return type of a function type are not usually considered to be *nested* within its full declarator.

The wording was changed by the response to DR #311.

C90

Support for variably modified types is new in C99.

C++

Support for variably modified types is new in C99 and is not specified in the C++ Standard.

Furthermore, any type derived by declarator type derivation from a variably modified type is itself variably modified. 1552

Commentary

This wording ensures that in code such as the following example, the declaration of y is also variably modified.

```
1  int x;
2
3  typedef int vla[x];
4  vla y[3];
```

This sentence was added by the response to DR #311.

In the following subclauses, consider a declaration 1553

T D1

where **T** contains the declaration specifiers that specify a type *T* (such as **int**) and **D1** is a declarator that contains an identifier *ident*.

Commentary

This is the simplest, most basic, form of declaration (the various possible declarators, D1, supported in C, are described in the following C sentences).

The type specified for the identifier *ident* in the various forms of declarator is described inductively using this notation. 1554

Commentary

abstract declarator syntax 1624

In the case of abstract declarators there is no identifier (although discussions involving these constructs sometimes refer to an *omitted* identifier).

If, in the declaration "**T D1**", **D1** has the form 1555

identifier

then the type specified for *ident* is *T*.

Commentary

This is the most common form of declaration, declaring an identifier to have type T.

If, in the declaration "**T D1**", **D1** has the form 1556

(D)

then *ident* has the type specified by the declaration "**T D**".

Commentary

That is, the use of parentheses is purely a syntactic device that may affect the parsing of a sequence of tokens.

1557 Thus, a declarator in parentheses is identical to the unparenthesized declarator, but the binding of complicated declarators may be altered by parentheses.

Commentary

This specifies that this parenthesis around declarators have no semantics associated with them (they have associated semantics when they appear to the right of an identifier, they cause it to denote a function type). It is also possible to use typedefs to achieve the same effect. For instance:

```
int (*V_1)[10]; /* Pointer to array of int. */

typedef int A10_INT[10];
A10_INT *V_2;   /* Pointer to array of int. */
```

Other Languages

Many languages do not support the bracketing of identifiers in declarations. It is only needed in C because the syntax of declarators uses tokens that can appear to the left or the right of the identifier whose type they specify. To specify some types parentheses are needed to alter the binding. For instance,

```
int *V[10];   /* Array of pointer to int. */
int (*V)[10]; /* Pointer to array of int. */

/*
 * Type information is Pascal always reads left-to-right.
 */
V : array[0..9] of ^ integer; /* Array of pointer to int. */
V : ^array[0..9] of integer;  /* Pointer to array of int. */
```

Common Implementations

Parentheses are processed as part of the syntax. Their presence can alter the parsing (binding) of declarators. There are no implementation issues associated by reordering declarators through parenthesis, like there are for expressions.

981 parenthesized expression

Coding Guidelines

Experience shows that declarators of the form `*x[3]` are a source of developer miscomprehension. Some developers reading it left-to-right "a pointer to an array of . . . ", rather than the correct right-to-left order "array of pointer to . . . ". The interpretation of an objects type affects how it is used in expressions. Depending on how x is accessed the final operand type may become "a pointer to a pointer to . . . " under both interpretations of the type of x (indexing an object having an array type causes it to be converted to a pointer type in many contexts). A consequence of this conversion is that it is possible for x to be accessed, under both interpretations of its type, without a translator diagnostic (pointing out a type mismatch) being issued.

729 array converted to pointer

If the guideline recommendation specifying the use of parenthesis in expressions is applied to declarations, a reader of the source may notice a discrepancy between their incorrect interpretation of the type specified in an objects declaration and the type implied by how that object is used in an expression. However, using parenthesis to unambiguously define the intended syntactic binding of the components of a declarator is a more reliable method of ensuring that readers comprehend the intended type.

943.1 expression shall be parenthesized

Cg 1557.1 The declarator for an object declared to have type "array of pointer to . . . " shall parenthesize the array portion of the declarator.

Dev 1557.1 The array portion of a declarator need not be parenthesized if its element type is specified using a typedef name.

Example

```
#define INT_PTR int *
typedef int * int_ptr;
int * arr_1  [3];
int (*arr_2) [3]; /* Parenthesis must be used to declare this type. */
int *(arr_3  [3]);
int_ptr arr_4[3]; /* Unlikely to be interpreted as a pointer to an array. */
INT_PTR arr_5[3]; /* Not covered by previous deviation because the usage is recommended against elsewhere. *
```

Implementation limits

declarator complexity limits

As discussed in 5.2.4.1, an implementation may limit the number of pointer, array, and function declarators that modify an arithmetic, structure, union, or incomplete type, either directly or via one or more **typedef**s. 1558

Commentary

limit 279 type complexity

This wording differs from that in 5.2.4.1 in that it includes types defined via typedefs in the count.

C90

The implementation shall allow the specification of types that have at least 12 pointer, array, and function declarators (in any valid combinations) modifying an arithmetic, a structure, a union, or an incomplete type, either directly or via one or more ***typedef****s.*

Forward references: array declarators (6.7.5.2), type definitions (6.7.7). 1559

6.7.5.1 Pointer declarators

Semantics

derived-declarator-type-list

If, in the declaration "**T D1**", **D1** has the form 1560

```
* type-qualifier-list_opt D
```

and the type specified for *ident* in the declaration "**T D**" is "*derived-declarator-type-list T*", then the type specified for *ident* is "*derived-declarator-type-list type-qualifier-list* pointer to *T*".

Commentary

The term *derived-declarator-type-list* is very rarely used outside of the C Standard, even during Committee discussions.

C++

The C++ Standard uses the term *cv-qualifier-seq* instead of *type-qualifier-list*.

For each type qualifier in the list, *ident* is a so-qualified pointer. 1561

Commentary

The C++ Standard says it better:

8.3.1p1

The `cv-qualifiers` *apply to the pointer and not to the object pointed to.*

So qualifiers to the right of the * token qualify the pointer type and qualifiers to the left of the * token qualify the pointed-to type.

Example

The following declares three objects to have the same type.

```
typedef int * p_i;

p_i   const g_1;
const p_i   g_2;
const int  *g_3;
```

1562 For two pointer types to be compatible, both shall be identically qualified and both shall be pointers to compatible types.

pointer types to be compatible

Commentary

There is no requirement that the declarators of the two pointer types, being checked for compatibility, be built from the same sequence of tokens. For instance:

631 compatible type if

```
typedef int * int_ptr;

int *   p1;
int_ptr p2; /* The type of p1 is compatible with that of p2. */
```

C++

The C++ Standard does not define the term *compatible type*, although in the case of qualified pointer types the term *similar* is defined (4.4p4). When two pointer types need to interact the C++ Standard usually specifies that the qualification conversions (clause 4) are applied and then requires that the types be the same. These C++ issues are discussed in the sentences in which they occur.

1563 EXAMPLE The following pair of declarations demonstrates the difference between a "variable pointer to a constant value" and a "constant pointer to a variable value".

```
const int *ptr_to_constant;
int *const constant_ptr;
```

The contents of any object pointed to by **`ptr_to_constant`** shall not be modified through that pointer, but **`ptr_to_constant`** itself may be changed to point to another object. Similarly, the contents of the **`int`** pointed to by **`constant_ptr`** may be modified, but **`constant_ptr`** itself shall always point to the same location.
The declaration of the constant pointer **`constant_ptr`** may be clarified by including a definition for the type "pointer to **`int`**".

```
typedef int *int_ptr;
const int_ptr constant_ptr;
```

declares **`constant_ptr`** as an object that has type "const-qualified pointer to **`int`**".

Commentary

A typename can be qualified with a type qualifier (e.g., `const int_ptr`), but the underlying type cannot be changed by adding a type specifier (e.g., `unsigned int_ptr`)

1378 type specifier syntax

6.7.5.2 Array declarators

Constraints

In addition to optional type qualifiers and the keyword **static**, the **[** and **]** may delimit an expression or *. 1564

Commentary

Saying in words what is specified in the syntax (and in a constraint!)

C90

*The expression delimited by **[** and **]** (which specifies the size of an array) shall be an integral constant expression that has a value greater than zero.*

Support for the optional type qualifiers, the keyword **static**, the expression not having to be constant, and support for * between **[** and **]** in a declarator is new in C99.

C++

Support for the optional type qualifiers, the keyword **static**, the expression not having to be constant, and * between **[** and **]** in a declarator is new in C99 and is not specified in the C++ Standard.

If they delimit an expression (which specifies the size of an array), the expression shall have an integer type. 1565

Commentary

The expression is usually thought of, by developers, in terms of specifying the number of elements, not the size.

Other Languages

Many languages require the value of the expression to be known at translation time, and some (e.g., Ada) allow execution time evaluation of the array bounds, while a few (e.g., APL, Perl, and Common Lisp) support dynamically resizeable arrays. In some languages (e.g., Fortran) there is an implied lower bound of one. The value given in the array declaration is the upper bound and equals the number of elements. Languages in the Pascal family require that a type be given. The minimum and maximum values of this type specifying the lower and upper bounds of the array. This type also denotes the type of the expression that must be used to index that array. For instance, in:

```
C_A :Array[Char] of Integer;
```

the array C_A can only be indexed with an expression having type **char**.

Coding Guidelines

At the time of this writing there is insufficient experience with use of this construct to known whether any guideline recommendation (e.g., on the appearance of side effects) might be worthwhile.

array declaration size greater than zero

If the expression is a constant expression, it shall have a value greater than zero. 1566

Commentary

C does not support the creation of named objects occupying zero bytes of storage.

Note that this constraint is applied before any implicit conversions of array types to pointer types (e.g., even although the eventual type of a in `extern int f(int a[-1]);` is pointer to **int**, a constraint violation still occurs).

Other Languages

Very few languages support the declaration of zero sized objects (Algol 68 allows the declaration of a flexible array variable to have zero size, assigning an array to such a variable also resulting in the new bounds being assigned). Languages in the Pascal family support array bounds less than one. For instance, the declaration:

```
C_A :Array[-7..0] of Integer;
```

creates an array object, C_A, that must be indexed with values between -7 and 0 (inclusive).

1567 The element type shall not be an incomplete or function type.

array element not incomplete type
array element not function type

Commentary

The benefits of allowing developers to declare arrays having element types that are incomplete types was not considered, by the C committee, to be worth the complications (i.e., cost) created for translator writers (the C language definition is intended to translatable in a single pass). C does not support treating functions as data, so while pointers to functions are permitted arrays of function types are not.

10 implementation single pass

C90

In C90 this wording did not appear within a Constraints clause. The requirement for the element type to be an object type appeared in the description of array types, which made violation of this requirement to be undefined behavior. The undefined behavior of all known implementations was to issue a diagnostic, so no actual difference in behavior between C90 and C99 is likely to occur.

526 array contiguously allocated set of objects

C++

8.3.4p1

T is called the array element type; this type shall not be a reference type, the (possibly cv-qualified) type **`void`***, a function type or an abstract class type.*

The C++ Standard does not disallow incomplete element types (apart from the type **`void`**). This difference permits a program, written using only C constructs, to be acceptable to a conforming C++ implementation but not be acceptable to a C implementation.

Other Languages

Few languages support arrays of functions (or pointers to functions).

1568 The optional type qualifiers and the keyword **`static`** shall appear only in a declaration of a function parameter with an array type, and then only in the outermost array type derivation.

array parameter qualifier only in outermost

Commentary

The functionality provided by the appearance of type qualifiers and the keyword **`static`** in this context is not needed for declarations involving array types in other contexts (because function parameters are the only context where the declaration of an object having an array type is implicitly converted to a pointer type).

729 array converted to pointer

C90

Support for use of type qualifiers and the keyword **`static`** in this context is new in C99.

C++

Support for use of type qualifiers and the keyword **`static`** in this context is new in C99 is not supported in C++.

Coding Guidelines

Support for these constructs is new in C99 and insufficient experience has been gained with their usage to know if any guideline recommendations are worthwhile.

1569 ~~Only an~~ An ordinary identifier (as defined in 6.2.3) ~~with both block scope or function prototype scope and no linkage shall have a variably modified type.~~ that has a variably modified type shall have either block scope and no linkage or function prototype scope.

variable modified only scope

Commentary

Ordinary identifiers do not include members of structure or union types. These members are prevented from having a variably modified type for practical implementation reasons. For instance, requirement on the relative ordering of storage allocated to members of a structure cannot be met without reserving impractically

444 ordinary identifiers

1206 structure members later compare later

large amounts of storage for any member having a variably modified type (variably modified types are usually implemented via a pointer to the actual, variable sized, storage allocated).

VLA 464
lifetime starts/ends
static storage 456
duration
when initialized

Storage for objects having external or internal linkage is only allocated once and it makes no sense for such objects to have a variably modified type.

This wording was changed by the response to DR #320.

C90

Support for variably modified types is new in C99.

C++

Support for variably modified types is new in C99 and is not specified in the C++ Standard.

If an identifier is declared to be an object with static storage duration, it shall not have a variable length array type. 1570

Commentary

static storage 456
duration
when initialized

The standard requires that storage for all objects having static storage duration be allocated during program startup. Thus the amount of storage to allocate must be known prior to the start of program execution, ruling out the possibility of execution time specification of the length of an array.

Semantics

---

qualified array of

If, in the declaration "**T D1**", **D1** has one of the forms: 1571

D[*type-qualifier-list*$_{opt}$ *assignment-expression*$_{opt}$ **]**
D[static *type-qualifier-list*$_{opt}$ *assignment-expression* **]**
D[*type-qualifier-list* **static** *assignment-expression* **]**
D[*type-qualifier-list*$_{opt}$ ***** **]**

and the type specified for *ident* in the declaration "**T D**" is "*derived-declarator-type-list T*", then the type specified for *ident* is "*derived-declarator-type-list* array of *T*".[121)]

Commentary

derived-declarator-type-list 1560

Phrases such as *derived-declarator-type-list* are rarely used outside of the C standard, even amongst the Committee.

C90

Support for forms other than:

D[*constant-expression*$_{opt}$ **]**

is new in C99.

C++

The C++ Standard only supports the form:

D[*constant-expression*$_{opt}$ **]**

A C++ translator will issue a diagnostic if it encounters anything other than a constant expression between the **[** and **]** tokens.

The type of the array is also slightly different in C++, which include the number of elements in the type:

8.3.4p1 *. . . the array has N elements numbered 0 to N-1, and the type of the identifier of D is "derived-declarator-type-list array of N T."*

Other Languages

Some languages (e.g., the Pascal family of languages) require both a lower and upper bound to be specified. Although BCPL uses the tokens **[ ]** to denote an array access (and also a function call), these tokens are not used in an array declaration. For instance, the following creates an array of 10 elements (lower bound of zero, upper bound of nine) and assigns a pointer to the first element to `N`:

```
1  let N = vec 9
```

1572 (See 6.7.5.3 for the meaning of the optional type qualifiers and the keyword **static**.)

Commentary

See elsewhere for commentary on optional type specifiers and the keyword **static**.

1598 array type
adjust to pointer to
1599 function declarator
static
array
incomplete type

1573 If the size is not present, the array type is an incomplete type.

Commentary

This is stated is a different way elsewhere. As well as appearing between **[]** tokens, the size may also be specified, in the definition of an object, via the contents of an initializer.

546 array
unknown size
1683 array of
unknown size
initialized

C++

The C++ Standard classifies all compound types as object types. It uses the term *incomplete object type* to refer to this kind of type.

475 object types

> *If the constant expression is omitted, the type of the identifier of* `D` *is "*`derived-declarator-type-list` *array of unknown bound of* `T`*," an incomplete object type.* 8.3.4p1

Coding Guidelines

The following are some of the contexts in which the size might not be present:

1683 array of
unknown size
initialized

- An automatically generated initializer, used in an object definition, may be written to a file that is **#include**d at the point of use (while the generation of the members of the initializer may be straightforward, the cost of automatically modifying the C source code, so that it contains an explicit value for the number of elements may be not be considered worth the benefit).
- A typedef name denoting an array type of unknown size is a useful way of giving a name to an array of some element type (the size being specified later when an object, of that named type, is defined).
- The type of a parameter in a function declaration. While this usage may seem natural to developers who have recently moved to C from some other languages, it looks unusual to experienced C developers (the parameter is not treated as an array at all, its type is converted to a pointer to the element type).

729 array
converted to
pointer

- The type of an object declared in a header, where there is a desire to minimize the amount of visible information. In this case a pointer could serve the same purpose. The only differences are in how the storage for the object is allocated (and initialized) and the machine code generated for accesses (a pointer requires an indirect load, a minor efficiency penalty; the use of an array can simplify an optimizers attempt to deduce which objects are not aliased, potentially leading to higher-quality machine code. The introduction of the keyword **restrict** in C99 has potentially removed this advantage).

While not having the number of elements explicitly specified in the declaration of an array type may be surprising to users of other languages (experienced users of other languages, sometimes promoted to a level whether they no longer write code and are not experienced with C, are surprisingly often involved in the creation of a company's coding guidelines) the usage is either cost effective or the alternatives offer no additional benefits. For these reasons no guideline recommendation is given here.

Example

In the following:

```
extern void f(int *p1, int *p2);
extern void f(int p1[], int p2[3]);
```

the first parameter is not an array of known size in either declaration, but the types are compatible. Possible composite types are:

```
extern void f(int *p1, int p2[3]);
```

and

```
extern void f(int p1[], int p2[3]);
```

In the following:

```
extern int g(int p3[3]);
extern int g(int p3[5]);
```

the parameter types are compatible (because both are first converted to pointers before checking for compatibility). Possible composite types are:

```
extern int g(int p3[3]);
```

and

```
extern int g(int p3[5]);
```

In the following:

```
extern int h(int n, int p4[2]);
extern int h(int n, int p4[n]);
```

The composite type is:

```
extern int h(int p4[2]);
```

---

variable length array specified by *

If the size is * instead of being an expression, the array type is a variable length array type of unspecified size, which can only be used in declarations with function prototype scope;[122)] 1574

Commentary

It is possible that implementations will want to use different argument passing conventions for variable length array types than for other array types. The * notation allows a variable length array type to be specified without having to specify the expression denoting its size, removing the need for the identifiers used in the size expression to be visible at the point in the source the function prototype is declared. If an expression is given in function prototype scope, it is treated as if it were replaced by *.

VLA 1581 size treated as *

Syntactically the size can be specified using * in any context that an array declarator can appear. If this context is not in function prototype scope the behavior is undefined.

C90

Support for a size specified using the * token is new in C99.

C++

Specifying a size using the * token is new in C99 and is not available in C++.

Other Languages

Several languages (e.g., Fortran) use * to denote an array having an unknown number of elements.

1575 such arrays are nonetheless complete types.

Commentary

The size of a parameters type in function prototype scope is not needed by a translator. Specifying that arrays declared using the * notation are complete types enables pointers to variable length arrays, and arrays having more than one variable length dimension, to be declared as parameters, e.g., `int f(int p_1[*][*], int (*p_2)[*])`.

1576 If the size is an integer constant expression and the element type has a known constant size, the array type is not a variable length array type;

variable length array type

Commentary

This defines a variable length array type in terms of what it is not. In:

548 known constant size

```
extern int n,
           m;
int a_1[5][n]; /* Size is not an integer constant expression. */
int a_2[m][6]; /* Element type is not a known constant size.  */
```

C90

Support for specifying a size that is not an integer constant expression is new in C99.

C++

Support for specifying a size that is not an integer constant expression is new in C99 and is not specified in the C++ Standard.

1577 121) When several "array of" specifications are adjacent, a multidimensional array is declared.

footnote 121

Commentary

Although not notated as such, this is the definition of the term *multidimensional array*.

Other Languages

The process of repeating array declarators to create multidimensional arrays is used in many languages. Some languages (e.g., those in the Algol family) support the notational short cut of allowing information on all dimensions to occur within one pair of brackets (when this short cut is used it is not usually possible to access slices of the array). For instance, a multidimensional array declaration in Pascal could be written using either of the following forms:

```
Arr_1 : Array[1..4] of Array[0..3] of Integer;
Arr_2 : Array[1..4, 0..3] of Integer;
```

while in Fortran it would be written:

```
INTEGER Arr_2(10,20)
```

Common Implementations

To improve performance, when accessing multidimensional arrays, Larsen, Witchel, and Amarasinghe[812] found that it was sometimes worthwhile to pad the lowest dimension array to ensure the next higher dimension started at a particular alignment (whole program analysis was used to verify that there was no danger of changing the behavior of the program; multidimensional arrays are required to have any no padding between dimensions). For instance, if the lowest dimension was specified to contain three elements, it might be worthwhile to increase this to four.

footnote 122

122) Thus, * can be used only in function declarations that are not definitions (see 6.7.5.3). 1578

Commentary

object 1361 type complete by end

The size of all parameters in a function definition are required to be known (i.e., they have complete types), even if the parameter is only passed as an argument in a call to another function.

array variable length

otherwise, the array type is a variable length array type. 1579

Commentary

This is true by definition.

If the size is an expression that is not an integer constant expression: 1580

Commentary

integer constant expression 1328

That is, the expression does not have a form that a translator is required to be able to evaluate to an integer constant during translation.

C90

Support for non integer constant expressions in this context is new in C99.

C++

Support for non integer constant expressions in this context is new in C99 and is not available in C++.

VLA size treated as *

if it occurs in a declaration at function prototype scope, it is treated as if it were replaced by *; 1581

Commentary

The implication of this wording is that the expression is not evaluated. A size expression occurring in a declaration at function prototype scope serves no purpose other than to indicate that the parameter type is a variably modified array type.

variable length array specified by * 1574

Other Languages

Languages that support execution time evaluation of an arrays size face the same problems as C. Few checks can be made on the type during translation and the expression essentially has to be treated as evaluating to some unknown value.

Coding Guidelines

The expression might be given for documentation purposes. It provides another means for developers to obtain information about the expected size of the array passed as an argument. Whether such usage is more likely to be kept in sync with the actual definition than information given in a comment is not known. A guideline recommendation that the expression be identical to that in the function definition is not given for the same reason that none is given for keeping comments up-to-date with the code.

comment disadvantages

otherwise, each time it is evaluated it shall have a value greater than zero. 1582

Commentary

array declaration size greater than zero 1566

This specification is consistent with that given when the expression is a constant. The expression is evaluated each time the function is called, even if the call is a recursive one.

Example

```
1  #include <stddef.h>
2
3  size_t fib(size_t n_elems, char arr[static n_elems],
4             char p_a[static (n_elems == 1) ? 1 : (n_elems + fib(n_elems-1, arr, arr))])
```

```
5   {
6   return sizeof(p_a);
7   }
```

1583 The size of each instance of a variable length array type does not change during its lifetime.

Commentary

The implication is that subsequent changes to the values of objects appearing in the expression do not affect to size of the VLA. The size expression is evaluated only when the declarator containing it is encountered during program execution. The number of elements in the array type is then fixed throughout its lifetime. In the following the change in the value of `glob` does not array the value of `sizeof(arr)`.

1711 object initializer evaluated when
1841 function entry parameter type evaluated

```
1   extern int glob;
2
3   void f(void)
4   {
5   int arr[glob];
6
7   glob++;
8   sizeof(arr);
9   }
```

A variable length array type need not denote a named object. For instance, in:

```
1   void f(int n)
2   {
3   static char (*p)[n++];
4   }
```

the pointer `p` has a variably modified type, but is not itself a VLA. Even although storage for `p` is allocated at program startup its type is not known until the array declarator is evaluated, each time `f` is called (any assignment to `p` has to be compatible with this type).

Other Languages

A few languages (e.g., APL and Perl) support arrays that change their size on an as-needed basis.

Coding Guidelines

It is possible that the expression denoting the size of the VLA array will also appear elsewhere in the function, e.g., to perform some array bounds test. Any modification of the value of an object appearing in this expression is likely to cause the value of the two expressions to differ. Until more experience is gained with the use of VLA types it is not possible to evaluate the cost/benefit of any potential guideline recommendations (e.g., recommending against the modification of objects appearing in the expression denoting the size of a VLA).

1584 Where a size expression is part of the operand of a **`sizeof`** operator and changing the value of the size expression would not affect the result of the operator, it is unspecified whether or not the size expression is evaluated.

sizeof VLA unspecified evaluation

Commentary

The rather poor argument (in your authors opinion) put forward, by some Committee members, for this unspecified behavior, was that there were existing implementations that did not evaluate sub-operands that did not affect the value returned by the **`sizeof`** operator.

C90

The operand of **`sizeof`** was not evaluated in C90. With the introduction of variable length arrays it is possible that the operand will need to be evaluated in C99.

Common Implementations

As part of the process of simplifying and folding expressions some translators only analyze as much of their intermediate representation as is needed. Such translators are unlikely to generate machine code to evaluate any operands of the **sizeof** operator that are not needed to obtain the value of an expression.

Coding Guidelines

Evaluation of the operands of **sizeof** only becomes an issue when it may appear to generate a side effect. However, no guideline recommendation is given here for the same reason that none was given for the non-VLA case.

sizeof 1123 operand not evaluated

Example

```
1  extern int glob;
2
3  void f(int n,
4         int arr[++n]) /* Expression evaluated. */
5  {
6  int (*p)[glob++];    /* Expression evaluated. */
7  /*
8   * To obtain the size of the type ++n must be evaluated,
9   * but the value of ++glob does not affect the final size.
10  */
11 n=sizeof(int * (int * [++glob])[++n]);
12 }
```

---

array type to be compatible

For two array types to be compatible, both shall have compatible element types, and if both size specifiers are present, and are integer constant expressions, then both size specifiers shall have the same constant value. 1585

Commentary

structural compatibility

structural 1585 compatibility
compatible 631 type if

While the compatibility rules for structure and union types are based on the names of the types, array type compatibility is based on what is sometimes called *structural compatibility*. The components of the type, rather than just its name, is compared. This requirement can be verified at translation time. If either size specifier is not present then the array types are always compatible (provide their element types are).

C++

compatible 631 type if

The C++ Standard does not define the concept of compatible type, it requires types to be the same.

Other Languages

Languages in the Pascal family usually compare the names of array types, rather than their components. This is sometimes considered too inconvenient when passing arguments having an array type and special rules for argument/parameter array type compatibility are sometimes created (e.g., conformant arrays in Pascal). Some languages (e.g., CHILL) use *structural compatibility* type checking rules. When the lower bound of an array is specified by the developer it is necessary to check that both the lower and upper bounds, for each dimension of the two arrays, have the same value.

If the two array types are used in a context which requires them to be compatible, it is undefined behavior if the two size specifiers evaluate to unequal values. 1586

Commentary

array 729 converted to pointer

In most contexts expressions having an array type are converted to a pointer to their element type. Contexts where the size specifiers need to be considered include the following:

function 1599 declarator static

- an argument whose corresponding parameter has an array type that includes the type qualifier **static**, and

- assignment to an object having type pointer to array of type.

1288 assignment-expression syntax

C90

The number of contexts in which array types can be incompatible has increased in C99, but the behavior is intended to be the same.

C++

There are no cases where the C++ Standard discusses a requirement that two arrays have the same number of elements.

Common Implementations

In practice the unexpected (undefined) behavior may not occur after the point of assignment. For instance, at the point where an object having the array type is accessed. For arrays having a single dimension, provided the access is within the bounds of the object, an implementation is likely to behave the same way as when the two array types have equal size specifiers. For multidimensional arrays the number of elements in each array declarator, except the last one, is used as a multiplier for calculating the index value. This means that even if the object, having an array type, is larger than required the incorrect element will still be accessed.

```
1  static int glob = 9;
2
3  void f(char p_arr[static 4][static 6])
4  {
5  /*
6   * The following will access location p_arr+(2+3*4) had the sizes
7   * been the same location p_arr+(2+3*9) would have been accessed.
8   */
9  p_arr[2][3] = 9;
10 }
11
12 void g(void)
13 {
14 char arr[glob][4];
15
16 f(arr);
17 }
```

Coding Guidelines

Developers may intentionally write code where the two array specifiers have different values, relying on the behavior being defined when only allocated storage is accessed. Support for VLA types are new in C99 and there is not yet sufficient experience to be able to judge the cost/benefit of recommending against this usage. Developers may also accidentally write code where two array specifiers have different values. However, these coding guidelines are not intended to recommend against the use of constructs that are obviously faults.

0 guidelines not faults

1587 EXAMPLE 1

EXAMPLE array of pointers

```
float fa[11], *afp[17];
```

declares an array of **float** numbers and an array of pointers to **float** numbers.

Commentary

The algorithm for reading declarations involving both array and pointer types is to:

1. start at the identifier and work right through each array size, until a semicolon or closing parenthesis is reached,
2. then restart at the identifier and work left through the type qualifiers and *'s,

3. if a closing parenthesis is reached on step 1, it the opening parenthesis will eventually be reached on step 2. This parentheses bracketed sequence is then treated as an identifier and the process repeated from step 1.

EXAMPLE function returning pointer to 1617 A similar rule can be applied to reading function types.

Coding Guidelines

symbolic name 822 The discussion on using symbolic names rather than integer constants is applicable here.

Example

```
int *   (*   (*glob[1]      [2])     [3])     [4];
/*
                    array of
                             array of
               pointer to
                                      array of
          pointer to
                                               array of
     pointer to

or in linear form:

array of array of pointer to array of pointer to array of pointer to int
*/
```

EXAMPLE array not pointer EXAMPLE 2 Note the distinction between the declarations 1588

```
extern int *x;
extern int y[];
```

The first declares **x** to be a pointer to **int**; the second declares **y** to be an array of **int** of unspecified size (an incomplete type), the storage for which is defined elsewhere.

Commentary

declarator syntax 1547 The issue of the same object being declared to have both pointer and array types, one in each of two translation units, is discussed elsewhere.

EXAMPLE 3 The following declarations demonstrate the compatibility rules for variably modified types. 1589

```
extern int n;
extern int m;
void fcompat(void)
{
        int a[n][6][m];
        int (*p)[4][n+1];
        int c[n][n][6][m];
        int (*r)[n][n][n+1];
        p = a;        // invalid: not compatible because 4 != 6
        r = c;        // compatible, but defined behavior only if
                      // n == 6 and m == n+1
}
```

Commentary

Array types having more than two dimensions are rarely seen in practice (see Table 991.1).

Other Languages

In some languages (e.g., APL, Perl) assigning a value may change the type of the object assigned to (to be that of the value assigned).

1590 EXAMPLE 4 All declarations of variably modified (VM) types have to be at either block scope or function prototype scope. Array objects declared with the **static** or **extern** storage-class specifier cannot have a variable length array (VLA) type. However, an object declared with the **static** storage-class specifier can have a VM type (that is, a pointer to a VLA type). Finally, all identifiers declared with a VM type have to be ordinary identifiers and cannot, therefore, be members of structures or unions.

```
extern int n;
int A[n];                           // invalid: file scope VLA
extern int (*p2)[n];                // invalid: file scope VM
int B[100];                         // valid: file scope but not VM

void fvla(int m, int C[m][m]);      // valid: VLA with prototype scope

void fvla(int m, int C[m][m])       // valid: adjusted to auto pointer to VLA
{
        typedef int VLA[m][m];      // valid: block scope typedef VLA

        struct tag {
                int (*y)[n];        // invalid: y not ordinary identifier
                int z[n];           // invalid: z not ordinary identifier
        };
        int D[m];                   // valid: auto VLA
        static int E[m];            // invalid: static block scope VLA
        extern int F[m];            // invalid: F has linkage and is VLA
        int (*s)[m];                // valid: auto pointer to VLA
        extern int (*r)[m];         // invalid: r has linkage and points to VLA
        static int (*q)[m] = &B;    // valid: q is a static block pointer to VLA
}
```

Commentary

In this example `m` is being used in the same way as a symbolic name might be used in the declaration of non-VM array types.

1591 **Forward references:** function declarators (6.7.5.3), function definitions (6.9.1), initialization (6.7.8).

6.7.5.3 Function declarators (including prototypes)

Constraints

1592 A function declarator shall not specify a return type that is a function type or an array type.

function declarator return type

Commentary

The wording given for function definitions is slightly different and the discussion given for that sentence is applicable here.

1823 function definition return type

Other Languages

It is quite common for languages to support functions returning array types. Support for functions returning function types is much less common (e.g., Lisp, Algol 68).

1593 The only storage-class specifier that shall occur in a parameter declaration is **register**.

parameter storage-class

Commentary

Parameters have block scope and automatic storage duration. Like any other object having block scope the developer might want to suggest that accesses to it be optimized. Use of any other storage-class specifier in a parameter declaration has no obvious semantics.

408 block scope terminates
457 automatic storage duration
1369 register storage-class

C++

7.1.1p2 *The* **auto** *or* **register** *specifiers can be applied only to names of objects declared in a block (6.3) or to function parameters (8.4).*

C source code developed using a C++ translator may contain the storage-class specifier **auto** applied to a parameter. However, usage of this keyword is rare (see Table 788.1) and in practice it is very unlikely to occur in this context.

The C++ Standard covers the other two cases with rather sloppy wording.

7.1.1p4 *There can be no* **static** *function declarations within a block, nor any* **static** *function parameters.*

7.1.1p5 *The* **extern** *specifier cannot be used in the declaration of class members or function parameters.*

An identifier list in a function declarator that is not part of a definition of that function shall be empty. 1594

Commentary

An identifier list provides little useful information in a function declaration that is not also a definition. The issue of an empty identifier list is discussed elsewhere.

function declarator empty list 1608

C++

The C++ Standard does not support the old style of C function declarations.

Example

```
1  extern int f_1(x, y); /* Constraint violation. */
2
3  int (*f_2(a, b))(x, y) /* The subject of an outstanding DR. */
4  { /* ... */ }
```

---

parameter adjustment in definition

After adjustment, the parameters in a parameter type list in a function declarator that is part of a definition of that function shall not have incomplete type. 1595

Commentary

Adjustment refers to array and function types, which are implicitly converted to a pointer to their first element (there is no such conversion for incomplete structure or union types). After adjustment, the types of parameters have the same requirements as the types of other block scope objects.

array type adjust to pointer to 1598

C translators need to know the number of bytes of storage needed by each parameter. Incomplete types do not have a known, at the point of declaration, size. Arguments having an array type are passed as the address of their first element, so their size is not needed.

size needed 1465

C90

The C90 Standard did not explicitly specify that the check on the parameter type being incomplete occurred "after adjustment".

C++

The C++ Standard allows a few exceptions to the general C requirement:

8.3.5p6

If the type of a parameter includes a type of the form "pointer to array of unknown bound of T" or "reference to array of unknown bound of T," the program is ill-formed.[87)]

This excludes parameters of type "`ptr-arr-seq` T2" where T2 is "pointer to array of unknown bound of T" and where `ptr-arr-seq` means any sequence of "pointer to" and "array of" derived declarator types. This exclusion applies to the parameters of the function, and if a parameter is a pointer to function or pointer to member function then to its parameters also, etc. Footnote 87

*The parameter list `(void)` is equivalent to the empty parameter list. Except for this special case, **`void`** shall not be a parameter type (though types derived from **`void`**, such as `void*`, can).* 8.3.5p2

The type of a parameter or the return type for a function declaration that is not a definition may be an incomplete class type. 8.3.5p6

```
1  void f(struct s1_tag ** p1) /* incomplete type, constraint violation */
2                              // defined behavior
3  {
4  struct s2_tag **loc; /* Size not needed, so permitted. */
5  }
```

Semantics

1596 If, in the declaration "**`T D1`**", **`D1`** has the form

`D(` *parameter-type-list* **`)`**

or

`D(` *identifier-list*$_{opt}$ **`)`**

and the type specified for *ident* in the declaration "**`T D`**" is "*derived-declarator-type-list T*", then the type specified for *ident* is "*derived-declarator-type-list* function returning *T*".

Commentary

This defines the terms *derived-declarator-type-list* and *derived-declarator-type-list*. They are very rarely used outside of the standard, even by the Committee.

C++

The form supported by the C++ Standard is:

D1 **`(`** *parameter-declaration-clause* **`)`** *cv-qualifier-seq*$_{opt}$ *exception-specification*$_{opt}$ 8.3.5p1

The term used for the identifier in the C++ Standard is:

8.3.5p1

"derived-declarator-type-list function of (parameter-declaration-clause) cv-qualifier-seq^{opt} returning T";

The old-style function definition *D(identifier-list$_{opt}$)* is not supported in C++.

8.3.5p2 *If the parameter-declaration-list is empty, the function takes no arguments. The parameter list (void) is equivalent to the empty parameter list.*

The C syntax treats D() as an instance of an empty identifier-list, while the C++ syntax treats it as an empty *parameter-type-list*. Using a C++ translator to translate source containing this form of function declaration may result a diagnostic being generated when the declared function is called (if it specifies any arguments).

Coding Guidelines

function declaration use prototype 1810.1 prototypes 1810 cost/benefit

If the guideline recommendation specifying the use of prototypes is followed the identifier list form will not occur in new source code. However, it may occur in existing source code and the cost/benefit issues associated with changing this existing usage are discussed elsewhere.

A parameter type list specifies the types of, and may declare identifiers for, the parameters of the function. 1597

Commentary

Rationale There was considerable debate about whether to maintain the current lexical ordering rules for variable length array parameters in function definitions. For example, the following old-style declaration

```
void f(double a[*][*], int n);

void f(a, n)
    int n;
    double a[n][n];
{
    // ...
}
```

cannot be expressed with a definition that has a parameter type list as in

```
void f(double a[n][n], int n)  // error
{
    /* ... */
}
```

Previously, programmers did not need to concern themselves with the order in which formal parameters are specified, and one common programming style is to declare the most important parameters first. With Standard C's lexical ordering rules, the declaration of a would force n to be undefined or captured by an outside declaration. The possibility of allowing the scope of parameter n to extend to the beginning of the parameter-type-list was explored (relaxed lexical ordering), which would allow the size of parameter a to be defined in terms of parameter n, and could help convert a Fortran library routine into a C function. Such a change to the lexical ordering rules is not considered to be in the "Spirit of C", however. This is an unforeseen side effect of Standard C prototype syntax.

C++

The `parameter-declaration-clause` *determines the arguments that can be specified, and their processing, when the function is called.*

Other Languages

Many languages allow parameters to be defined to have types in the same way that they support the definition of objects. Some languages provide no explicit mechanism for defining the types of the parameters (e.g., Perl).

Coding Guidelines

Some coding guideline documents recommend that no identifiers be given for the parameters in a function prototype declaration. The rationale is that such identifiers could also match some earlier defined macro name. In practice, the effect of such a match is likely to be a syntax violation. Even if this does not occur the spelling of the identifier appearing in the prototype declaration is not significant. Whatever happens there will not be a quiet change in program behavior. The cost of a syntax violation (the identifier spelling will need to be changed) has to be balanced against the benefit of including an identifier in the parameter type list.

Some coding guideline documents recommend that any identifiers given for the parameters in a function prototype declaration have the same spelling as those given in the function definition. Such usage may provide readers with a reminder of information about what the parameter denotes. A comment could provide more specific information. Using identifiers in this way also provides visible information that might help detect changes to a functions interface (e.g., a change in the order of the parameters).

There does not appear to be compelling evidence for any of these options providing sufficient cost/benefit for a guideline recommendation to be worthwhile.

Example

```
#define abc xyz

void f_1(int abc);

int cost_weight_ratio(int cost, int weight);

int cost_weight_ratio(int weight, int cost)
{
return cost / weight;
}
```

1598 A declaration of a parameter as "array of *type*" shall be adjusted to "qualified pointer to *type*", where the type qualifiers (if any) are those specified within the `[` and `]` of the array type derivation.

array type adjust to pointer to

Commentary

This is a requirement on the implementation.

```
void f(      int a1[10],       /* equivalent to       int *       a1 */
       const int a2[10],       /* equivalent to const int *       a2 */
             int a3[const 10], /* equivalent to       int * const a3 */
       const int a4[const 10]) /* equivalent to const int * const a4 */
{ /* ... */ }
```

Occurrences of an object, not declared as a parameter, having an array type are implicitly converted to a pointer type in most contexts. The parameter declaration in:

729 array converted to pointer

```
void f(int a[const 10][const 20])
{ /* ... */ }
```

is permitted by the syntax, but violates a constraint.

1568 array parameter qualifier only in outermost

C90

Support for type qualifiers between **[** and **]**, and the consequences of their use, is new in C99.

C++

This adjustment is performed in C++ (8.3.5p3) but the standard does not support the appearance of type qualifiers between **[** and **]**.

Source containing type qualifiers between **[** and **]** will cause a C++ translator to generate a diagnostic.

Other Languages

Using qualifiers within the **[** and **]** of an array declaration may be unique to C.

Coding Guidelines

A qualifier appearing outside of **[** and **]** qualifies the element type, not the array type. For non-parameter declarations this distinction is not significant, the possible consequences are the same. However, the implicit conversion to pointer type, that occurs for parameters having an array type, means that the distinction is significant in this case. Experience shows that developers are not always aware of the consequences of this adjustment to parameters having an array type. The following are two of the consequences of using a qualifier in the incorrect belief that the array type, rather than the element type, will be qualified:

- The **volatile** qualifier— the final effect is very likely to be the intended effect (wanting to **volatile** qualify an object having a pointer type is much rarer than applying such a qualifier to the object it points at).
- The **const** qualifier— attempts to modify the pointed-to objects will cause a translator diagnostic to be issued and attempts to modify the parameter itself does not require a translator to issue a diagnostic.

Support for qualifiers appearing between **[** and **]** is new in C99 and there is insufficient experience in their use to know whether any guideline recommendation is cost effective.

---

function declarator static

If the keyword **static** also appears within the **[** and **]** of the array type derivation, then for each call to the function, the value of the corresponding actual argument shall provide access to the first element of an array with at least as many elements as specified by the size expression. 1599

Commentary

Rationale

It would be a significant advantage on some systems for the translator to initiate, at the beginning of the function, prefetches or loads of the arrays that will be referenced through the parameters.

The use of the keyword **static** within the **[** and **]** of an array type is a guarantee from the developer to the translator. The translator can assume that at least the value of the parameter will not be NULL and that storage for at least the specified number of elements will be available.

Rules for forming the composite type of function types, one or more of which included the keyword **static**, were given by the response to DR #237.

DR #237

The effect is as if all of the declarations had used static and the largest size value used by any of them. Each declaration imposes requirements on all calls to the function in the program; the only way to meet all of these requirements is to always provide pointers to as many objects as the largest such value requires.

```
1  void WG14_DR_237(int x[static 10]);
2  void WG14_DR_237(int x[static 5]);
3
4  void WG14_DR_237(int x[1])
5  /*
6   * Composite type is void WG14_DR_237(int x[static 10])
7   */
8  { /* ... */ }
```

C90

Support for the keyword **static** in this context is new in C99.

C++

Support for the keyword **static** in this context is new in C99 and is not available in C++.

Other Languages

Most strongly typed languages require an exact correspondence between the number of elements in the parameter array declaration and the number of elements in the actual argument passed in a call.

Coding Guidelines

The information provided by constant expressions appearing within the **[** and **]** of the declaration of a parameter, having an array type, can be of use to static analysis tools. However, in practice because no semantics was associated with such usage in C90, such arrays were rarely declared. It remains to be seen how the semantics given to this usage in C99 will change the frequency of occurrence of parameters having an array type (i.e., will developers use this construct to provide information to translators that might enable them to generate higher-quality code, or to source code analysis tools to enable them to issue better quality diagnostics).

Example

Rationale

```
void fadd(      double a[static restrict 10],
          const double b[static restrict 10])
{
    int i;

    for (i = 0; i < 10; i++) {
        if (a[i] < 0.0)
            return;

        a[i] += b[i];
    }

    return;
}
```

This function definition specifies that the parameters `a` and `b` are restricted pointers. This is information that an optimizer can use, for example, to unroll the loop and reorder the loads and stores of the elements referenced through `a` and `b`.

1600 A declaration of a parameter as "function returning *type*" shall be adjusted to "pointer to function returning *type*", as in 6.3.2.1.

function type adjust to pointer to

Commentary

This is a requirement on the implementation. Occurrences of an object, not declared as a parameter, having a function type are implicitly converted to a pointer type in most contexts.

732 function designator converted to type

Other Languages

Languages that support parameters having some form of function type usually have their own special rules for handling them. A few languages treat function types as first class citizens and they are treated the same as any other type.

Coding Guidelines

While developers might not be aware of this implicit conversion, their interpretation of the behavior for uses of the parameter is likely to match what actually occurs (experience suggests that the lack of detailed knowledge of behavior is not replaced by some misconception that alters developer expectations of behavior).

---

ellipsis supplies no information

If the list terminates with an ellipsis (`, ...`), no information about the number or types of the parameters after the comma is supplied.[123)] 1601

Commentary

That is, no information is supplied by the developer to the translator. The ellipsis notation is intended for use in passing a variable number of argument values (at given positions in the list of arguments) having different types. The origin of support for variable numbers of arguments was the desire to treat functions handling input/output in the same as any other function (i.e., the handling of I/O functions did not depend on special handling by a translator, such as what is needed in Pascal for the `read` and `write` functions).

Prior to the publication of the C Standard there existed a programming technique that relied on making use of information on an implementation's argument passing conventions (invariable on a stack that either grew up or down from the storage location occupied by the last named parameter). Recognizing that developers sometimes need to define functions that were passed variable numbers of arguments the C Committee introduced the ellipsis notation, in function prototypes. The presence of an ellipsis gives notice to a translator that different argument types may be passed in calls to that function. Access to any of these arguments is obtained by encoding information on the expected ordering and type, via calls to library macros, within the body of the function.

C++

The C++ Standard does not make this observation.

Other Languages

The need to pass variable number of arguments, having different types, is a common requirement for languages that specify functions to handle I/O (some languages, e.g., Fortran, handle I/O as part of the language syntax). Many languages make special cases for some I/O functions, those that are commonly required to input or output a number of different values of different types. Having to call a function for each value and the appropriate function used depending on the type of the value is generally thought onerous by language designers.

Coding Guidelines

Many coding guideline documents recommend against the use of ellipsis. The view being taken that use of this notation represents an open-ended charter for uncontrolled argument passing. What are the alternative and how would developers handle the lack of an ellipsis notation? The following are two possibilities:

- *Use file scope objects.* Any number of file scope objects having any available type could be declared to be visible to a function definition and the contexts in which it is called.
- *Use of unions and dummy parameters.* In practice, most functions are passed a small number of optional arguments. A function could be defined to take the maximum number of arguments. In those cases where a call did not need to pass values to all the arguments available to it, a dummy argument could be passed. The number of different argument types is also, usually, small. A union type could be used to represent them.

In both cases the body of the function needs some method of knowing which values to access (as it does when the ellipsis notation is used).

Is the cure worse than the problem? The ellipsis notation has the advantage of not generating new interface issues, which the use of file scope objects is likely to do. The advantage to declaring functions to take the maximum number of arguments (use of union types provides the subset of possible types that argument values

may have) is that information about all possible arguments is known to readers of the function definition. The benefit of the availability of this information is hard to quantify. However, the cost (developer effort required to analyze the arguments in the call, working out which ones are dummy and which unions members are assigned to) is likely to be significant.

Recommending that developers not use the ellipsis notation may solve one perceived problem, but because of the cost of the alternatives does not appear to result in any overall benefit.

While there is existing code that does not use the macros in the **<stdarg.h>** header to access arguments, but makes use of information on stack layout to access arguments, such usage is rarely seen in newly written code. A guideline recommendation dealing with this issue is not considered worthwhile.

1602 The special case of an unnamed parameter of type **void** as the only item in the list specifies that the function has no parameters.

parameter type void

Commentary

The base document had no special syntax for specifying a function declaration that took no parameters. The convention used to specify this case was an empty parameter list. However, an empty parameter list was also used to indicate another convention (which is codified in the standard), a function declaration that provided no information about the arguments it might take (although it might take one or more). Use of the keyword **void** provides a means of explicitly calling out the case of a function taking no parameters (had C90 specified that an empty parameter list denoted a function taking no parameters, almost every existing C program would have become non standards conforming).

1608 function declarator empty list

C90

The C90 Standard was reworded to clarify the intent by the response to DR #157.

Other Languages

Strongly typed languages treat a function declared with no parameters as a function that does not take any arguments, and they sometimes (e.g., Pascal) require the empty parentheses to be omitted from the function call. Other languages vary in their handling of this case.

Example

```
1  typedef void Void;
2
3  extern int f(Void);
4
5  int f(Void)
6  { /* ... */ }
```

1603 If, ~~i~~In a parameter declaration, ~~a single typedef name in parentheses is taken to be an abstract declarator that specifies a function with a single parameter, not as redundant parentheses around the identifier for a declarator.~~ an identifier can be treated as a typedef name or as a parameter name, it shall be taken as a typedef name.

parameter declaration typedef name in parentheses

Commentary

This is a requirement on the implementation. It is an edge case of the language definition. In:

```
1  typedef int T;
2  int f(int *(T));
```

`f` is declared as function returning **int**, taking a single parameter of type pointer to function returning **int** and taking a parameter of type `T`. Without the above rule it could also be interpreted as function returning **int**, taking a single parameter of type pointer to **int**, with redundant parentheses around the identifier `T`.

Wording changes to C90, made by the response to DR #009, were not made to the text of C99 (because the committee thought that forbidding implicit types would eliminate this problem, but an edge case still remained). The response to DR #249 agreed that these changes should have been made and have now been made.

function declarator return type 1592

In the following declaration of `WG14_N852` the identifier `what` is treated as a typedef name and violates the constraint that a function not return a function type.

```
typedef int what;

int WG14_N852(int (what)(int)); /* Constraint violation. */
```

type name empty parentheses 1628

The case of empty parentheses is discussed elsewhere.

C90

The response to DR #009 proposed adding the requirement: "If, in a parameter declaration, an identifier can be treated as a typedef name or as a parameter name, it shall be taken as a typedef name."

Other Languages

Most languages do not allow the identifier being declared to be surrounded by parentheses. Neither do they have the C style of declarators.

Coding Guidelines

Developers are unlikely to be familiar with this edge case of the language. However, the types involved (actual and incorrectly deduced) will be sufficiently different that a diagnostic is very likely to be produced for uses of an argument or parameter based on the incorrect type.

If the function declarator is not part of a definition of that function, parameters may have incomplete type and may use the `[*]` notation in their sequences of declarator specifiers to specify variable length array types. 1604

Commentary

Functions declared with a parameter having an incomplete structure or union type will only be callable after the type is completed. For instance:

```
void f_1(struct T); /* No prior declaration of T visible here, a new type that can never be completed. */
struct T;
void f_2(struct T); /*    Prior declaration of T visible here, refers to existing type. */
/*
 * Cannot define an argument to have type struct T at
 * this point so the function is not yet callable.
 */
struct T {
          int mem;
         };
/*
 * Can now define an object to pass as an argument to f_2.
 */
```

The following declarations of `f` are all compatible with each other (the operand of **`sizeof`** does not need to be evaluated in this context):

```
int f(int n, int a[*]);
int f(int n, int a[sizeof(int [*][*])]);
int f(int n, int a[sizeof(int [n][n+1])]);
```

footnote 109 1465

Use of incomplete types where the size is not needed is discussed elsewhere.

C90

Support for the `[*]` notation is new in C99.

C++

The wording:

> *If the type of a parameter includes a type of the form "pointer to array of unknown bound of T" or "reference to array of unknown bound of T," the program is ill-formed.*[87)] 8.3.5p6

does not contain an exception for the case of a function declaration.

Support for the **[*]** notation is new in C99 and is not specified in the C++ Standard.

Other Languages

Most languages require that structure types appearing in function declarations be complete. A number of languages provide some form of [*] notation to indicate parameters having a variable length array type.

Coding Guidelines

Functions declared with a parameter having an incomplete structure or union type might be regarded as redundant declarations. This issue is discussed elsewhere. 190 redundant code

Example

```
1  void f_1(struct T_1 *p_1);
2
3  struct T_2;
4  void f_2(struct T_2 *p1);
5
6  void f_3(void)
7  {
8  struct T_1 *loc_1 = 0;
9  struct T_2 *loc_2 = 0;
10
11 f_1(loc_1); /* Constraint violation, different structure type. */
12 f_2(loc_2); /* Argument has same structure type as parameter.  */
13 }
```

1605 The storage-class specifier in the declaration specifiers for a parameter declaration, if present, is ignored unless the declared parameter is one of the members of the parameter type list for a function definition.

Commentary

The only storage-class specifier that can occur on a parameter declaration is **register**. The interpretation of objects having this storage-class only applies to accesses to them, which can only occur in the body of the function definition. 1593 parameter storage-class

Coding Guidelines

Whether or not function declarations are token for token identical to their definitions is not considered worthwhile addressing in a guideline recommendation.

1606 An identifier list declares only the identifiers of the parameters of the function.

Commentary

In a function declaration such a list provides no information to the translator, but it may provide useful commentary for readers of the source (prior to the availability of function prototypes). In a function definition this identifier list provides information to a translator on the number and names of the parameters.

C++

This form of function declarator is not available in C++.

An empty list in a function declarator that is part of a definition of that function specifies that the function has no parameters. 1607

Commentary

For a definition of a function, for instance `f`, there is no difference between the forms `f()` and `f(void)`. There is a difference for declarations, which is covered in the following C sentence.

Other Languages

An empty list is the notation commonly used in other languages to specify that a function has no parameters. Some languages also require that the parentheses be omitted.

Coding Guidelines

Differences in the costs and benefits of using either an empty list or requiring the use of the keyword **`void`** are not sufficient to warrant a guideline recommendation dealing with this issue.

function declarator empty list

The empty list in a function declarator that is not part of a definition of that function specifies that no information about the number or types of the parameters is supplied.[124)] 1608

Commentary

This specification differs from that of a function declarator that whose parameter list contains the keyword **`void`**.

parameter 1602 type void

C++

The following applies to both declarations and definitions of functions:

8.3.5p2 *If the `parameter-declaration-clause` is empty, the function takes no arguments.*

A call made within the scope of a function declaration that specifies an empty parameter list, that contains arguments will cause a C++ translator to issue a diagnostic.

Common Implementations

Some translators remember the types of the arguments used in calls to functions declared using an empty list. Inconsistencies between the argument types in different calls being flagged as possibly coding defects.

Coding Guidelines

function declaration use prototype 1810.1

The guideline recommendation specifying the use of function prototypes is discussed elsewhere.

footnote 123

123) The macros defined in the **`<stdarg.h>`** header (7.15) may be used to access arguments that correspond to the ellipsis. 1609

Commentary

These are the `va_*` macros specified in the library section.

footnote 124

124) See "future language directions" (6.11.6). 1610

function compatible types

For two function types to be compatible, both shall specify compatible return types.[125)] 1611

Commentary

compatible type if 631

This is a necessary conditions for two function declarations to be compatible. The second condition is specified in the following C sentence.

C++

compatible type if 631

The C++ Standard does not define the concept of compatible type, it requires types to be the same.

3.5p10

After all adjustments of types (during which typedefs (7.1.3) are replaced by their definitions), the types specified by all declarations referring to a given object or function shall be identical, . . .

All declarations for a function with a given parameter list shall agree exactly both in the type of the value returned and in the number and type of parameters; the presence or absence of the ellipsis is considered part of the function type. 8.3.5p3

If one return type is an enumerated type and the another return type is the compatible integer type. C would consider the functions compatible. C++ would not consider the types as agreeing exactly.

Other Languages

Compatibility of function types only becomes an issue when a language's separate translation model allows more than one declaration of a function, or when pointers to functions are supported. In these cases the requirements specified are usually along the lines of those used by C.

Coding Guidelines

The rationale for the guideline recommendations on having a single textual declaration and including the header containing it in the source file that defines the function is to enable translators to check that the two declarations are compatible.

422.1 identifier declared in one file
1818.1 identifier definition shall #include

1612 Moreover, the parameter type lists, if both are present, shall agree in the number of parameters and in use of the ellipsis terminator;

Commentary

This condition applies if both function declarations use prototypes.

C++

A parameter type list is always present in C++, although it may be empty.

Other Languages

Most other languages require that the parameter type lists agree in the number of parameters.

Coding Guidelines

If the guideline recommendation specifying the use of prototypes is followed the parameter type lists will always be present.

1810.1 function declaration use prototype

1613 corresponding parameters shall have compatible types.

Commentary

This requirement applies between two function declarations, not between the declaration of a function and a call to it.

998 function call arguments agree with parameters

C++

All declarations for a function with a given parameter list shall agree exactly both in the type of the value returned and in the number and type of parameters; the presence or absence of the ellipsis is considered part of the function type. 8.3.5p3

The C++ Standard does not define the concept of compatible type, it requires types to be the same. If one parameter type is an enumerated type and the corresponding parameter type is the corresponding compatible integer type. C would consider the functions to be compatible, but C++ would not consider the types as being the same.

631 compatible type if

Other Languages

Most languages require the parameter types to be compatible.

If one type has a parameter type list and the other type is specified by a function declarator that is not part of a function definition and that contains an empty identifier list, the parameter list shall not have an ellipsis terminator and the type of each parameter shall be compatible with the type that results from the application of the default argument promotions. 1614

Commentary

This C sentence deals with the case of a function prototype (which may or may not be a definition) and an old style function declaration that is not a definition. One possible situations where it can occur is where a function definition has been rewritten using a prototype, but there are still calls made to it from source where an old style declaration is visible. Function prototypes were introduced in C90 (based on the C++ specification). The committee wanted to ensure that developers could gradually introduce prototypes in to existing code. For instance, using prototypes for newly written functions. It was therefore necessary to deal with the case of source code containing so called *old style* and function prototype declarations for the same function.

default argument promotions 1009

Calls where the visible function declaration uses an old style declaration, have their arguments promoted using the default argument promotions. The types of the promoted arguments are required to be compatible with the parameter types in the function definition (which uses a prototype). This requirement on the parameter types in the function definition ensures that argument/parameter storage layout calculations (made by an implementation) are consistent.

The ellipsis terminator is a special case. Some translators are known to handle arguments passed to this parameter differently than when there is a declared type (the unknown nature of the arguments sometimes means that this special processing is a necessity). Given the possibility of this implementation technique the Committee decided not to require the behavior to be defined if the two kinds of declarations were used.

arguments same number as parameters 1010

There can be no check on the number of parameters in the two declarations, since one of them does not have any. This issue is covered elsewhere.

C++

The C++ Standard does not support the C identifier list form of parameters. An empty parameter list is interpreted differently:

8.3.5p2 *If the* `parameter-declaration-clause` *is empty, the function takes no arguments.*

The two function declarations do not then agree:

3.5p10 *After all adjustments of types (during which typedefs (7.1.3) are replaced by their definitions), the types specified by all declarations referring to a given object or function shall be identical, . . .*

A C++ translator is likely to issue a diagnostic if two declarations of the same function do not agree (the object code file is likely to contain function signatures, which are based on the number and type of the parameters in the declarations).

Other Languages

Very few languages (Perl does) have to deal with the issue of developers being able to declare functions using two different sets of syntax rules.

Common Implementations

Implementations are not required to, and very few do, issue diagnostics if these requirements are not met. Whether programs fail to work as expected, if these requirements are not met, often depends on the characteristics of the processor. For those processors that have strict alignment requirements translators

alignment 39

usually assign parameters at least the same alignment as those of the type **int** (ensuring that integer types with less rank are aligned on the storage boundaries of their promoted type). For processors that have more relaxed alignment requirements, or where optimisations are possible for the smaller integer types, parameters having a type whose rank less than that of the type **int** are sometime assigned a different storage location than if they had a type of greater rank. In this case the arguments, which will have been treated as having at least type **int**, will be at different storage locations in the function definitions stack frame.

Coding Guidelines

This case shows that gradually introducing function prototypes into existing source code can cause behavioral differences that did not previously exist. Most of the benefits of function prototype usage come from the checks that translators perform at the point of call. Defining a function using prototype notation and having an old style function declaration visible in a header offers little benefit (unless the function has internal linkage and is visible at all the places it is called). If an existing old style function definition is modified to use a function prototype in its definition, then it is effectively new code and any applicable guideline recommendations apply.

1615 If one type has a parameter type list and the other type is specified by a function definition that contains a (possibly empty) identifier list, both shall agree in the number of parameters, and the type of each prototype parameter shall be compatible with the type that results from the application of the default argument promotions to the type of the corresponding identifier.

Commentary

In this C sentence the two types are a function declaration that uses a prototype and a function definition that uses an old style declaration. In both cases the developer has specified the number and type of two sets of parameters. Both declarations are required to agree in the number of parameters (if the number and type of each parameter agrees there cannot be an ellipsis terminator in the function prototype).

A function defined using an identifier list will be translated on the basis that the arguments, in calls to it, have been promoted according to the default argument promotions. Calls to functions where the visible declaration is a function prototype will be translated on the basis that the definition expects the arguments to be converted at the point of call (to the type of the corresponding parameter). This C sentence describes those cases where the two different ways of handling arguments results in the same behavior. In all other cases the behavior is undefined.

1009 default argument promotions

C++

The C++ Standard does not support the C identifier list form of parameters.

If the `parameter-declaration-clause` *is empty, the function takes no arguments.* 8.3.5p2

The C++ Standard requires that a function declaration always be visible at the point of call (5.2.2p2). Issues involving argument promotion do not occur (at least for constructs supported in C).

```
1  void  f(int, char);
2  void  f(char, int);
3  char a, b;
4  f(a,b);             // illegal: Which function is called?  Both fit
5                      // equally well (equally badly).
```

Common Implementations

Implementations are not required to, and very few do, issue diagnostics if these requirements are not met.

Coding Guidelines

Adding prototype declarations to an existing program may help to detect calls made using arguments that are not compatible with the corresponding functions parameters, but they can also change the behavior of correct

identifier 1818.1 definition shall #include

calls if they are not properly declared. Adhering to the guideline recommendation specifying that the header containing the function prototype declaration be **#include**d in the source file that defines the function is not guaranteed to cause a translator to issue a diagnostic if the above C sentence requirements are not met. The following guideline recommendation addresses this case.

Cg 1615.1

If a program contains a function that is declared using both a prototype and an old style declaration, then the type of each parameter in the prototype shall be compatible with the type of corresponding parameter in the old style declaration after the application of the default argument promotions to those parameter types.

Example

file_1.c

```
int f(p_1)
signed char p_1; /* Expecting argument to have been promoted to int. */
{
return p_1+1;
}
```

file_2.c

```
int f(signed char p_1);

int g(void)
{
return f('0'); /* Argument converted to type signed char. */
}
```

---

parameter qualifier in composite type

(In the determination of type compatibility and of a composite type, each parameter declared with function or array type is taken as having the adjusted type and each parameter declared with qualified type is taken as having the unqualified version of its declared type.) 1616

Commentary

parameter type 1835 adjusted function 646 composite type compatible type 631 if composite type 642

This specifies the relative ordering of requirements on adjusting types, creating composite types and determining type compatibility. While the composite type of a parameter is always its unqualified type, the wording of the response to DR #040 question 1 explains how composite types are to be treated.

The type of a parameter is independent of the composite type of the function, . . .

DR #040 question 1

In the body of a function the type of a parameter is the type that appears in the function definition, not any composite type. In the following example DR_040_a and DR_040_b have the same composite types, but the parameter types are not the same in the bodies of their respective function definitions.

```
void DR_040_a(const int c_p);
void DR_040_a(      int   p)
{
p=1;                        /* Not a constraint violation. */
}

void DR_040_b(      int   p);
void DR_040_b(const int c_p)
{
c_p=1;                      /*     A constraint violation. */
}
```

Calls to functions will make use of information contained in the composite type. The fact that any parameter types, in the composite type, will be unqualified is not significant because it is the unqualified parameter type that is used when processing the corresponding arguments.

649 prior declaration visible

999 argument type may be assigned

C90

The C90 wording:

> *(For each parameter declared with function or array type, its type for these comparisons is the one that results from conversion to a pointer type, as in 6.7.1. For each parameter declared with qualified type, its type for these comparisons is the unqualified version of its declared type.)*

was changed by the response to DR #013 question 1 (also see DR #017q15 and DR #040q1).

C++

The C++ Standard does not define the term *composite type*. Neither does it define the concept of compatible type, it requires types to be the same.

642 composite type

631 compatible type if

The C++ Standard transforms the parameters' types and then:

> *If a* `storage-class-specifier` *modifies a parameter type, the specifier is deleted. [Example:* `register char*` *becomes* `char*` *—end example] Such* `storage-class-specifiers` *affect only the definition of the parameter within the body of the function; they do not affect the function type. The resulting list of transformed parameter types is the function's parameter type list.*

8.3.5p3

It is this parameter type list that is used to check whether two declarations are the same.

Coding Guidelines

Adhering to the guideline recommendation specifying the use of function prototypes does not guarantee that the composite type will always contain the same parameter type information as in the original declarations.

1810.1 function declaration use prototype

It is possible that while reading the source of a function definition a developer will make use of information, that exists in their memory, that is based on the functions declaration in a header, rather than the declaration at the start of the definition. The consequences of this usage, in those cases where the parameter types differ in qualification, do not appear to be sufficiently costly (in unintended behavior occurring) to warrant a guideline recommendation.

Example

```
1  void f_1(int  p_a[3]);
2  void f_1(int *p_a   );      /* Compatible with previous f_1 */
```

1617 EXAMPLE 1 The declaration

EXAMPLE function returning pointer to

```
int f(void), *fip(), (*pfi)();
```

declares a function **f** with no parameters returning an **int**, a function **fip** with no parameter specification returning a pointer to an **int**, and a pointer **pfi** to a function with no parameter specification returning an **int**. It is especially useful to compare the last two. The binding of ***fip()** is ***(fip())**, so that the declaration suggests, and the same construction in an expression requires, the calling of a function **fip**, and then using indirection through the pointer result to yield an **int**. In the declarator **(*pfi)()**, the extra parentheses are necessary to indicate that indirection through a pointer to a function yields a function designator, which is then used to call the function; it returns an **int**.

If the declaration occurs outside of any function, the identifiers have file scope and external linkage. If the declaration occurs inside a function, the identifiers of the functions **f** and **fip** have block scope and either internal or external linkage (depending on what file scope declarations for these identifiers are visible), and the identifier of the pointer **pfi** has block scope and no linkage.

Commentary

EXAMPLE 1587 array of pointers

The algorithm for reading declarations involving both function and pointer types follows a right then left rule similar to that used for reading declarations involving array and pointer types. However, it is not possible to declare a function of functions, so only one function type on the right is *consumed*.

C++

Function declared with an empty parameter type list are considered to take no arguments in C++.

EXAMPLE 2 The declaration 1618

```
int (*apfi[3])(int *x, int *y);
```

declares an array **apfi** of three pointers to functions returning **int**. Each of these functions has two parameters that are pointers to **int**. The identifiers **x** and **y** are declared for descriptive purposes only and go out of scope at the end of the declaration of **apfi**.

Commentary

array element 1567 not function type

The parentheses are necessary because `int *apfi[3](int *x, int *y);` declares `apfi` to be an array of three functions returning pointer to **int** (which is a constraint violation).

EXAMPLE 3 The declaration 1619

```
int (*fpfi(int (*)(long), int))(int, ...);
```

declares a function **fpfi** that returns a pointer to a function returning an **int**. The function **fpfi** has two parameters: a pointer to a function returning an **int** (with one parameter of type **long int**), and an **int**. The pointer returned by **fpfi** points to a function that has one **int** parameter and accepts zero or more additional arguments of any type.

Commentary

The declaration

```
1  int (* (*fpfpfi(int (*)(long), int))(int, ...))(void);
```

declares a function `fpfpfi` that returns a pointer to a function returning a pointer to a function returning an **int** involves parenthesizing part of the existing declaration and adding information on the parameters (in this case `(void)`).

---

footnote 125

125) If both function types are "old style", parameter types are not compared. 1620

Commentary

For *old style* function types there is no parameter information to compare (technically there is information available in one case, when one is a definition; however, the standard considers this information to be local to the function body).

C++

The C++ Standard does not support *old style* function types.

Other Languages

Some languages do not specify whether declarations of the same function should be compared for compatibility.

EXAMPLE 4 The following prototype has a variably modified parameter. 1621

```
void addscalar(int n, int m,
       double a[n][n*m+300], double x);
```

```
int main()
{
        double b[4][308];
        addscalar(4, 2, b, 2.17);
        return 0;
}

void addscalar(int n, int m,
        double a[n][n*m+300], double x)
{
        for (int i = 0; i < n; i++)
                for (int j = 0, k = n*m+300; j < k; j++)
                        // a is a pointer to a VLA with n*m+300 elements
                        a[i][j] += x;
}
```

C90

Support for variably modified types is new in C99.

C++

Support for variably modified types is new in C99 and is not specified in the C++ Standard.

Coding Guidelines

The expression n*m+300 occurs in a number of places in the source. Replacing this expression with a symbolic name will reduce the probability of future changes to one use of this expression not being reflected in other uses.

1622 EXAMPLE 5 The following are all compatible function prototype declarators.

EXAMPLE compatible function prototypes

```
double maximum(int n, int m, double a[n][m]);
double maximum(int n, int m, double a[*][*]);
double maximum(int n, int m, double a[ ][*]);
double maximum(int n, int m, double a[ ][m]);
```

as are:

```
void f(double (* restrict a)[5]);
void f(double a[restrict][5]);
void f(double a[restrict 3][5]);
void f(double a[restrict static 3][5]);
```

(Note that the last declaration also specifies that the argument corresponding to **a** in any call to **f** must be a non-null pointer to the first of at least three arrays of 5 doubles, which the others do not.)

Commentary

The conversion of parameters having array type to pointer type allows the **restrict** type qualifier to occur in this context.

729 array converted to pointer

1623 **Forward references:** function definitions (6.9.1), type names (6.7.6).

6.7.6 Type names

1624

abstract declarator syntax

type-name:
        specifier-qualifier-list abstract-declarator$_{opt}$
abstract-declarator:
        pointer
        pointer$_{opt}$ *direct-abstract-declarator*
direct-abstract-declarator:

```
( abstract-declarator )
direct-abstract-declarator_opt [ assignment-expression_opt ]
direct-abstract-declarator_opt [ type-qualifier-list_opt assignment-expression_opt ]

direct-abstract-declarator_opt [ static type-qualifier-list_opt assignment-expression ]
direct-abstract-declarator_opt [ type-qualifier-list static assignment-expression ]
direct-abstract-declarator_opt [ * ]
direct-abstract-declarator_opt ( parameter-type-list_opt )
```

Commentary

An abstract declarator specifies a type without defining an associated identifier. The term *type-name* is slightly misleading since there is no name, the type is anonymous. The *direct-declarator* productions:

declarator 1547 syntax

```
direct-declarator [ type-qualifier-list_opt assignment-expression_opt ]
direct-declarator [ static type-qualifier-list_opt assignment-expression ]
direct-declarator [ type-qualifier-list static assignment-expression ]
```

are not supported for abstract declarators (some committee members say this was intended, others that it was an accidental omission).

The wording was changed by the response to DR #289 and makes the syntax consistent with that for *direct-declarator*.

declarator 1547 syntax

C90

Support for the form:

```
direct-abstract-declarator_opt [ * ]
```

is new in C99. In the form:

```
direct-abstract-declarator_opt [ assignment-expression^opt ]
```

C90 only permitted *constant-expression*$_{opt}$ to appear between **[** and **]**.

C++

The C++ Standard supports the C90 forms. It also includes the additional form (8.1p1):

```
direct-abstract-declarator_opt ( parameter-declaration-clause )
cv-qualifier-seq_opt exception-specification_opt
```

Other Languages

A few languages (e.g., Algol 68) have a concept similar to that of abstract declarator (i.e., an unnamed type that can appear in certain contexts, such as casts).

Coding Guidelines

The term *type* is applied generically to all type declarations, whether they declare identifiers or not. Developers do not appear to make a distinction between declarators and abstract declarators.

More cognitive effort is needed to comprehend an abstract declarator than a declarator because of the additional task of locating the position in the token sequence where the identifier would have been, had it not

been omitted. Whether there is sufficient benefit in providing an identifier (taking into account the costs of providing it in the first place) to make a guideline recommendation worthwhile is a complex question that your author does not yet feel capable of answering.

Semantics

1625 In several contexts, it is necessary to specify a type.

Commentary

These contexts are: a compound literal, the type in a cast operation, the operand of **sizeof**, and parameter types in a function prototype declaration that omits the identifiers.

1626 This is accomplished using a *type name*, which is syntactically a declaration for a function or an object of that type that omits the identifier.[126)]

Commentary

This defines the term *type name* (and saying in words what is specified in the syntax).

C++

Restrictions on the use of type names in C++ are discussed elsewhere.

1118 sizeof constraints
1134 cast scalar or void type
1592 function declarator return type

Coding Guidelines

A *type-name* is syntactically a declaration and it is possible to declare identifiers using it. For instance:

```
1  void f_1(int p)
2  {
3  p=(enum {apple, orange, pair})sizeof(enum {brazil, cashu, almond});
4  }
5
6  struct T {int mem;} f_2(void)
7  {
8  struct T loc;
9  /* ... */
10 return loc;
11 }
```

Such uses are not common and might come as a surprise to some developers. The cost incurred by this usage is that readers of the source may have to spend additional time searching for the identifiers declared, because they do not appear in an expected location. There is no obvious worthwhile benefit (although there is a C++ compatibility benefit) in a guideline recommendation against this usage.

1627 EXAMPLE The constructions

EXAMPLE abstract declarators

```
(a)     int
(b)     int *
(c)     int *[3]
(d)     int (*)[3]
(e)     int (*)[*]
(f)     int *()
(g)     int (*)(void)
(h)     int (*const [])(unsigned int, ...)
```

name respectively the types (a) **int**, (b) pointer to **int**, (c) array of three pointers to **int**, (d) pointer to an array of three **int**s, (e) pointer to a variable length array of an unspecified number of **int**s, (f) function with no parameter specification returning a pointer to **int**, (g) pointer to function with no parameters returning an **int**, and (h) array of an unspecified number of constant pointers to functions, each with one parameter that has type **unsigned int** and an unspecified number of other parameters, returning an **int**.

Commentary

The following is one algorithm for locating where the omitted identifier occurs in an abstract declarator. Starting on the left and working right:

1. skip all keywords, identifiers, and any matched pairs of braces along with their contents (the latter are **struct/union/enum** declarations), then
2. skip all open parentheses, asterisks, and type qualifiers. The first unskipped token provides the context that enables the location of the omitted identifier to be deduced:
   - A **[** token is the start of an array specification that appears immediately after the omitted identifier.
   - A *type-specifier* is the start of the *declaration-specifier* of the first parameter of a parameter list. The omitted identifier occurs immediately before the last skipped open parenthesis.
   - A **)** token immediately after a **(** token is an empty parameter list. The omitted identifier occurs immediately before the last skipped open parenthesis.
   - A **)** token that is not immediately after a **(** token is the end of a parenthesized abstract declarator with no array or function specification. The omitted identifier occurs immediately before this **)** token.

C90

Support for variably length arrays is new in C99.

C++

Support for variably length arrays is new in C99 and is not specified in the C++ Standard.

---

footnote 126 type name empty parentheses

126) As indicated by the syntax, empty parentheses in a type name are interpreted as "function with no parameter specification", rather than redundant parentheses around the omitted identifier. 1628

Commentary

That is in the following declaration of `f`:

```
1  typedef char x;
2  void f(int (x), /* Function returning int having a single int parameter. */
3         int ()); /* Function returning int with no parameter information specified. */
4
5  void g(int (y)  /* Parameter having type int and name y. */
6        );
```

parameter 1603 declaration typedef name in parentheses

The behavior of parentheses around an identifier is also described elsewhere.

Other Languages

This notation is used by many languages (many of which don't allow parentheses around identifiers).

Coding Guidelines

function declaration use prototype 1810.1

The guideline recommendation dealing with the use of prototypes in function declarators is applicable here.

6.7.7 Type definitions

typedef name syntax

1629

typedef-name:

identifier

Commentary

A typedef name exists in the same name space as ordinary identifiers. The information that differentiates an identifier as a *typedef-name*, from other kinds of identifiers is the visibility, or not, of a typedef definition of that identifier. For instance, given the declarations:

444 name space ordinary identifiers

```
typedef int type_ident;
type_ident(D_1);           /* Function call or declaration of D_1?  */
type_ident * D_2;          /* Multiplication or declaration of D_2? */
```

it is not possible to decide, using syntax only, whether `type_ident(D_1);` is a function call or a declaration of `D_1` using redundant parentheses. In the declaration of `D_2` a parser does not know this is a declaration, rather than a syntax violation, until it has seen the sixth token after the `type_ident` at the start of the line (i.e., more than one token lookahead is required).

There are some contexts where the status of an identifier as a *typedef-name* can be deduced. For instance, the token sequence `; x y;` is either a declaration of `y` to have the type denoted by `x`, or it is a violation of syntax (because a definition of `x` as a typedef name is not visible).

Other Languages

Languages invariably use ordinary identifiers to indicate both objects and their equivalent (if supported) of typedef names.

Common Implementations

The syntax of most languages is such that it is possible to parse their source without the need for a symbol table holding information on prior declarations. It is also usually possible to parse them by looking ahead a single token in the input stream (tools such as `bison` support such language grammars).

The syntax of C declarations and the status of *typedef-name* as an identifier token creates a number of implementation difficulties. The parser either needs access to a symbol table (so that it knows which identifiers are defined as *typedef-name*s), or it needs to look ahead more than one token and be able to handle more than one parse of some token sequences. Most implementations use the symbol table approach (which in practice is more complicated than simply accessing a symbol table; it is also necessary to set or reset a flag based on the current syntactic context, because an identifier should only be looked up, to find out if it is currently defined as a *typedef-name*, in a subset of the contexts in which an identifier can occur).

Coding Guidelines

It is common developer practice to use the term *type name* (as well as the term *typedef name*) to refer to the identifier defined by a typedef declaration. There is no obvious benefit in attempting to change this common developer usage. The issue of naming conventions for typedef names is discussed elsewhere.

792 typedef naming conventions

The higher-level source code design issues associated with the use of typedef names are discussed below. Given some of the source reading techniques used by developers it is possible that a typedef name appearing in a declaration will be treated as one of the identifiers being declared. This issue is discussed elsewhere. This coding guideline subsection discusses the lower-level issues, such as processing of the visible source by readers and naming conventions.

770 reading kinds of 1348 declaration syntax

The only time the visible form of declarations is likely to contain two identifiers adjacent to each other (separated only by white space) is when a typedef name is used (such adjacency can also occur through the use of macro names, but is rare). The two common cases are for the visible source lines, containing a declaration, to either start with a keyword (e.g., **`int`** or **`struct`**) or an identifier that is a member of an identifier list (e.g., a list of identifiers being declared).

Some of the issues involved in deciding whether to use a typedef name of a tag name, for structure and union types, is discussed elsewhere. Using a typedef name provides a number of possible benefits, including the following:

792 tag naming conventions

- Being able to change the type used in more than declaration by making a change to one declaration (the typedef name). In practice this cost saving is usually only a significant factor when the type category

553 type category

is not changed (e.g., an integer type is changed to an integer type, or a structure type is changed to another structure type). In this case the use of objects, declared using these typedef name, as operands in expressions does not need to be modified (changing, for instance, an array type to a structure type is likely to require changes to the use of the object in expressions).

- The spelling of the type name may providing readers with semantic information about the type that would not be available if the sequence of tokens denoting the type had appeared in the source. The issue of providing semantic information via identifier spellings is discussed elsewhere.

identifier 792
semantic associations

- The use of typedef names is sometimes recommended in coding guideline documents because it offers a mechanism for hiding type information. However, readers are likely to be able to deduce this (from looking at uses of an object), and are also likely to need to know an objects type category (which is probably the only significant information that type abstraction is intended to hide).

type category 553

Usage

A study by Neamtiu, Foster, and Hicks[998] of the release history of a number of large C programs, over 3-4 years (and a total of 43 updated releases), found that in 16% of releases one or more existing typedef names had the type they defined changed.[997]

Table 1629.1: Occurrences of types defined in a **typedef** definition (as a percentage of all types appearing in **typedef** definition). Based on the translated form of this book's benchmark programs.

Type	Occurrences	Type	Occurrences
struct	58.00	**unsigned long**	1.47
enum	9.50	**int** *()	1.46
other-types	8.86	**enum** *()	1.46
struct *	6.97	**union**	1.38
unsigned int	2.68	**long**	1.29
int	2.46	**void** *()	1.18
unsigned char	2.21	**unsigned short**	1.07

Constraints

If a typedef name specifies a variably modified type then it shall have block scope. 1630

Commentary

Allowing a typedef name to occur at file scope appears to be useful; the identifier name provides a method of denoting the same type in declarations in different functions, or translation units. However, the expression denoting the number of elements in the array has to be evaluated during program execution. The committee decided that this evaluation would occur when the type declaration was encountered during program execution. This decision effectively prevents any interpretation being given tor such declarations at file scope.

array size 1632
evaluated when declaration reached

C90

Support for variably modified types is new in C99.

C++

Support for variably modified types is new in C99 and not specified in the C++ Standard.

Coding Guidelines

The extent to which more than one instance of a variably modified type using the same size expression and element type will need to be defined in different functions is not known. A macro definition provides one mechanism for ensuring the types are the same. Variably modified types are new in C99 and experience with their use is needed before any guideline recommendations can be considered.

Semantics

1631 In a declaration whose storage-class specifier is **typedef**, each declarator defines an identifier to be a typedef name that denotes the type specified for the identifier in the way described in 6.7.5.

Commentary

The association between **typedef** and storage class is a syntactic one (they share the same declarator forms), not a semantic one.

Other Languages

Many languages that support developer defined type names define a syntax that is specific to that usage (which may simply involve the use of different keyword, for instance Pascal requires that type definitions be introduced using the keyword **type**).

Coding Guidelines

The issues involved in declarations that declare more than one identifier are discussed elsewhere.

1348 declaration visual layout

Example

```
1  extern  int i, j[3];
2  typedef int I, J[3];
```

1632 Any array size expressions associated with variable length array declarators are evaluated each time the declaration of the typedef name is reached in the order of execution.

array size evaluated when declaration reached

Commentary

Using a **typedef** to declare a variable length array object (see §6.7.5.2) could have two possible meanings. Either the size could be eagerly computed when the **typedef** is declared, or the size could be lazily computed when the object is declared. For example Rationale

```
{
    typedef int VLA[n];
    n++;
    VLA object;

    // ...
}
```

The question arises whether `n` should be evaluated at the time the type definition itself is encountered or each time the type definition is used for some object declaration. The Committee decided that if the evaluation were to take place each time the typedef name is used, then a single type definition could yield variable length array types involving many different dimension sizes. This possibility seemed to violate the spirit of type definitions. The decision was made to force evaluation of the expression at the time the type definition itself is encountered.

In other words, a typedef declaration does not act like a macro definition (i.e., with the expression evaluated for every invocation), but like an initialization (i.e., the expression is evaluated once).

C90

Support for variable length array declarators is new in C99.

C++

Support for variable length array declarators is new in C99 and is not specified in the C++ Standard.

Other Languages

Other languages either follow the C behavior (e.g., Algol 68), or evaluated on each instance of a typedef name usage (e.g., Ada).

Coding Guidelines

While support for this construct is new in C99 and at the time of this writing insufficient experience with its use is available to know whether any guideline recommendation is worthwhile, variable length array declarations can generate side effects, a known problem area. The guideline recommendation applicable to side effects in declarations is discussed elsewhere.

full declarator 187.2
all orderings give same type

Example

In the following the objects `q` and `r` will contain the same number of elements as the object `p`.

```
1  void f(int n)
2  {
3  START_AGAIN: ;
4
5  typedef int A[n];
6
7  A p;
8  n++;
9  A q;
10
11    {
12    int n = 99;
13    A r; /* Uses the object n visible when the typedef was defined. */
14    }
15
16 if ((n % 4) != 0)
17    goto START_AGAIN;
18
19 if ((n % 5) != 0)
20    f(n+2)
21 }
```

---

typedef is synonym

A **`typedef`** declaration does not introduce a new type, only a synonym for the type so specified. 1633

Commentary

Typedef names provide a mechanism for easily modifying (by changing a single definition) the types of a set of objects (those declared using a given typedef name) declared within the source code. The fact that a **`typedef`** only introduces a synonym for a type, not a new type, is one of the reasons C is considered to be a typed language but not a strongly typed language.

It is not possible to introduce a new name for a tag. For instance:

```
1  typedef oldtype newtype;                /* Supported usage.  */
2  typedef struct oldtype struct newtype;  /* Syntax violation. */
```

One difference between a typedef name and a tag is that the former may include type qualifier information. For instance, in:

```
1  typedef const struct T {
2                           int mem;
3                          } cT;
```

the typedef name cT is **`const`** qualified, while the tag T is not.

Other Languages

Some languages regard all typedef declarations as introducing new types. A few languages have different kinds of typedef declarations, one introducing a new type and the other introducing a synonym.

Common Implementations

Some static analysis tools support an option that allows typedef names to be treated as new (i.e., different) types (which can result in diagnostics being issued when mixing operands having types).

Coding Guidelines

Experienced users of strongly typed languages are aware of the advantages of having a typedef that creates a new type (rather than a synonym). They enable the translator to aid the developer (by detecting mismatches and issuing diagnostics) in ensuring that objects are not referenced in inappropriate contexts. Your author is not aware of any published studies that have investigated the costs and benefits of strong typing (there have been such studies comparing so called *strongly typed* languages against C, but it is not possible to separate out the effects of typing from other language features). Also there does not appear to have been any work that has attempted to introduce strong typing into C in a commercial environment.

Your authors experience (based on teaching Pascal and analyzing source code written in it) is that it takes time and practice for developers to learn how to use strong type names effectively. While the concepts behind individual type names may be quickly learned and applied, handling the design decisions behind the interaction between different type names requires a lot of experience. Even in languages such as Pascal and Ada, where implementations enforced strong typing, developers still required several years of experience to attain some degree of proficiency.

Given C's permissive type checking (e.g., translators are not required to perform much type checking on the standard integer types), only a subset of the possible type differences are required to generate a diagnostic to be generated. Given the lack of translator support for strong type checking and the amount of practice needed to become proficient in its use, there is no cost/benefit in recommending the use of typedef names for type checking purposes. The cost/benefit of using typedef names for other purposes, such as enabling the types of a set of objects to be changed by a single modification to the source, may be worthwhile.

493 standard integer types

Measurements of the translated form of this book's benchmark programs show that typedef names occur much more frequently than the tag names (by a factor of 1.7:1; although this ratio is switched in some programs, e.g., tag names outnumber typedef names by 1.5:1 in the Linux kernel). Why is this (and should the use of typedef names be recommended)? The following are some of the possible reasons:

- Developers new to C imitate what they see others doing and what they read in books.
- The presence of the **`struct`**/**`union`**/**`enum`** keyword is considered to be useful information, highlighting the kind of type that is being used (structure types in particular seem to be regarded as very different animals than other types). While this rationale goes against the design principle of hiding representation details, experience shows that uses of structure types are rarely changed to non-structure types.
- The usage is driven by the least effort principle being applied by a developer at the point where the structure type is defined. While the effort needed in subsequent references to the type may be less, had a typedef name had been used, the cost of subsequent uses is not included in the type definition decision process.

1634 That is, in the following declarations:

```
typedef T type_ident;
type_ident D;
```

`type_ident` is defined as a typedef name with the type specified by the declaration specifiers in **`T`** (known as *T*), and the identifier in **`D`** has the type "*derived-declarator-type-list T*" where the *derived-declarator-type-list* is specified by the declarators of **`D`**.

Commentary

Declarations of the form `type_ident D;` is the only situation where two identifier tokens are adjacent in the preprocessed source.

C++

This example and its associated definition of terms is not given in the C++ Standard.

A typedef name shares the same name space as other identifiers declared in ordinary declarators. 1635

Commentary

name space 444 ordinary identifiers

This issue is discussed elsewhere.

EXAMPLE 1 After 1636

```
typedef int MILES, KLICKSP();
typedef struct { double hi, lo; } range;
```

the constructions

```
MILES distance;
extern KLICKSP *metricp;
range x;
range z, *zp;
```

are all valid declarations. The type of **`distance`** is **`int`**, that of **`metricp`** is "pointer to function with no parameter specification returning **`int`**", and that of **`x`** and **`z`** is the specified structure; **`zp`** is a pointer to such a structure. The object **`distance`** has a type compatible with any other **`int`** object.

Coding Guidelines

typedef 792 naming conventions

The use of uppercase in typedef names is discussed elsewhere.

EXAMPLE 2 After the declarations 1637

```
typedef struct s1 { int x; } t1, *tp1;
typedef struct s2 { int x; } t2, *tp2;
```

type **`t1`** and the type pointed to by **`tp1`** are compatible. Type **`t1`** is also compatible with type **`struct s1`**, but not compatible with the types **`struct s2`**, **`t2`**, the type pointed to by **`tp2`**, or **`int`**.

Coding Guidelines

member 792 naming conventions

The issue of different structure types declaring members having the same identifier spelling is discussed elsewhere.

EXAMPLE 3 The following obscure constructions 1638

```
typedef signed int t;
typedef int plain;
struct tag {
        unsigned t:4;
        const t:5;
        plain r:5;
};
```

declare a typedef name **`t`** with type **`signed int`**, a typedef name **`plain`** with type **`int`**, and a structure with three bit-field members, one named **`t`** that contains values in the range [0, 15], an unnamed const-qualified bit-field which (if it could be accessed) would contain values in either the range [-15, +15] or [-16, +15], and one named **`r`** that contains values in one of the ranges [0, 31], [-15, +15], or [-16, +15]. (The choice of range is implementation-defined.) The first two bit-field declarations differ in that **`unsigned`** is a type specifier (which forces **`t`** to be the name of a structure member), while **`const`** is a type qualifier (which modifies **`t`** which is still visible as a typedef name). If these declarations are followed in an inner scope by

```
t f(t (t));
long t;
```

then a function **f** is declared with type "function returning **signed int** with one unnamed parameter with type pointer to function returning **signed int** with one unnamed parameter with type **signed int**", and an identifier **t** with type **long int**.

Coding Guidelines

The guideline recommendation dealing with the reuse of identifiers is applicable here.

792.3 identifier reusing names

1639 EXAMPLE 4

On the other hand, typedef names can be used to improve code readability. All three of the following declarations of the **signal** function specify exactly the same type, the first without making use of any typedef names.

```
typedef void fv(int), (*pfv)(int);

void (*signal(int, void (*)(int)))(int);
fv *signal(int, fv *);
pfv signal(int, pfv);
```

Commentary

The algorithm for locating the omitted identifier in abstract declarators can be used to locate the identifier declared by the declarator in complex declarations.

1627 EXAMPLE abstract declarators

1640 EXAMPLE 5 If a typedef name denotes a variable length array type, the length of the array is fixed at the time the typedef name is defined, not each time it is used:

```
void copyt(int n)
{
        typedef int B[n];   // B is n ints, n evaluated now
        n += 1;
        B a;                // a is n ints, n without += 1
        int b[n];           // a and b are different sizes
        for (int i = 1; i < n; i++)
                a[i-1] = b[i];
}
```

Other Languages

Some languages (e.g., Ada) support parameterized typedefs that allow information, such as array size, to be explicitly specified when the type is instantiated (i.e., when an object is declared using it).

Coding Guidelines

At the time of this writing there is insufficient experience available with how variable length array types are used to know whether a guideline recommendation dealing with modifications to the values of objects used in the declaration of typedef names, such as n in the above example, is worthwhile.

6.7.8 Initialization

---

initialization syntax

1641

initializer:
    assignment-expression
    { *initializer-list* **}**
    { *initializer-list* **,** **}**
initializer-list:
    $designation_{opt}$ *initializer*
    initializer-list **,** $designation_{opt}$ *initializer*

```
designation:
                designator-list =
designator-list:

                designator
                designator-list designator
designator:
                [ constant-expression ]
                . identifier
```

Commentary

The term *designated initializer* is sometimes used in discussions by members of the committee. However, the C Standard does not use or define this term, it uses the term *designation initializer*.

Rationale

A new feature of C99: Designated initializers provide a mechanism for initializing sparse arrays, a practice common in numerical programming. They add useful functionality that already exists in Fortran so that programmers migrating to C need not suffer the loss of a program-text-saving notational feature.

This feature also allows initialization of sparse structures, common in systems programming, and allows initialization of unions via any member, regardless of whether or not it is the first member.

C90

Support for designators in initializers is new in C99.

C++

Support for designators in initializers is new in C99 and is not specified in the C++ Standard.

Other Languages

Ada supports the initialization of multiple objects with a single value.

```
1  Total_val,
2  Total_average : INTEGER : = 0;
```

Ada (and Extended Pascal) does not require the name of the member to be prefixed with the `.` token and uses the token `=>` (Extended Pascal uses `:`), rather than `=`.

Extended Pascal supports the specification of default initial values in the definition of a type (that are then applied to objects defined to have that type).

The Fortran **DATA** statement is executed once, prior to program startup, and allows multiple objects to be initialized (sufficient values are used to initialize each object and it is the authors responsibility for ensuring that each value is used to initialize the intended object):

```
1       CHARACTER*5 NAME
2       INTEGER I, J, K
3       DATA NAME, I, J, K / 'DEREK', 1, 2, 3/
```

Ada, Extended Pascal, and Fortran (since the 1966 standard) all provide a method of specifying a range of array elements that are to be initialized with some value.

Algol 68 uses the token `=` to specify that the declared identifier is a constant, and `:=` to specify that declared identifier is a variable with an initial value. For instance:

```
INT c = 5;       # constant #
INT d = c + 1;   # constant #
INT e := d;      # initialized variable #
```

BCPL supports parallel declarations, for instance:

```
LET a, b, c = x, y, z; // declare a, b, and c, and then in some order assign x to a, y to b, and z to c
```

Common Implementations

Some prestandard implementations (e.g., `pcc`) parsed initializers bottom-up, instead of top-down (as required by the standard). A few modern implementations provide an option to specify a bottom-up parse (e.g., the Diab Data C compiler[353] supports the `-Xbottom-up-init` option). For instance, in:

```
struct T { int a, b; };
struct  {
          struct T c[2];
          struct T d[2];
         } x = {
                 {1, 2},
                 {3, 4}
                };
```

the initialization of x is equivalent to:

```
{ { {1, 2}, {0, 0} },
  { {3, 4}, {0, 0} } };
```

An implementation performing a bottom-up parse would treat it as being equivalent to:

```
{ { {1, 2}, {3, 4} },
  { {0, 0}, {0, 0} } };
```

`gcc` supports the use of a range notation in array initializer designators. For instance:

```
int my_array[100] = { [0 ... 99] = 1 };
int my_parts[PART_1 + PART_2] = { [0 ... PART_1-1] = 1,
                                  [PART_1 ... PART_1+PART_2-1] = 2 };
```

Coding Guidelines

Constant values often occur in initializer lists. Such occurrences may be the only instance of the constant value in the source, or the values appearing in the list may have semantic or mathematical associations with each other. In these cases the guideline recommendation that names be given to constants may not have a worthwhile benefit.

Dev 825.3 An integer constant may appear in the list of initializers for an object having an array or structure type.

Dev 842.1 A floating constant may appear in the list of initializers for an object.

What are the costs and benefits of organizing the visible appearance of initializers in different ways (like other layout issues, experience suggests that developers have an established repertoire of layout rules which provide the template for laying out individual initializers, e.g., a type based layout with array elements in columns and nested structure types indented like nested conditionals)?

1707 statement visual layout
1348 declaration visual layout

- *Cost*— the time taken to create the visual layout and to maintain it when new initializers are added, or existing ones removed. Experience suggests that developers tend to read aggregate initializers once (to comprehend what their initial value denotes) and ignore them thereafter. Given this usage pattern, initializers are likely to be a visual distraction most of the time (another cost).
- *Benefit*— the visual layout may reduce the effort needed by readers to comprehend them.

Until more is known about the frequency with which individual initializers are read for comprehension, as opposed to being given a cursory glance (almost treated as distractions) it is not possible to reliably provide cost effective recommendations about how to organize their layout. The following discusses some possibilities.

gestalt principles 770

The gestalt principle of organization suggest that related initializers be visually grouped together. It is not always obvious what information needs to be visually grouped. For instance, for an array of structure type initializer might be grouped by array element or by structure member, or perhaps an application oriented grouping:

```
/* Low visual distraction to rest of source. */
{ {1, 'w'}, {2, 'q'}, {3, 'r'} {4, 'a'} }

/* Grouped by array element. */
{
 {1, 'w'},
 {2, 'q'},
 {3, 'r'},
 {4, 'a'}
}

/* Application may suggest an odd/even array element grouping. */
{
 {1, 'w'},
            {2, 'q'},
 {3, 'r'},
            {4, 'a'}
}

/* Perhaps initializers should be grouped by member. */
{
 {1,     'w'},
 {2,     'q'},
 {3,     'r'},
 {4,     'a'}
}
```

Other considerations on initializer layout include making it easy to check that all required initializers are present and visually exposing patterns in the constants appearing in the initializer (with the intent of reducing the effort needed, by subsequent, to deduce them):

```
int bit_pattern[] = {
                     0001, /* octal constant */
                     0010,
                     0100,
                     1000, /* Context may cause reader treat this as an octal constant. */
                    };
```

Other cognitive factors include subitizing and the Stroop effect.

subitizing

When people are asked to enumerate how many dots, for instance, are visible in a well defined area their response time depends on the number of dots. However, when there are between one and four dots performance varies between 40 ms to 100 ms per dot. With five or more dots performance varies between

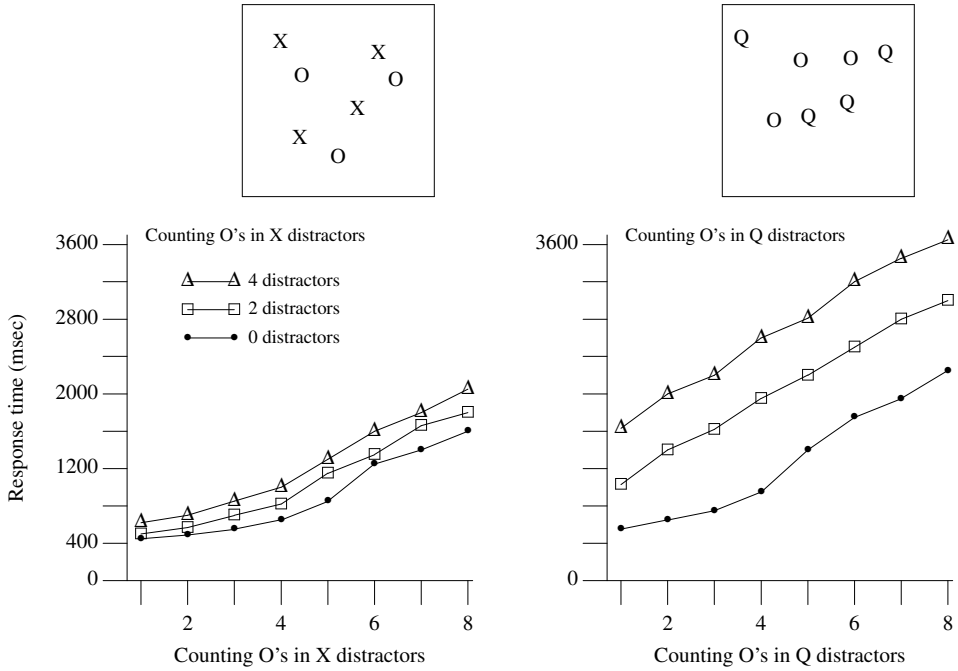

Figure 1641.1: Average time (in milliseconds) taken for subjects to enumerate O's in a background of X or Q distractors. Based on Trick and Pylyshyn.[1365]

250 ms to 350 ms per dot. The faster process used when there are four or fewer dots is called *subitizing* (people effortlessly *see* the number of dots), while the slower process is called *counting*.

Subitizing has been shown[1365] to rely on information available during the preattentive stage of vision. 770 vision preattentive Items that rely on later stages of visual processing (e.g., those requiring spatial attention, such as enumerating the number of squares along a given line) cannot be subitized, they have to be counted. The limit on the maximum number of items that can be subitized is thought to be caused by capacity limits in the preattentive stages of vision.[1366] The extent to which other items, distractors, visible on the display reduce enumeration performance depends on the number of distractors and whether it is possible to discriminate between the visible items during the visual systems preattentive stage. For instance, it is possible to subitize the letter *O* when the distractors are the letter *X*, but not when the distractors are the letter *Q* (see Figure 1641.1).

A study by Stroop[1309] asked subjects to name the color of ink that words were written in. For instance, stroop effect the word *red* was printed in black, blue, and green inks and the word *blue* was printed in black, red, and green inks. The results showed that performance (response time and error rate) suffered substantial interference from the tendency to name the word, rather than its color.

The explanation for what has become known as the *Stroop* effect is based on interference, in the human brain, between the two tasks of reading a word and naming a colour (which are performed in parallel; in general words are read faster, an automatic process in literate adults, than colors can be named). Whether the interference occurs in the output unit, which is serial (one word arriving just before the other and people only being able to say one word at a time), or occurs between the units doing the naming and reading, is still an open question.

Experiments using a number of different kinds of words and form of visual presentation had replicated the effect. For instance, the Stroop effect has been obtained using lists of numbers. Readers might like to try counting the number of characters occurring in each separate row appearing in the margin.

3 3 3 3
a a a a a a
8 8 8
z z
1 1
t t t t
6 6 6 6 6

The effort of counting the digit sequences is likely to have been greater and more error prone than for the letter sequences.

Studies[1064] have found that when subjects are asked to enumerate visually presented digits, the amount of Stroop-like interference depends on the arithmetic difference between the magnitude of the digits used and the number of those digits displayed. Thus a short, for instance, list of large numbers is read more quickly and with fewer errors than a short list of small numbers. Alternatively a long list of small numbers (much smaller than the length of the list) is read more quickly and with fewer errors than a long list of numbers where the number has a similar magnitude to the length of the list.

Initializers often contain lists of similar numbers. The extent to which initializer layout interacts with readers using subitizing/counting and the Stroop effect is not known.

Example

If the `wchar_t` type is different from type **char**, then:

```
#include <stddef.h>

char str1[] = L"abc";               /* Constraint violation, if (wchar_t != char) */
char str2[] = {L'a', L'b', L'c'};   /* OK    */

wchar_t wstr1[] = "abc";            /* Constraint violation, if (wchar_t != char) */
wchar_t wstr2[] = {'a', 'b', 'c'};  /* OK    */
```

Table 1641.1: Occurrence of object types, in block scope, whose declaration includes an initializer (as a percentage of the type of all such declarations with initializers). Based on the translated form of this book's benchmark programs. Usage information on the types of all objects declared at file scope is given elsewhere (see Table 1348.2).

Type	%	Type	%
struct *	39.5	**long**	2.6
int	22.6	**char**	2.5
other-types	9.1	**unsigned short**	2.4
unsigned int	4.5	**unsigned char**	1.5
union *	4.3	**unsigned char** *	1.4
char *	4.0	**unsigned int** *	1.2
unsigned long	3.4	**enum**	1.1

Table 1641.2: Occurrence of object types with internal linkage, at file scope, whose declaration includes an initializer (as a percentage of the type of all such declarations with initializers). Based on the translated form of this book's benchmark programs. Usage information on the types of all objects declared at file scope is given elsewhere (see Table 1348.4).

Type	%	Type	%
const char []	22.5	**char** *	2.2

(const char * **const)** []	2.9	**const unsigned char** []	1.2
unsigned short []	2.5	**const short** []	1.2

Constraints

initializer value not contained in object

No initializer shall attempt to provide a value for an object not contained within the entity being initialized. 1642

Commentary

This constraint can apply to any initializer where a designator is not used and more values are given than are available to be initialized in the type. It can also apply to an array being initialized with a designator

that specifies an element not contained within the array type (structure member designators are covered by another constraint).

1648 designator
. identifier

C90

There shall be no more initializers in an initializer list than there are objects to be initialized.

Support for designators in initializers is new in C99 and a generalization of the wording is necessary to cover the case of a name being used that is not a member of the structure or union type, or an array index that does not lie within the bounds of the object array type.

C++

The C++ Standard wording has the same form as C90, because it does not support designators in initializers.

An `initializer-list` is ill-formed if the number of initializers exceeds the number of members or elements to initialize. 8.5.1p6

1643 The type of the entity to be initialized shall be an array of unknown size or an object type that is not a variable length array type.

Commentary

An array of unknown size is an incomplete type and therefore not an object type.

546 array
unknown size
475 object types

There is no mechanism for specifying a repeat factor for initializers in C, the number of elements is known at translation time. By the nature of their intended usage the number of elements in an object having a variable length array type is not known at translation time and is likely to vary between different instances of type instantiation during program executions. Providing support for initializations would involve specifying many different combinations of events, a degree of complexity that is probably not worth the cost. It is not possible to specify a single initial value, in the declaration of an object having a variable length array type, as a means of implicitly causing all other elements to be initialized to zero.

1682 initializer
fewer in list than members

C90

Support for variable length array types is new in C99.

1644 All the expressions in an initializer for an object that has static storage duration shall be constant expressions or string literals.

initializer
static storage duration object

Commentary

This requirement ensures that the initial value of objects is known at translation time. This simplifies program startup and avoids the complications involved in deducing dependencies between initialization values (needed to define an order of static initialization, on program startup, that gives consistent behavior).

C90

All the expressions in an initializer for an object that has static storage duration or in an initializer list for an object that has aggregate or union type shall be constant expressions.

C99 has relaxed the requirement that aggregate or union types always be initialized with constant expressions.

Support for string literals in this context was added by the response to DR #150.

C++

8.5p2 *Automatic, register, static, and external variables of namespace scope can be initialized by arbitrary expressions involving literals and previously declared variables and functions.*

A program, written using only C constructs, could be acceptable to a conforming C++ implementation, but not be acceptable to a C implementation.

C++ translators that have an *operate in C mode* option have been known to fail to issue a diagnostic for initializers that would not be acceptable to conforming C translators.

Other Languages

Not all languages require the values of initializers to be known at translation time.

---

identifier linkage at block scope

If the declaration of an identifier has block scope, and the identifier has external or internal linkage, the declaration shall have no initializer for the identifier. 1645

Commentary

Existing code, prior to C90, contained declarations of identifiers with external linkage (but without initializers) in block scope and the C committee sanctioned its continued use. Providing an initializer for an object having external or internal linkage, is one method of specifying that it denotes the definition of that object. However, support for such usage has no obvious benefit in block scope.

object 1354 reserve storage

no linkage 435 block scope object

Block scope definitions that include the **`static`** storage-class specifier have no linkage and may contain an initializer.

C++

The C++ Standard does not specify any equivalent constraint.

Coding Guidelines

If the guideline recommendation dealing with declaring identifiers with external or internal linkage at file scope is followed this situation can never occur.

identifier 422.1 declared in one file

---

designator constant-expression

If a designator has the form 1646

```
[ constant-expression ]
```

then the current object (defined below) shall have array type and the expression shall be an integer constant expression.

Commentary

While it is possible for the initialization value to be a nonconstant, the designator of the element being initialized must be constant. Requiring support for nonconstant designators would have introduced a number of complexities. For instance, in the following example:

```
1  int n;
2  /* ... */
3  int vec_1[]   = { [n] = 2 };
4  int vec_2[10] = { [n] = 2 };
```

the declaration of `vec_1` is essentially a new way of specifying a VLA, while in the initializer for `vec_2` a translator cannot enforce the constraint that initializers only provide values for objects contained within the entity being initialized until program execution.

initializer 1642 value not contained in object

C90

Support for designators is new in C99.

C++

Support for designators is new in C99 and is not specified in the C++ Standard.

Coding Guidelines

Some of the coding guideline issues involved in using designators are discussed elsewhere.

1670 initialization using a designator

1647 If the array is of unknown size, any nonnegative value is valid.

Commentary

The number of elements in an array declarator that does not specify a size is deduced from its initializer. Hence, any nonnegative value is guaranteed to be permitted by the standard. However, an implementation may fail to translate a source file containing an object whose size exceeds the minimum required limits.

1683 array of unknown size initialized
294 limit minimum object size

Coding Guidelines

There is not sufficient experience available with the use of designators to know if any particular nonnegative value should be considered suspicious (e.g., very large values, or gaps in a consecutive range).

1648 If a designator has the form

designator . identifier

```
. identifier
```

then the current object (defined below) shall have structure or union type and the identifier shall be the name of a member of that type.

Commentary

This requirement mimics that specified for the `.` operator.

1029 operator . first operand shall

C90

Support for designators is new in C99.

C++

Support for designators is new in C99 and is not specified in the C++ Standard.

Coding Guidelines

The issue of two or more designators specifying a value for the same member of a subobject is discussed elsewhere.

1676 initialization in list order

Semantics

1649 An initializer specifies the initial value stored in an object.

initializer initial value

Commentary

Here the term *initial* refers to the behavior from an executing programs perspective. When initialization occurs depends on the storage duration of the object being initialized. Objects with static storage duration are initialized on program startup, while objects with automatic storage duration are initialized when the objects declaration is encountered during program execution (although their lifetime starts when the block that contains the declaration is entered), and objects with allocated storage duration can be given an initial value to zero by calling the `calloc` library function.

151 static storage duration initialized before startup
1711 object initializer evaluated when
451 lifetime of object

Common Implementations

The machine code generated to initialize scalar objects with automatic storage duration is usually the same as that used to assign a value in an expression statement.

It is much easier to generate efficient machine code for aggregate objects, with automatic storage duration, when an initializer is used compared to when the developer has used a sequence of assignment statements (the translator does not need to perform any analysis to deduce that the values being assigned are all associated with the same object). Using compound literals is likely to result in translators allocating additional storage for the unnamed object (unless it can be deduced that such storage is unnecessary).

1058 compound literal unnamed object

Coding Guidelines

Some coding guideline documents recommend that an initializer always be used to store an initial value in an object. The rationale being that providing an initial value in the definition of the object guarantees that the object is always initialized before use (the concern seems to be more oriented towards ensuring an object does not have an indeterminate value than that it have the correct value, which it might not be possible to assign at the point of definition).

One potential advantage, in providing an initializer, is that if the definition is moved from an inner to an outer scope (moving from an outer to an inner scope will cause a diagnostic to be issued for any references from outside the new scope), during program modification, its initialization is moved at the same time (if the initial value is assigned in a statement, then that statement also needs to be moved; forgetting to do this is a potential source of faults). The following lists several potential disadvantages to this usage:

- The values of the operands in the expression providing the initial value may not be correct, at the point in the source where the initializer occurs. It is also possible that the object represents some temporary value that depends on the value of other objects defined in the same scope.
- A strong case can be made for initializing objects close to their point of use, so the associated source forms a readily comprehensible grouping (this is also an argument for moving the definition closer to its point of use). This issue is discussed in more detail elsewhere.

statement 1707 syntax

- Use of an initializer has been found to sometimes give developers a false sense of security, causing the assignment of a value to be overlooked. For instance, when two very similar sequences of source code occur in a function the second is often created by modifying a copy of the first one. A commonly seen mistake, when initializers are used, is to forget to give some object a new initial value.

```
1  struct T;
2  extern struct T *p_list;
3
4  void f(void)
5  {
6  struct T *walk_p_list = p_list;
7
8  while (walk_p_list)
9     {
10 /* Walk p_list doing something. */
11    }
12
13 /*
14  * Copied above loop, but overlooked giving walk_p_list an initial value.
15  */
16 while (walk_p_list)
17    {
18 /* Walk p_list doing something similar (but loops cannot be merged). */
19    }
20 }
```

In C99 it is possible to intermix declarations and statements. This means that the point of declaration, of an object, could be moved closer to where it is first used. The issue of where to declare objects is discussed elsewhere.

identifier 1348 definition close to usage

There is no evidence to suggest that the benefits of unconditionally providing an initializer in the definition of objects are greater than the costs. For this reason no guideline recommendation is given.

---

unnamed members initialization of

Except where explicitly stated otherwise, for the purposes of this subclause unnamed members of objects of structure and union type do not participate in initialization. 1650

Commentary

This is explicitly stated otherwise in one other instance and is discussed there. The fact that a member is unnamed suggests the author did not intend any value it might happen to contain to be accessed. Providing a mechanism to specify their initial value has no obvious benefit.

1663 initializing including unnamed members

C90

The C90 Standard wording "All unnamed structure or union members are ignored during initialization." was modified by the response to DR #017q17.

C++

This requirement is not explicitly specified in the C++ Standard.

1651 Unnamed members of structure objects have indeterminate value even after initialization.

Commentary

Many developers are aware of the common implementation practice, if a sufficient number of members are initialized to zero, of zeroing all of the storage occupied by an object having a structure type. This C sentence points out that as far as the abstract machine is concerned unnamed members are not affected by the initializer in a definition.

184 abstract machine C

C90

This was behavior was not explicitly specified in the C90 Standard.

C++

This behavior is not explicitly specified in the C++ Standard.

Common Implementations

For objects having an aggregate type and where many members are initialized to zero, many implementations generate machine code to loop over the entire object, setting all bytes to zero; the nonzero values are then individually assigned.

1652 If an object that has automatic storage duration is not initialized explicitly, its value is indeterminate.

object value indeterminate

Commentary

This is a conceptual indeterminate value, an implementation is not required to create and assign it (when the declaration of such an object is encountered during program execution).

75 indeterminate value

```
1   extern _Bool g(void);
2
3   void f (void)
4   {
5   loop: ;
6   int i = 42; /* Explicit initialization occurs every time declaration is encountered */
7   int j;      /* as does implicit initialization to indeterminate value. */
8   if (g())    /* j always has an indeterminate value here. */
9      return;
10  i = 69;     /* Change value of i.   */
11  j = 0;      /* Assign a value to j. */
12  goto loop;
13  }
```

The behavior resulting from reading the value of an object having an indeterminate value depends on the type of the object. Objects having type **`unsigned char`** are guaranteed to contain a representable value (or an object having type array of **`unsigned char`**). In this case a read access results in unspecified behavior. The indeterminate value of objects having other types may be a trap representation (accessing an object having such a value results in undefined behavior).

571 unsigned char pure binary

581 trap representation

Other Languages

Some languages (e.g., Perl) implicitly assign a value to all objects before they are explicitly assigned to (in the case of Perl this is the value `undef`, which evaluates to either 0 or the zero length string). Some languages (e.g., Ada and Extended Pascal) allow the definition of a type to include an initial value that is implicitly assigned to objects defined to have that type.

Common Implementations

The value of such objects is usually the bit pattern that happened to exist in the storage allocated at the start its lifetime. This bit pattern may have been created by assigning a value to an object whose lifetime has ended, or the storage may have been occupied by more than one object, or it may have been used to hold housekeeping information. A few implementations zero the storage area, reserved for defined objects, on function entry.

Example

```
1  { float f=1.234; }
2  { int i;  /* i will probably be allocated storage previous occupied by f */ }
```

---

static initialization default value

If an object that has static storage duration is not initialized explicitly, then: 1653

Commentary

In the past many implementations implicitly initialized the storage occupied by objects having static storage duration to all bits zero prior to program startup. This practice is codified in the C Standard here; where the intent of *all bits zero*, i.e., a value representation of zero, is specified. The issue of initializing objects with static storage duration is discussed elsewhere.

static storage duration 151
initialized before startup
static storage duration 456
when initialized

C++

The C++ Standard specifies a two-stage initialization model. The final result is the same as that specified for C.

8.5p6 *The memory occupied by any object of static storage duration shall be zero-initialized at program startup before any other initialization takes place. [Note: in some cases, additional initialization is done later.]*

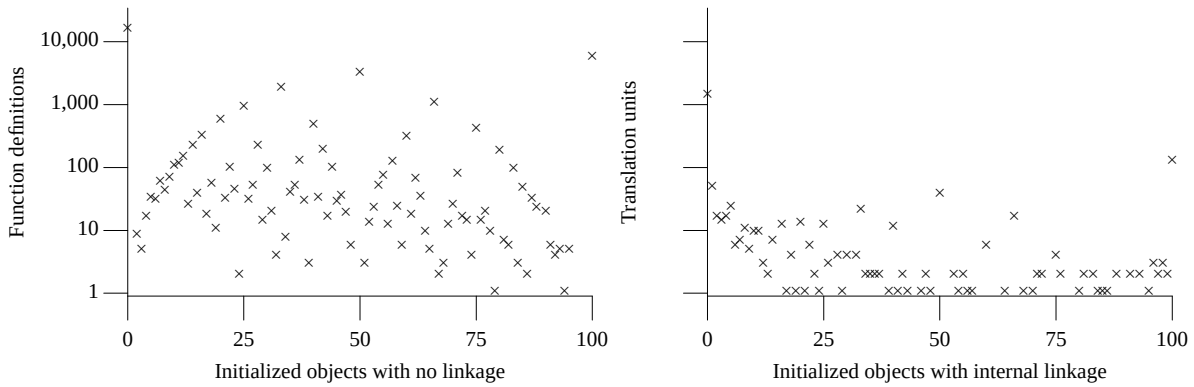

Figure 1652.1: Number of object declarations that include an initializer (as a percentage of all corresponding object declarations), either within function definitions (functions that did not contain any object definitions were not included), or within translation units and having internal linkage (while there are a number of ways of counting objects with external linkage, none seemed appropriate and no usage information is given here). Based on the translated form of this book's benchmark programs.

Other Languages

Most other languages do not treat one kind of uninitialized objects any differently than another kind.

Coding Guidelines

The behavior described in the following sentences is common developer knowledge. There is no obvious benefit in recommending against making use of it, on the basis that all behavior should be explicit.

1654 — if it has pointer type, it is initialized to a null pointer;

Commentary

The null pointer is also the only pointer value that is compatible with all pointer types.

749 null pointer
750 null pointer conversion yields null pointer

1655 — if it has arithmetic type, it is initialized to (positive or unsigned) zero;

Commentary

Zero is the constant most frequently assigned to an object and the most commonly occurring constant literal in source code. It is the initial value most likely to be chosen by a developer, if one had to be explicitly supplied.

825 integer constant usage

C90

The distinction between the signedness of zero is not mentioned in the C90 Standard.

Common Implementations

In most implementations this value is represented by all bits zero for all arithmetic types.

1656 — if it is an aggregate, every member is initialized (recursively) according to these rules;

member initialized recursively

Commentary

In the case of array types every element is assigned the same value.

Common Implementations

Most implementations treat an aggregate, that is being implicitly initialized, as a single entity. That is the most efficient way of assigning all bits zero is used.

1657 — if it is a union, the first named member is initialized (recursively) according to these rules.

Commentary

Having decided to support the initialization of objects having a union type, the specification either had to provide a mechanism for denoting a member to be initialized, or provide a rule to enable readers to deduce the member that will be initialized. The rule that the first named member is initialized fit in with the general English (and perhaps other cultures) convention of starting at the top and working down (rather than starting at the bottom and working up). It is also less likely to cause maintenance problems (since developers tend to add new members at the end of the list of current members).

If the first named member is an aggregate all the members of that aggregate are initialized.

C90

This case was not called out in the C90 Standard, but was added by the response in DR #016.

C++

The C++ Standard, 8.5p5, specifies the first data member, not the first named data member.

1658 The initializer for a scalar shall be a single expression, optionally enclosed in braces.

initializer scalar

Commentary

Allowing initializers for scalars to be enclosed in braces can simplify the automatic generation of C source (the generator does not need any knowledge of the type being initialized, it can always output braces). Braces are not optional when a value appears as the right operand of an assignment operator.

C++

8.5p13 *If T is a scalar type, then a declaration of the form*

```
T x = { a };
```

is equivalent to

```
T x = a;
```

This C++ specification is not the same the one in C, as can be seen in:

```
struct DR_155 {
                int i;
               } s = { { 1 } }; /* does not affect the conformance status of the program */
                                // ill-formed
```

8.5p14 *If the conversion cannot be done, the initialization is ill-formed.*

While a C++ translator is required to issue a diagnostic for a use of this ill-formed construct, such an occurrence causes undefined behavior in C (the behavior of many C translators is to issue a diagnostic).

Other Languages

Most languages that support initializers do not allow redundant braces to be used for scalars.

Coding Guidelines

Initializers for objects having scalar type are rarely enclosed in braces. For this reason they are not discussed further here.

The initial value of the object is that of the expression (after conversion); 1659

Commentary

The conversion is to the type of the object being initialized.

C90

The C90 wording did not include "(after conversion)". Although all known translators treated initializers just like assignment and performed the conversion.

---

initializer type constraints

the same type constraints and conversions as for simple assignment apply, taking the type of the scalar to be the unqualified version of its declared type. 1660

Commentary

simple assignment constraints 1296

simple assignment 1303

The unqualified type needs to be specified because the constraints for simple assignment do not permit object having a const-qualified type to be assigned a value. A consequence of taking the unqualified type is that initialization does not have exactly the same semantics as simple assignment if the object has a volatile-qualified type.

C++

Initialization is not the same as simple assignment in C++ (5.17p5, 8.5p14). However, if only the constructs available in C are used the behavior is the same.

Coding Guidelines

simple assignment constraints 1296

The applicable guideline recommendation are those that apply to simple assignment.

1661 The rest of this subclause deals with initializers for objects that have aggregate or union type.

Commentary

The standard defines additional syntax and semantics for initializers of objects having aggregate or union type.

1662 The initializer for a structure or union object that has automatic storage duration shall be either an initializer list as described below, or a single expression that has compatible structure or union type.

Commentary

Just like simple assignment, it is possible to initialize a structure or union object with the value of another object having the same type. In the case of a union object the value assigned need not be that of the first named member.

C++

The C++ Standard permits an arbitrary expression to be used in all contexts (8.5p2).

This difference permits a program, written using only C constructs, to be acceptable to a conforming C++ implementation but not be acceptable to a C implementation. C++ translators that have an *operate in C mode* switch do not always diagnose initializers that would not be acceptable to all conforming C translators.

1663 In the latter case, the initial value of the object, including unnamed members, is that of the expression.

initializing including unnamed members

Commentary

The former case is the subject of discussion of most of the rest of the C subclause. There is one case where unnamed members participate in initialization.

1650 unnamed members initialization of

```
1  #include <stdio.h>
2
3  struct T_1 {
4              int mem_1;
5              unsigned : 4;
6              double mem_2;
7             };
8  struct T_2 {
9              int mem_1;
10             unsigned int mem_name: 4;
11             double mem_2;
12            };
13 union T_3 {
14            struct T_1 su;
15            struct T_2 sn; /* Both structure types have a common initial sequence. */
16           } gu;
17 struct T_1 s;
18
19 int main(void)
20 {
21 union T_3 lu_1 = {{0, 0.0}};
22 /*
23  * The value of lu_1.sn.mem_name is unspecified here.
24  */
25 gu.sn.mem_name = 1;
26 union T_3 lu_2 = gu;
27
28 if (lu_2.sn.mem_name != 1)
29    print("This is not a conforming implementation\n");
30 }
```

C++

The C++ Standard does not contain this specification.

---

initialize array of char

An array of character type may be initialized by a character string literal, optionally enclosed in braces. 1664

Commentary

A string literal is represented in storage as a contiguous sequence of characters, an array is a contiguous sequence of members. This specification recognizes parallels between them. The rationale for permitting optional braces is the same as that for scalars.

initializer scalar 1658

Coding Guidelines

What are the cost/benefit issues of expressing the initialization value using a string literal compared to expressing it as a comma separated list of values? The string literal form is likely to have a more worthwhile cost/benefit when:

- the value is likely to be familiar to readers as a character sequence (for instance, it is a word or sentence). There is a benefit in making use of this existing reader knowledge, or
- the majority of the individual characters in the string literal are represented in the visible source using characters, rather than escape sequences, the visually more compact form may require less effort, from a reader, to process.

One situation where use of a string literal may not be cost effective is when the individual character values are used independently of each other. For instance, they represent specific data values or properties. In this case it is possible that macro names have been defined to represent these values. Referencing these macro names in the initializer eliminates the possibility that a change to their value will not be reflected in the initializer.

---

initialize uses successive characters from string literal

Successive characters of the character string literal (including the terminating null character if there is room or if the array is of unknown size) initialize the elements of the array. 1665

Commentary

The declaration:

```
unsigned char uc[] = "\xFF";
```

is equivalent to:

```
unsigned char uc[2] = { (unsigned char)(char) 0xFF, 0 };
```

C++

The C++ Standard does not specify that the terminating null character is optional, as is shown by an explicit example (8.5.2p2).

An object initialized with a string literal whose terminating null character is not included in the value used to initialize the object, will cause a diagnostic to be issued by a C++ translator.

```
char hello[5] = "world"; /* strictly conforming */
                         // ill-formed
```

Common Implementations

Some implementations store the string literal as part of the program image and copy it during initialization. Others generate machine code to store constants (the individual character values, often concatenated to form larger constants, reducing the number of store instructions) into the object.

Coding Guidelines

Developers sometimes overlook a string literal's terminating null character in their calculation of the number of array elements it will occupy (either leaving insufficient space to hold the null character, when an array size is specified, or forgetting that storage will be allocated for one, in the case of an incomplete array type). There is no obvious guideline recommendation that might reduce the probability of a developer making these kind of mistakes.

Example

```
char a_1[3] = "abc", /* storage holds | a | b | c |         */
     a_2[4] = "abc", /* storage holds | a | b | c | 0 |     */
     a_3[5] = "abc", /* storage holds | a | b | c | 0 | 0 | */
     a_4[]  = "abc"; /* storage holds | a | b | c | 0 |     */
```

In (assuming any undefined behavior does not terminate execution of the program):

```
unsigned char s[] = "\x80\xff";
```

the first element of `s` is assigned the value `(unsigned char)(char)128` and the second element the value `(unsigned char)(char)255`.

1666 An array with element type compatible with **`wchar_t`** may be initialized by a wide string literal, optionally enclosed in braces.

initialize array of wchar_t

Commentary

The applicable issues are the same as for an array of character type.

1664 initialize array of char

Coding Guidelines

The cost/benefit of using a wide string literal in the visible source, rather than a comma separated list, will be affected by the probability that the wide characters will appear, to a reader, as a glyph rather than some multibyte sequence (or other form of encoding).

1664 initialize array of char

1667 Successive wide characters of the wide string literal (including the terminating null wide character if there is room or if the array is of unknown size) initialize the elements of the array.

initialize uses successive wchar_t from string literal

Commentary

The applicable issues are the same as for an array of character type

1665 initialize uses successive characters from string literal

---

1668 Otherwise, the initializer for an object that has aggregate or union type shall be a brace-enclosed list of initializers for the elements or named members.

Commentary

The syntax requires a list of initializers to be brace enclosed (the braces serve to disambiguate what would otherwise look like a declarator list). While the braces are not strictly necessary for union types (there is only one initializer), their visual appearance is consistent with braces being used in structure and union type definitions.

Other Languages

Many languages support this form of initializer (although the delimiters are not always braces).

1669 Each brace-enclosed initializer list has an associated *current object*.

current object brace enclosed initializer

Commentary

This introduces the term *current object*. This terminology is new in C99 and is not commonly used by developers. Current objects are associated only with brace-enclosed initializer lists.

footnote 1685 127

A lot of background knowledge of how "things are supposed to work" is needed to understand out how the *current object* maps to the object being initialized. Some of this knowledge is encoded in the extensive examples provided in the Standard.

C90

The concept of *current object* is new in C99.

C++

The concept of *current object* is new in C99 and is not specified in the C++ Standard. It is not needed because the ordering of the initializer is specified (and the complications of designation initializers don't exist, because they are not supported):

8.5.1p2 *. . . , written in increasing subscript or member order. If the aggregate contains subaggregates, this rule applies recursively to the members of the subaggregate.*

Other Languages

Fortran does not restrict the initializer list to providing initial values for one object. Its **DATA** statement may contain a list of separate, unrelated, objects followed by a list of values (used to initialize the separate objects at program startup).

---

initialization no designator member ordering

When no designations are present, subobjects of the current object are initialized in order according to the type of the current object: array elements in increasing subscript order, structure members in declaration order, and the first named member of a union.[127)] 1670

Commentary

This selection of mapping between members and initializers is the one that is most consistent with what people are likely to expect to occur.

C90

Otherwise, the initializer for an object that has aggregate type shall be a brace-enclosed list of initializers for the members of the aggregate, written in increasing subscript or member order; and the initializer for an object that has union type shall be a brace-enclosed initializer for the first member of the union.

The wording specifying named member was added by the response to DR #016.

Other Languages

This convention is common to most languages that support some form of initializer.

Coding Guidelines

An object declaration, whose derived type includes a structure type, that includes an initializer where no designations are present contains an ordering dependency between the structure members and the values given in the initializer. For instance, the following definition contains a member ordering assumption that is not guaranteed by the C Standard:

EXAMPLE 1702 div_t

```
1  #include <stdlib.h>
2
3  div_t val = {3, 4};
```

initialization using a designator

Is there worthwhile cost/benefit in a guideline recommendation specifying that initialization values corresponding to structure members always include a designator? Designators are not supported by C++ or C90, so such a recommendation would be C99 specific. The following are some of the potential benefits of using designators in the initialization lists of objects having a structure type:

- Removing the dependency between members and their corresponding initialization value. This benefit is only realized if the ordering of existing members changes (adding new members after the existing members does not change the existing dependencies). The possibility of developers writing code that contains dependencies on member ordering is appreciated by developers (and third-party library vendors) and the cost of changes to existing code (customer complaints) are factored into any consideration of changing structure member order. Experience shows that new members are usually added to the end of existing structure types.
- As a memory aid for the reader of the initializer. While comprehending an initializer readers have to process its components, while remembering information about their position within the being initialized. Having a designator visible provides a mechanism for readers to for holding and refreshing information in the visuo-spatial sketch pad, freeing up other working memory resources for other tasks.

0 visuo-spatial memory
0 memory developer

Given the existing practice of adding new members to the end of an existing structure type (the C++/C90 compatibility issue could be solved via the use of a macro) there does not appear to be sufficient benefit for a guideline recommending that designators always be used.

Initialization of objects having an array type involves a (potentially) large number of values of the same type. Experience shows that the value of many elements is often zero. Designators provide a method of reducing the number of zeroes that appear in the source. However, specifying the conditions under which there is a worthwhile cost/benefit for their usage is likely to involve a complex calculation. At the time of this writing there is insufficient experience with the use of this construct to know whether simple rules can be specified. For this reason no guideline recommendation is given.

1671 In contrast, a designation causes the following initializer to begin initialization of the subobject described by the designator.

initialization using a declarator

Commentary

The designator explicitly specifies which member (of the current object) the initialization value refers to.

```
1   int a[5] = { [2] = 3 };
```

C90

Support for designations is new in C99.

C++

Support for designations is new in C99, and is not available in C++

Other Languages

Some languages (e.g., Ada) support an equivalent construct.

Coding Guidelines

Some of the costs and benefits of using designators are discussed elsewhere.

1670 initialization no designator member ordering

1672 Initialization then continues forward in order, beginning with the next subobject after that described by the designator.[128)]

Commentary

The designation can be thought of as a "goto" within the current object. Once a designator has specified a member at which initialization is to occur, subsequent initializations continue from that point until another designator or the end of the type of the current object is reached.

Other Languages

Ada requires that initializers either be written without using any designators or be written only using designators (i.e., no mixing).

Coding Guidelines

initialization 1670
no designator
member ordering

Is the use of designators an all or nothing choice? This question is a special case of the member ordering dependency issue discussed elsewhere. At the time of this writing there is not sufficient experience available with the use of this construct to be able to reliably make any recommendations.

In the two definitions:

```
int a1[] = {
             [10] = 5, 9, 3,
             [23] = 1, 0, 16,
            };
int a2[] = {
             [10] = 5, [11] = 9, [12] = 3,
             [23] = 1, [24] = 0, [25] =16,
            };
```

it is possible to imagine the following two scenarios— where modifications to a program:

- require the three initial values starting at `[10]` need to be offset by four elements, to `[14]`. In this case there is greater potential for mistakes being introduced by incorrectly modifying (or not modifying) the two following designators, in the initializer for `a2`, or
- require that the initial value at `[10]` be moved by four elements to `[14]`. In this case there is greater potential for mistakes being introduced by failing to create a designator for `[11]` (or incorrectly specifying it), in the initializer for `a1`.

---

designator list
current object

Each designator list begins its description with the current object associated with the closest surrounding brace pair. 1673

Commentary

Here usage of the term *designator list* refers to the syntactic terminal of that name. The member specified by a designator is context dependent. While it is not necessary to specify the path from the outermost object to the current object, it is necessary to specify a path to any nested subobject being initialized (or use nested braces). An initializer enclosed in a brace pair is used to initialize the members of a contained subaggregate or union.

initializer 1679
brace pair

C90

Support for designators is new in C99.

C++

Support for designators is new in C99, and is not available in C++

Coding Guidelines

It is possible to write initializers without using any nested brace pair. However, the additional cost of inserting pairs of braces into an initializer is minimal and the potential benefit is large. These benefits include the following:

- Providing a visual aid that can be used, in conjunction with white space and new line characters, to highlight individual sequences of initializers. In particular the appearance of an opening brace helps disambiguate whether initializers at the start of a line are a continuation of the initializers from the previous line, or denote the start of the initializers for a different object. A closing brace provides explicit visual information that any following initializers belong to a different subobject.

- An increased likelihood of developer mistakes (e.g., a missing initializer value or unintended additional initializer value) resulting in diagnostics being generated by translators. It is possible to specify fewer initializers than there are objects to initialize, and many initializers and objects have an integer type (which reduces the probability of a mismatched initializer value and object having an incompatible type, i.e., no diagnostic will be generated). An opening brace may only appear when the current object has an aggregate or union type, and translators are required to perform this check. There is a limit to the number of initializers that can occur between matching braces (the number of subobjects being initialized) and translators are required to perform this check.

Enclosing initializers in matching braces isolates them from other initializers for other members. Such usage also enables translators to perform a finer grained level of checking on the expected number of initializers for each member.

Cg 1673.1 Any optional braces shall not be omitted in an initializer for an aggregate or union type.

Example

In the following, the initializers all assign the same value to the same members:

```
struct S {
           char m_1_1;
           struct {
                   char m_2_1;
                   struct {
                           char m_3_1;
                           char m_3_2;
                          } m_2_2;
                   char m_2_3;
                  } m_1_2;
           char m_1_3;
          };

struct S x_1 = {'a',           'b', 0,             'c', 0, 'd'};
struct S x_2 = {'a', .m_1_2 = {'b',      {.m_3_2 = 'c'} }, 'd'};
struct S x_3 = {'a',          {'b',            {0, 'c'} }, 'd'};
struct S x_4 = {'a', {.m_2_1 = 'b', .m_2_2.m_3_2 = 'c'},   'd'};
```

1674 Each item in the designator list (in order) specifies a particular member of its current object and changes the current object for the next designator (if any) to be that member.[129)]

Commentary

Each designator list is independent of any other designator list and any change of current object only applies during the evaluation of a given designator list.

1689 designator list independent

Coding Guidelines

The cost/benefit issues associated with using designators are discussed elsewhere. This coding guideline subsection discusses whether any guideline recommendations on the forms of usage, if it was decided to use them in initializers, might be cost effective.

1670 initialization no designator member ordering
1670 initialization using a designator

There may be a reason for automatically generated source to initialize members in what appears to be a random order. Having a designator list specify members in the same order as they occur in the declaration of the aggregate type is a consist mapping in many cultures and is also consistent with the order used when no designators are present. However, one of the benefits of using designators is that the relative order of values within an initializer is independent of the order used in the declaration of an aggregate.

1670 initialization no designator member ordering

There is no evidence to suggest that (designators are a new construct and at the time of this writing little experience has been gained in how they are used), in practice, developers will commonly order designators in any way other than an order that matches the order of the member in the declaration of the aggregate type (or at least the one visible at the time the code was first written, which may subsequently change). Until more experience has been gained in how developers use this construct there is no point in idle speculation over what guideline recommendations might be appropriate.

Example

In the following the initializers all assign the same values to the same members:

```
1  struct S {
2            char m_1_1;
3            struct {
4                   char m_2_1;
5                   struct {
6                             char m_3_1;
7                             char m_3_2;
8                            } m_2_2;
9                   char m_2_3;
10                  } m_1_2;
11           char m_1_3;
12           };
13
14 struct S x_1 = {'a',                'b', 0,             'c'      , 0, 'd'};
15 struct S x_2 = {'a',      {.m_2_1 = 'b', .m_2_2.m_3_2 = 'c'},         'd'};
16 struct S x_3 = {'a', .m_1_2.m_2_1 = 'b', .m_1_2.m_2_2.m_3_2 = 'c', 0, 'd'};
```

The current object that results at the end of the designator list is the subobject to be initialized by the following initializer. 1675

Commentary

The following initializer can be a brace enclosed initializer.

```
1  struct S {
2            char m_1_1;
3            struct {
4                   struct {
5                          char m_3_1;
6                          char m_3_2;
7                          } m_2_1;
8                   char m_2_2;
9                   } m_1_2;
10           };
11 struct S x_1 = {.m_1_2 =       {1, 2,  0}};
12 struct S x_2 = {.m_1_2 =     { {1, 2}, 0}};
13 struct S x_3 = {.m_1_2.m_2_1 = {1, 2}};
```

---

initialization in list order

The initialization shall occur in initializer list order, each initializer provided for a particular subobject overriding any previously listed initializer for the same subobject;[130)] 1676

Commentary

Objects with automatic storage duration are not required to have initializers that are constant expressions. Expressions can cause side effects. While this requirement specifies the order in which initialization occurs it does not specify the order in which the initializers are evaluated. The following declaration:

footnote 130 1690

```
union { char x[5]; } u = { .x[1] = 7 };
```

is a shorthand for:

```
union { char x[5]; } u = { .x = { [1] = 7 } };
```

Expanding out shorthand forms can help make it easier to deduce the initial values of some members. For instance, in:

```
union {
       char a[5];
       char b[5];
      } u = {
              .a[1] = 7,
              .b[2] = 8
             };
```

it might be thought that the value of `u.b[1]` is 7. However, writing it out in non-shorthand form we get:

```
union {
       char a[5];
       char b[5];
      } u = {
             .a = { [1] = 7 },
             .b = { [2] = 8 }
             };
```

where it is easily seen that the value of `u.b[1]` is 0.

C++

The C++ Standard does not support designators and so it is not possible to specify more than one initializer for an object.

Other Languages

Ada does not permit more than one initializer to be specified for the same subobject.

Common Implementations

It is too early to know whether it is worthwhile for optimizers to invest in looking for and removing overridden initializers. Initializers that are overridden and do not generate side effects or are depended on by other initializers may be removed general dead code elimination optimizations.

Coding Guidelines

The guideline recommendation dealing with the evaluation ordering between sequence points is applicable here. Providing an initializer for an object that is subsequently overridden might be treated as suspicious for several reasons, including the following:

187.1 sequence points all orderings give same value
1704 EXAMPLE overriding values

- A reader may only see the first initializer value and not any later ones, leading to an incorrect interpretation of program behavior.
- Evaluation of the initializer may be expected to cause side effects, or be used as an operand in the initializer for another subobject. Not evaluating an initializer, that is overridden, may have unexpected consequences.

```
extern int glob;
struct S {
          int m_1;
          int m_2;
          int m_3;
          };
```

```
7
8   void f(void)
9   {
10  struct S loc = {
11                  .m_1 = glob++,
12                  .m_2 = loc.m2+1,
13                  .m_1 = 1
14                  };
15  }
```

dead code 190

- The overridden initializer is essentially dead code. This issue is discussed elsewhere.
- The usage might be considered suspicious, especially if another member had not been explicitly initialized.

Designations are new in C99 and it is too early to know whether a specific guideline recommending against their use is worthwhile (there are many constructs guidelines could recommend against, but don't because they rarely appear in source code). The conclusions of the discussion on dead code may be sufficient.

dead code 190

---

object initialized but not explicitly

all subobjects that are not initialized explicitly shall be initialized implicitly the same as objects that have static storage duration. 1677

Commentary

The presence of an initializer in an object definition causes different behavior than the absence of an initializer. If the definition includes an initializer, even if it only initializes a single member, all members are given a known value. However, all members of an object defined without an initializer (and not having static storage duration) have an indeterminate value, at the point of definition.

object 463 indeterminate each time declaration reached

The implicit value assigned to objects that have static storage duration is zero (or null).

static initialization 1653 default value

C++

The C++ Standard specifies that objects having static storage duration are zero-initialized (8.5p6), while members that are not explicitly initialized are default-initialized (8.5.1p7). If constructs that are only available in C are used the behavior is the same as that specified in the C Standard.

Other Languages

Some languages (e.g., Ada and Extended Pascal) require that initializers be specified for all subobjects.

Common Implementations

Two implementation strategies are to zero all members of the initializer (using a loop) and then assigning specific values to specific members, or to assign specific values (which may include the implicit values) to all members. The better optimizers perform a cost/benefit analysis to select the strategy to use (which for large objects may involve applying different ones for different subobjects).

Coding Guidelines

coding guidelines 0 other documents

A general principle promoted in many coding guideline documents is that all operations should be explicit. However, explicitly specifying zero values for members of an aggregate object has a number of costs that the implicit usage does not, including the following:

- A large number of zeros in the visible source increase the effort needed, by readers, to locate the nonzero values. The zeros have become visual noise, that do not provide information to readers.
- Increased maintenance costs. Having to update the initializer list every time the aggregate type changes (either because of a change in the number of elements, or the number of members). If designators are used member names may also need to be updated.

Given these costs and the fact that developers are generally aware of the default behavior, there does not appear to be a worthwhile benefit in a guideline recommending that the behavior be made explicit.

1678 If the aggregate or union contains elements or members that are aggregates or unions, these rules apply recursively to the subaggregates or contained unions.

Commentary

There are no special cases that apply to nested aggregates or unions.

1679 If the initializer of a subaggregate or contained union begins with a left brace, the initializers enclosed by that brace and its matching right brace initialize the elements or members of the subaggregate or the contained union.

initializer brace pair

Commentary

The brace pair provide a mechanism for explicitly specifying which initializers belong to a subaggregate or contained union. Only the initializers enclosed by the braces are used to initialize its corresponding subaggregate or union. If there are fewer initializers than members the remaining members are implicitly initialized. Each brace-enclosed initializer list also has an associated current object.

1669 current object brace enclosed initializer

Other Languages

Fortran uses parenthesis and forward slash (e.g., `(/.../)` and `/.../`), Ada uses parenthesis (e.g., `(...)`) and Extended Pascal uses square brackets (e.g., `[...]`).

Coding Guidelines

The guideline recommendation that braces always be used is discussed elsewhere.

1673.1 initializer use braces

1680 Otherwise, only enough initializers from the list are taken to account for the elements or members of the subaggregate or the first member of the contained union;

Commentary

If the initializer values are not enclosed by a matching pair of braces, values from the current list of initializers are used.

Other Languages

The Fortran `DATA` statement also specifies this behavior. However, most languages that support some form of initialization, associated with an objects declaration, require stricter correspondence between initializer value and subobject being initialized.

Coding Guidelines

The coding guideline issues associated with this form of initializer are discussed elsewhere.

1673.1 initializer use braces

1681 any remaining initializers are left to initialize the next element or member of the aggregate of which the current subaggregate or contained union is a part.

Commentary

That is, any remaining initializers up until the matching right brace.

C90

This behavior was not pointed out in the C90 Standard.

1682 If there are fewer initializers in a brace-enclosed list than there are elements or members of an aggregate, or fewer characters in a string literal used to initialize an array of known size than there are elements in the array, the remainder of the aggregate shall be initialized implicitly the same as objects that have static storage duration.

initializer fewer in list than members

Commentary

This wording spells out particular cases, removing the possibility of other interpretations being applied to the general wording on implicit initialization given earlier.

1677 object initialized but not explicitly

C90

The string literal case was not explicitly specified in the C90 Standard, but was added by the response to DR #060.

C++

The C++ Standard specifies that objects having static storage duration are zero-initialized (8.5p6), while members that are not explicitly initialized are default-initialized (8.5.1p7). If only constructs available in C are used the behavior is the same as that specified in the C Standard.

Other Languages

Many other languages (e.g., Ada and Extended Pascal) do not explicitly specify a behavior for this case.

Coding Guidelines

object initialized but not explicitly 1677

The coding guideline discussion given elsewhere is applicable here.

---

array of unknown size initialized

If an array of unknown size is initialized, its size is determined by the largest indexed element with an explicit initializer. 1683

Commentary

An initializer provides another method of specifying the size (number of elements) of an array type.

C90

If an array of unknown size is initialized, its size is determined by the number of initializers provided for its elements.

Support for designators is new in C99.

Other Languages

Ada specifies a similar rule for deducing both the lower and upper bounds of an array.

Coding Guidelines

Specifying the size of the array via the contents of an initializer reduces the amount of effort needed to write the array definition. In this case the number of elements in the array has to be obtained using a constant expression of the form `(sizeof(arr) / sizeof(arr[0]))`. However, in some cases developers do not specify a size between the **`[]`** tokens, even although the value is readily available to them. Such usage becomes a potential cause of maintenance problems if two unrelated mechanisms are used to denote the number of array elements (e.g., some numeric literal, and an expression using **`sizeof`**). Using the known size value in the declaration of the array provides some degree of checking (i.e., translators are required to issue a diagnostic if too many initializers are specified, but not if too few are specified).

Example

```
#define A_SIZE 9

int a_1[]       = {0, 1, 2, 3, 4, 5, 6, 7, 8, 9};
int a_2[A_SIZE] = {0, 1, 2, 3, 4, 5, 6, 7, 8, 9}; /* Diagnostic issued. */
int a_3[A_SIZE] = {0, 1, 2, 3, 4, 5, 6, 7      }; /* Diagnostic not issued. */
```

---

initializer completes incomplete array type

At the end of its initializer list, the array no longer has incomplete type. 1684

Commentary

The initializer provides all of the information needed to complete the type. However, the single pass translation nature of C means that the completion of the type does not affect any constraint requirements that apply to constructs appearing earlier in the processing of the declaration. For instance, in: 10 implementation single pass

```
int a[][] = {{1}, {2}, {3}};    /* Only one array size can be deduced from initializer. */
int b[sizeof(b)*2] = {1, 2, 3}; /* Operand of sizeof has incomplete type when it is processed. */
```

C++

The C++ Standard does not specify how an incomplete array type can be completed. But the example in 8.5.1p4 suggests that with an object definition, using an incomplete array type, the initializer creates a new array type. The C++ Standard seems to create a new type, rather than completing the existing incomplete one (which is defined, 8.3.4p1, as being a different type).

1685 127) If the initializer list for a subaggregate or contained union does not begin with a left brace, its subobjects are initialized as usual, but the subaggregate or contained union does not become the current object: current objects are associated only with brace-enclosed initializer lists. footnote 127

Commentary

```
struct S {
          int m_1_1;
          struct {
                 int m_2_1;
                 int m_2_2;
                 } m_1_2;
          int m_1_3;
          };

struct S x_1 = {1,
                2, /* Current object does not become m_1_2 */
        .m_2_2 = 3, /* Constraint violation, designator should be .m_1_2.m_2_2 */
                4
               };
```

C90

The concept of current object is new in C99.

C++

The concept of current object is new in C99 and is not specified in the C++ Standard.

Coding Guidelines

Developer misunderstandings, in this case, about what constitutes the current object could be harmless in that incorrect use of designators causes a diagnostic to be issued. However, the same member name appearing on its own (e.g., `.next`) in more than one designator is a possible source of reader visual confusion. One way of reducing the possibility of visual confusion is to use additional members in designator (e.g., `.left.next` and `.right.next`). But this usage is dependent on which subaggregate the current member denotes, which will be affected by the brace nesting. Until more experience has been gained in the use of designators it is not possible to estimate the cost/benefit trade-offs involved in using braces or designators containing more member selections.

1686 128) After a union member is initialized, the next object is not the next member of the union; footnote 128

Commentary

Only one member of a union is required to hold a value at any time. 563 footnote 37

C90

The C90 Standard explicitly specifies, in all the relevant places in the text, that only the first member of a union is initialized.

---

instead, it is the next subobject of an object containing the union. 1687

Commentary

member initialized recursively 1656

Or, if that is a union or if the last member of an aggregate has just been processed, the next subobject of the containing type (and so on returning through any recursion) .

---

footnote 129

129) Thus, a designator can only specify a strict subobject of the aggregate or union that is associated with the surrounding brace pair. 1688

Commentary

A designator cannot, for instance, denote a member of an object contained in the type of a member outside of the surrounding brace.

```
1  struct S {
2            int m_1_1;
3            struct {
4                    int m_2_1;
5                    int m_2_2;
6                   } m_1_2;
7            int m_1_3;
8           };
9
10 struct S x_1 = {1,
11                   {2,
12                    .m_1_3 = 3 /* Constraint violation. */
13                   }
14                 };
```

Coding Guidelines

Any attempt to specify, in a designator, a member that is not in the strict subobject will cause a diagnostic to be generated.

---

designator list independent

Note, too, that each separate designator list is independent. 1689

Commentary

current object 1669 brace enclosed initializer

Each separate designator list is independent in the sense that a designator list does not change the current object in the way that a brace-enclosed initializer does.

```
1  struct S {
2            int m_1_1;
3            struct {
4                    int m_2_1;
5                    int m_2_2;
6                   } m_1_2;
7           };
8  struct S x_1 = {
9                   .m_1_2.m_2_1 = 1, /* Does not change the current object to be m_1_2. */
10                        .m_2_2 = 3  /* Constraint violation. */
11                 };
12 struct S x_2 = {
13                  .m_1_2 = {.m_2_1 = 1,  /* { Changes the current object to be m_1_2. */
14                            .m_2_2 = 3}  /* OK. */
15                 };
```

footnote 130

1690 130)Any initializer for the subobject which is overridden and so not used to initialize that subobject might not be evaluated at all.

Commentary

This sentence was added by the response to DR #208.

DR #208

Committee Response

The question asks about the expression

```
int a [2] = { f (0), f (1), [0] = f (2) };
```

and the meaning of the wording

each initializer provided for a particular subobject overriding any previously listed initializer for the same subobject;

It was the intention of WG14 that the call `f(0)` might, but need not, be made when a is initialized. If the call is made, the order in which `f(0)` and `f(2)` occur is unspecified (as is the order in which `f(1)` occurs relative to both of these). Whether or not the call is made, the result of `f(2)` is used to initialize `a[0]`.

The wording of paragraph 23:

The order in which any side effects occur among the initialization list expressions is unspecified.

should be taken to only apply to those side effects which actually occur.

1691 The order in which any side effects occur among the initialization list expressions is unspecified.[131)]

Commentary

1714 full expression initializer

An initializer was defined to be a full expression in C90. However, support for nonconstant initial values is new in C99 and this sentence points out the consequences. While operators (the comma in an initialization list is a punctuator, not an operator) that have sequence points may occur in the initialization list, just like in an expression, there is no requirement that these sequence points occur in a particular order.

C90

The C90 Standard requires that the expressions used to initialize an aggregate or union be constant expressions. Whatever the order of evaluation used the external behavior is likely to be the same (it is possible that one or more members of a structure type are volatile-qualified).

C++

The C++ Standard does not explicitly specify any behavior for the order of side effects among the initialization list expressions (which implies unspecified behavior in this case).

Other Languages

Ada explicitly states that the order of evaluation is unspecified.

Coding Guidelines

187.1 sequence points all orderings give same value

The guideline recommendation dealing with the evaluation order between sequence points is applicable here. The extent to which developers will incorrectly believe the comma punctuators between designators is a sequence point is not known. Correcting any such a belief is an educational issue and is outside the scope of these coding guidelines. Because of the declaration nature of an initializer it is more difficult to break it up into smaller, independent, components (as is possible for expressions in a statement context). The extent to which this will lead to complicated and difficult to comprehend initializers is not known.

Example

```
#include <stdio.h>

void f(void)
{
int loc_1 [] = {printf("Hello"), printf("world")};
}
```

there are two possible character sequences that may be output, either **Helloworld**, or **worldHello**.

EXAMPLE 1 Provided that **<complex.h>** has been **#included**, the declarations 1692

```
int i = 3.5;
double complex c = 5 + 3 * I;
```

define and initialize **i** with the value 3 and **c** with the value *5.0 + i3.0*.

Commentary

In this example the macro I expands to a constant expression of type **const float _Complex**. The initialization value is actually equivalent to `5.0f+i3.0f`.

The wording was changed by the response to DR #293.

C90

Support for complex types is new in C99.

C++

The C++ Standard does not define an identifier named **I** in **<complex>**.

Coding Guidelines

integer 688 conversion to floating

Some of the issues applicable to this example are discussed elsewhere.

EXAMPLE 2 The declaration 1693

```
int x[] = { 1, 3, 5 };
```

defines and initializes **x** as a one-dimensional array object that has three elements, as no size was specified and there are three initializers.

Commentary

array element 1567 not incomplete type

An arrays element type is required to be an object type, not an incomplete type. This means it is not possible to use an initializer to specify the size of more than one array dimension.

```
int y[][] = { {1, 2}, {3, 4}, {5, 6} }; /* Constraint violation. */
```

EXAMPLE 3 The declaration 1694

```
int y[4][3] = {
        { 1, 3, 5 },
        { 2, 4, 6 },
        { 3, 5, 7 },
};
```

is a definition with a fully bracketed initialization: 1, 3, and 5 initialize the first row of **y** (the array object **y[0]**), namely **y[0][0]**, **y[0][1]**, and **y[0][2]**. Likewise the next two lines initialize **y[1]** and **y[2]**. The initializer ends early, so **y[3]** is initialized with zeros. Precisely the same effect could have been achieved by

```
int y[4][3] = {
        1, 3, 5, 2, 4, 6, 3, 5, 7
};
```

The initializer for **y[0]** does not begin with a left brace, so three items from the list are used. Likewise the next three are taken successively for **y[1]** and **y[2]**.

Other Languages

Some languages (e.g., Ada and Extended Pascal) require the initializer to have a form similar to the first declaration and do not support a form equivalent to the second.

Coding Guidelines

The guideline recommendation that might be applicable to this example is the use braces to delimit initializers for members having an aggregate type.

1673.1 initializer use braces

1695 EXAMPLE 4 The declaration

```
int z[4][3] = {
        { 1 }, { 2 }, { 3 }, { 4 }
};
```

initializes the first column of **z** as specified and initializes the rest with zeros.

Other Languages

Some languages (e.g., Ada and Extended Pascal) require that initializers be specified for all subobjects.

1696 EXAMPLE 5 The declaration

EXAMPLE inconsistently bracketed initialization

```
struct { int a[3], b; } w[] = { { 1 }, 2 };
```

is a definition with an inconsistently bracketed initialization. It defines an array with two element structures: **w[0].a[0]** is 1 and **w[1].a[0]** is 2; all the other elements are zero.

Commentary

An additional pair of braces is needed for the declaration:

```
1  struct { int a[3], b; } w[] = { { { 1 }, 2 } };
```

to define an array having a single element (i.e., b is initialized to 2). An example of an alternative form of initializer is given elsewhere.

1703 EXAMPLE designators with inconsistently brackets

1697 131) In particular, the evaluation order need not be the same as the order of subobject initialization.

footnote 131

Commentary

In the following:

```
1  #include <stdio.h>
2
3  void f(void)
4  {
5  int loc_1 [] = {2, loc_1[0]+1};
6  int loc_2 [] = {2, loc_2[0]++};
7  }
```

the element `loc_1[1]` is not guaranteed to be initialized with a value that is one greater than `loc_1[0]`. The initializer for `loc_2` exhibits undefined behavior because the same object is modified more than once between sequence points.

1714 full expression initializer

C++

The C++ Standard does explicitly specify the ordering of side effects among the expressions contained in an initialization list.

Common Implementations

While some implementations might evaluate each designator in an initializer in a first to last order, others might treats it as a sequence of independent simple assignments (relying on existing optimization routines within the translator to generate the best quality machine code).

sequence points 187.1
all orderings give same value

Coding Guidelines

The guideline recommendation dealing with expression evaluation is applicable here.

EXAMPLE 6 The declaration 1698

```
short q[4][3][2] = {
        { 1 },
        { 2, 3 },
        { 4, 5, 6 }
};
```

contains an incompletely but consistently bracketed initialization. It defines a three-dimensional array object: `q[0][0][0]` is 1, `q[1][0][0]` is 2, `q[1][0][1]` is 3, and 4, 5, and 6 initialize `q[2][0][0]`, `q[2][0][1]`, and `q[2][1][0]`, respectively; all the rest are zero. The initializer for `q[0][0]` does not begin with a left brace, so up to six items from the current list may be used. There is only one, so the values for the remaining five elements are initialized with zero. Likewise, the initializers for `q[1][0]` and `q[2][0]` do not begin with a left brace, so each uses up to six items, initializing their respective two-dimensional subaggregates. If there had been more than six items in any of the lists, a diagnostic message would have been issued. The same initialization result could have been achieved by:

```
short q[4][3][2] = {
        1, 0, 0, 0, 0, 0,
        2, 3, 0, 0, 0, 0,
        4, 5, 6
};
```

or by:

```
short q[4][3][2] = {
        {
                { 1 },
        },
        {
                { 2, 3 },
        },
        {
                { 4, 5 },
                { 6 },
        }
};
```

in a fully bracketed form.

Note that the fully bracketed and minimally bracketed forms of initialization are, in general, less likely to cause confusion.

Coding Guidelines

designator list 1673
current object

The use of braces to delimit designator lists reduces the probability that changes to the size of any array will cause a fault to be generated (because the change is not reflected in the number of initializer values needed).

Developers are familiar with non-initialized elements implicitly being assigned a value of zero. Explicitly specifying trailing zeros in a designator list requires effort from readers to visually process them.

1699 EXAMPLE 7

One form of initialization that completes array types involves typedef names. Given the declaration

```
typedef int A[];        // OK - declared with block scope
```

the declaration

```
A a = { 1, 2 }, b = { 3, 4, 5 };
```

is identical to

```
int a[] = { 1, 2 }, b[] = { 3, 4, 5 };
```

due to the rules for incomplete types.

Commentary

An example similar to this was submitted as DR #010 against the C90 Standard.

C++

The C++ Standard does not explicitly specify this behavior.

1700 EXAMPLE 8 The declaration

EXAMPLE
array initialization

```
char s[] = "abc", t[3] = "abc";
```

defines "plain" **char** array objects **s** and **t** whose elements are initialized with character string literals. This declaration is identical to

```
char s[] = { 'a', 'b', 'c', '\0' },
     t[] = { 'a', 'b', 'c' };
```

The contents of the arrays are modifiable. On the other hand, the declaration

```
char *p = "abc";
```

defines **p** with type "pointer to **char**" and initializes it to point to an object with type "array of **char**" with length 4 whose elements are initialized with a character string literal. If an attempt is made to use **p** to modify the contents of the array, the behavior is undefined.

Commentary

Initialization is a context where the implicit conversion of an array type to a pointer to its first element is dependent on the type of the object it initializes.

729 array converted to pointer

C++

The initializer used in the declaration of `t` would cause a C++ translator to issue a diagnostic. It is not equivalent to the alternative, C, form given below it.

Other Languages

A few languages (e.g., Pascal, provided the, stronger, type compatibility rules are met) allow strings to be assigned to an object having an array of character type.

Coding Guidelines

The issues associated with using a string literal to represent a sequence of character constants are discussed elsewhere.

1664 initialize array of char

1701 EXAMPLE 9 Arrays can be initialized to correspond to the elements of an enumeration by using designators:

```
enum { member_one, member_two };
const char *nm[] = {
        [member_two] = "member two",
        [member_one] = "member one",
};
```

Commentary

The only type associations created by this usage exist in the readers head.

C90

Support for designators is new in C99.

C++

Support for designators is new in C99 and they are not specified in the C++ Standard.

Other Languages

Languages in the Pascal family allow the type of the indexing expression to be specified in the array type declaration. For instance:

```
1  TYPE
2        member_enum = (member_one, member_two);
3  VAR
4        nm[] : Array[member_enum] of char;
```

Coding Guidelines

initialization 1670 no designator member ordering

The issue of the order of designators used in member initialization is discussed elsewhere.

EXAMPLE div_t

EXAMPLE 10 Structure members can be initialized to nonzero values without depending on their order: 1702

```
div_t answer = { .quot = 2, .rem = -1 };
```

Commentary

Use of designators in this way removes the dependency between the order of values in an initializer and the order of members in a structure (which in the case of `div_t` is not specified).

C90

Support for designators is new in C99.

C++

Support for designators is new in C99 and they are not specified in the C++ Standard.

Coding Guidelines

initialization 1670 no designator member ordering

The issue of member initialization order is discussed elsewhere.

EXAMPLE designators with inconsistently brackets

EXAMPLE 11 Designators can be used to provide explicit initialization when unadorned initializer lists might be misunderstood: 1703

```
struct { int a[3], b; } w[] =
       { [0].a = {1}, [1].a[0] = 2 };
```

Commentary

EXAMPLE 1696 inconsistently bracketed initialization

Initializers for an object having this type are discussed elsewhere.

C90

Support for designators is new in C99.

C++

Support for designators is new in C99 and they are not specified in the C++ Standard.

EXAMPLE overriding values

EXAMPLE 12 Space can be “allocated” from both ends of an array by using a single designator: 1704

```
int a[MAX] = {
       1, 3, 5, 7, 9, [MAX-5] = 8, 6, 4, 2, 0
};
```

In the above, if **`MAX`** is greater than ten, there will be some zero-valued elements in the middle; if it is less than ten, some of the values provided by the first five initializers will be overridden by the second five.

Commentary

A MAX value of less than five would be a constraint violation.

1642 initializer value not contained in object

C90

Support for designators is new in C99.

C++

Support for designators is new in C99 and they are not specified in the C++ Standard.

Coding Guidelines

The discussion on initialization list order is applicable here.

1676 initialization in list order

1705 EXAMPLE 13 Any member of a union can be initialized:

```
union { /* ... */ } u = { .any_member = 42 };
```

Commentary

This form of initialization has the benefit that it is not dependent on the relative ordering of members within the union.

C90

Support for designators is new in C99.

C++

Support for designators is new in C99 and they are not specified in the C++ Standard.

1706 **Forward references:** common definitions **<stddef.h>** (7.17).

6.8 Statements and blocks

---

statement syntax

1707

statement:
labeled-statement
compound-statement
expression-statement
selection-statement
iteration-statement
jump-statement

Commentary

A statement is the basic unit of executable code. The term *statement header* is sometimes used to refer to the keyword (e.g., **if**, **for**) and the immediately following sequence of tokens between, and including, parentheses in a *selection-statement* or *iteration-statement*.

statement header

C++

In C++ local declarations are classified as statements (6p1). They are called *declaration statements* and their syntax nonterminal is *declaration-statement*.

Other Languages

Imperative languages use statements to specify a programs execution time control flow, while *functional* languages use expressions. Other language families use fundamentally different building blocks, for instance *Logic*, or *constraint-based* languages specify relationships and a program *execution* is an attempt to find values that meet these relationships.

Common Implementations

A number of implementations[42, 476, 515, 1314] have added extensions that provide support for either concurrent execution of groups of statements, or parallel operations on arrays of values. These extensions tend to be very dependent on particular hardware implementations (whose architecture is usually driven by the kinds of problems they have been designed to solve) and no single model of concurrency, or parallel execution, has achieved a significant market share (compared to the others).

Coding Guidelines

The discussion in the following two subsections is based on drawing a parallel between natural language sentences and source code statements (i.e., statements are the sentences of a programs source code; sequences of them are used to create a compound statement (paragraph) and sequences of these used to build a function definition, a subsection).[1707.1] The reason for drawing this parallel is the desire to make use of some of the findings from research on human sentence processing (there being no equivalent studies performed on source code statements). The following is a broad summary of these findings:

compound statement 1729 syntax
function definition 1821 syntax

- Over short time periods the syntax of what is read (i.e., words) is remembered, while over longer periods of time only the semantics (i.e., the meaning; which may differ between readers because of integration into their personal world model) is remembered.
- The measure of a persons working memory capacity that has the highest correlation with their performance in reading comprehension tasks is the reading span test.

reading span 1707

- The closer previously obtained information is (i.e., the more recently the sentence containing it was read) to the point it is referenced, the higher the probability that readers will correctly integrate it into the information extracted from what they are currently reading.

What is remembered

Having read a sentence, what does the reader remember about it? Studies[152] have found that over short time periods the syntax (i.e., words) is remembered, while over longer periods of time only the semantics (i.e., the meaning) is remembered. Readers might like to try the following test (based on Jenkins[666]). Part 1: A line at a time, (1) read the sentence on the left, (2) look away and count to five, (3) answer the question on the right, and (4) repeat process for the next line.

```
The girl broke the window on the porch.                    Broke what?
The hill was steep.                                        What as?
The cat, running from the barking dog, jumped on the table.  From what?
The tree was tall.                                         Was what?
The old car climbed the hill.                              What did?
The cat running from the dog jumped on the table.          Where?
The girl who lives next door broke the window on the porch.  Lives where?
The car pulled the trailer.                                Did what?
The scared cat was running from the barking dog.           What was?
The girl lives next door.                                  Who does?
The tree shaded the man who was smoking his pipe.          What did?
The scared cat jumped on the table.                        What did?
The girl who lives next door broke the large window.       Broke what?
The man was smoking his pipe.                              Who was?
The old car climbed the steep hill.                        The what?
The large window was on the porch.                         Where?
The tall tree was in the front yard.                       What was?
```

[1707.1] In practice a better parallel might be between statements and the *intonation units* commonly used in spontaneous spoken speech. Individual statements often contain a single piece of information and need to be considered in association with other statements, much like speech e.g., "hey . . . ya know that guy John . . . down the poolhall . . . he bought a Harley . . . if you can believe that.".

The car pulling the trailer climbed the steep hill.	Did what?
The cat jumped on the table.	Where?
The tall tree in the front yard shaded the man.	Did what?
The car pulling the trailer climbed the hill.	Which car?
The dog was barking.	Was what?
The window was large.	What was?

You have now completed part 1. Please do something else for a minute or so, before moving on to part 2 (which immediately follows).

Part 2: when performing this part, do not look at the sentences from part 1 above. Now, a line at a time, (1) read the sentence on the left, (2) if you think that sentence appeared as a sentence in part 1 write a number between one and five expressing your confidence (one expressing very little confidence and five expressive a lot of confidence in the decision) next to *old*, otherwise write a number representing your confidence level next to *new*, and (3) repeat process for the next line.

The car climbed the hill.	old___, new ___
The girl who lives next door broke the window.	old___, new ___
The old man who was smoking his pipe climbed the steep hill.	old___, new ___
The tree was in the front yard.	old___, new ___
The window was on the porch.	old___, new ___
The barking dog jumped on the old car in the front yard.	old___, new ___
The cat was running from the dog.	old___, new ___
The old car pulled the trailer.	old___, new ___
The tall tree in the front yard shaded the old car.	old___, new ___
The scared cat was running from the dog.	old___, new ___
The old car, pulling the trailer, climbed the hill.	old___, new ___
The girl who lives next door broke the large window on the porch.	old___, new ___
The tall tree shaded the man.	old___, new ___
The cat was running from the barking dog.	old___, new ___
The cat was old.	old___, new ___
The girl broke the large window.	old___, new ___
The car climbed the steep hill.	old___, new ___
The man who lives next door broke the window.	old___, new ___
The cat was scared.	old___, new ___

You have now completed part 2. Count the number of sentences you judged to be *old*.

The surprise is that all of the sentences are new.

While reading you abstracted and remembered the general ideas contained in the sentences (they are based on the four *idea sets*, (1) “The scared cat running from the barking dog jumped on the table.”, (2) “The old car pulling the trailer climbed the steep hill.”, (3) “The tall tree in the front yard shaded the man who was smoking his pipe.”, and (4) “The girl who lives next door broke the large window on the porch.”).

In a study by Bransford and Franks[152] each idea unit was broken down into sentences containing single ideas (e.g., “The cat was scared.”), two ideas (e.g., “The scared cat jumped on the table.”), three ideas (e.g., “The scared cat was running from the dog.”), and four ideas (e.g., “The scared cat running from the barking dog jumped on the table.”). The results (see Figure 1707.1) show that the greater the number of ideas units included in a sentence, the greater a subjects confidence that the sentence was previously seen (independently of whether it had been).

The issue of what people remember about what they have previously read is discussed in more detail elsewhere. 1821 function definition syntax

Processing single sentences

Individual sentence complexity[225] has a variety of effects on human performance. A study by Kintsch and Keenan[735] asked subjects to read single sentences, each containing the same number of words, but

propositional form

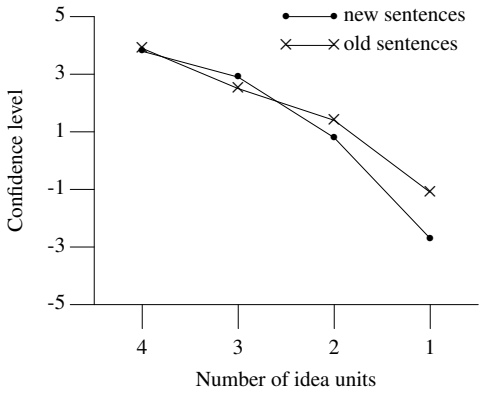

Figure 1707.1: Subject confidence level for having previously seen a sentence containing different numbers of idea units. Based on Bransford and Franks.[152]

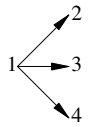
Romulus, the legendary founder of Rome, took the women of the Sabine by force.

1 (took, Romulus, women, by force)
2 (found, Romulus, Rome)
3 (legendary, Romulus)
4 (Sabine, women)



Cleopatra's downfall lay in her foolish trust in the fickle political figures of the Roman world.

1 (because, α, β)
2 $\alpha \rightarrow$ (fell down, Cleopatra)
3 $\beta \rightarrow$ (trust, Cleopatra, figures)
4 (foolish, trust)
5 (fickle, figures)
6 (political, figures)
7 (part of, figures, world)
8 (Roman, world)

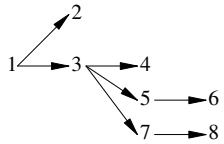


Figure 1707.2: Two sentences, one containing four and the other eight propositions, and their propositional analyses. Based on Kintsch and Keenan.[735]

varying in the number of propositions they contained (see Figure 1707.2). The time taken to read each sentence and recall it (immediately after reading it) was measured.

The results (see Figure 1707.3) show that reading rate decreases as the number of propositions in a sentence is increased (with the total number of words remaining the same). A later study[736] found that reader performance was also affected by the number of word concepts in a sentence and the grammatical form of the propositions (subordinate or superordinate).

Developers are often told to break up a complex statement or expression into several simpler ones. However, in many cases the quantity of interest is the comprehension cost of all of the code (it is possible that in some cases readers may only need to comprehend a subset of the simpler statements). It is therefore necessary to ask whether reader comprehension effort is minimized by having a single complex statement or having several simpler statements? While it is not yet possible to answer this question, some of the issues are known and the following subsection discusses the integration of information between related sentences.

statements integrating information between

Integrating information between sentences

This subsection discusses peoples performance in integrating information between (or across) sentences they have read. Developers need to integrated information from different source code statements, to obtain a

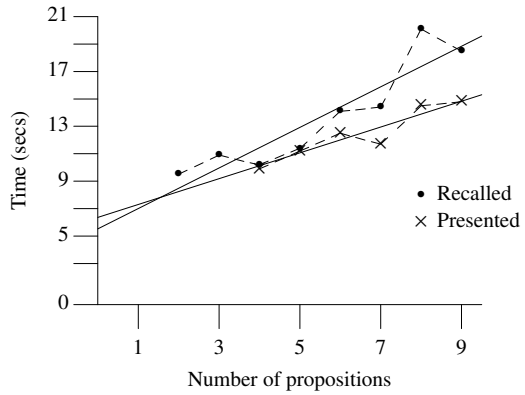

Figure 1707.3: Reading time (in seconds) and recall time for sentences containing different numbers of propositions (straight lines represent a least squares fit; for reading $t = 6.37 + .94P_{pres}$, and for recall $t = 5.53 + 1.48P_{rec}$). Adapted from Kintsch and Keenan.[735]

higher-level view of a programs behavior. It is assumed that the main factors affecting the performance of a reader of prose sentences are also the main factors, and in the same proportions, that affect the performance of readers of source code statements. The factors are working memory and the processing performed on the information it contains (see Just and Carpenter[697] for a capacity theory of comprehension).

The relative order in which a developer has to write many statements is dictated by dependencies between the operands they contain. However, there is often a degree of flexibility in the absolute order in which they occur. For instance, some developers initialize all locally declared objects at the start of a function, while others initialize them close to where they are used.

Although various theories of text comprehension have been proposed,[697, 734] it is not yet possible to give reliable answers to detailed questions. For instance, in the following three assignments, would moving the assignment to x after the assignment to y reduce the cognitive effort needed to comprehend the value of the expression assigned to z?

```
1  x = ex_1 + ex_2;            /* Could be reordered to follow assignment to y.   */
2  y = complicated_expression; /* Contains no dependencies on previous statement. */
3  z = y + ex_1;
```

Optimizing statement ordering, in those cases where some flexibility is available, to minimize reader cognitive effort when integrating information between statements requires that the relationships between all statements within a function be taken into account. For instance, ex_2 may also appear prior to the assignment to x and there may be a greater benefit to this assignment appearing close to this usage, rather than close to the assignment to z.

Because there is no method of measuring adherence, no guideline recommendation, dealing with statement ordering, is given here.

reading span
0 memory
developer

A study by Daneman and Carpenter[313] investigated the connection between various measures of subjects working memory span and their performance on a reading comprehension task. The two measures of working memory used were the *reading span* and *word span*. In the reading span test subjects have to read, out loud, sequences of sentences while remembering the last word of each sentence, which have to be recalled at the end of the sequence. The number of sentences in each sequence is increased until subjects are unable to successfully recall all the last words. The word span measure is a variant of the digit span test discussed elsewhere, using words rather than digits.

0 memory
digit span

In the Daneman and Carpenter study the reading comprehension task involved subjects reading a narrative passage containing approximately 140 words and then answering questions about facts and events described in the passage. Various passages were constructed, where the distance between information needed to answer

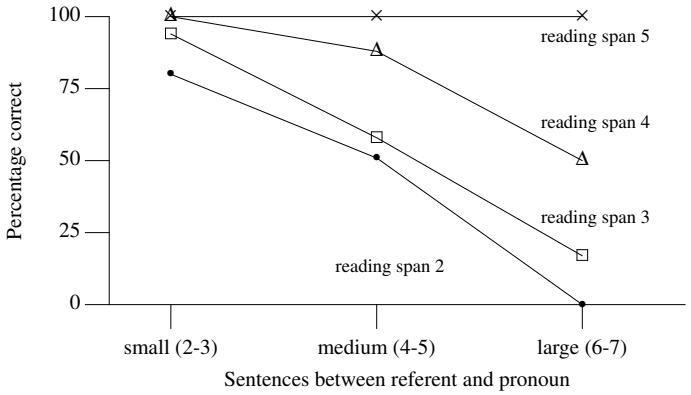

Figure 1707.4: Percentage of correct subject responses to the pronoun reference questions as a function of the number of sentences between the pronoun and the referent noun. Plotted lines are various subject reading spans. Adapted from Daneman and Carpenter.[313]

some of the questions was varied. For instance, the final sentence of the passage contained a pronoun (e.g., she, her, he, him, or it) that referred to a noun occurring in a previous sentence. Different passages contained the referenced noun in either the second, third, fourth, fifth, sixth, or seventh sentence before the last sentence.

In the excerpt: " . . . river clearing . . . The proceedings were delayed because the leopard had not shown up yet. There was much speculation as to the reason for this midnight alarm. Finally he arrived and the meeting could commence." the question "Who finally arrived?" refers to information contained in the last and third to last sentence. The question "Where was the meeting held?" requires the recall of a fact.

The results showed that there was little correlation between a subjects performance in the word span test and the reading comprehension test. However, there was a strong correlation between their performance in the reading span test and the reading comprehension test (see Figure 1707.4). A similar pattern of results was obtained when the task involved listening, rather than reading. A second experiment included controls to ensure that subjects processed the sentences in the reading span test (rather than simply looking for and remembering the last word) and that differences in rate of reading were not a factor. The pattern of results was unchanged. A study by Turner and Engle[1371] found that having subjects verify simple arithmetic identities, rather than a reading comprehension test, did not alter the results. However, altering the difficulty of the background task (e.g., using sentences that required more effort to comprehend) reduced performance.

The difference between word span and reading span as measures of working memory is that the first is purely a measure of memory usage while the second also involves processing information (the extent to which processing information consumes, interferes with, or competes with working memory resources is a hotly debated issue). Comprehension of prose involves integrating information within and between sentences. Other studies have found that reading span correlates with performance in a number other tasks, including:

- A study by Daneman and Carpenter[314] investigated subjects performance in integrating information within a single sentence and across two sentences. For instance, is there a difference in comprehension performance between the sentence "There is a sewer near our home who makes terrific suits" (this is an example of what is known as a *garden path* sentence) and "There is a sewer near our home. He makes terrific suits"? The results (see Figure 1707.5) show that a sentence boundary can affect comprehension performance. It was proposed that this difference in performance was caused by readers purging any verbatim information they held, in working memory, about a sentence on reaching its end. The availability of previously read words, in the single sentence case, making it easier to change the interpretation made on the basis of what has already been read.
- There are a number of structural components involved in the reading of prose. For instance, at the microstructure level words are formed from character sequences and syntactic processing of words

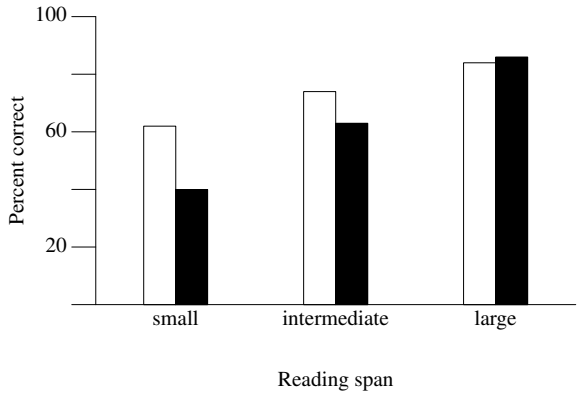

Figure 1707.5: Percentage of correct answers as a function of subject's reading span and the presence or absence of a sentence boundary. Adapted from Daneman and Carpenter.[314]

occurs, while at the macrostructure level information has to be integrated across sentences and the narrative has to be followed. A study by Graesser, Hoffman, and Clark[510] found that (1) more cognitive resources are allocated to macrostructure than microstructure processing, (2) differences in reading speed could be attributed to different rates of microstructure processing, and (3) variations in reader goals affect the rate at which the macrostructure is processed.

- A study by Glanzer, Fischer, and Dorfman[495] investigated the affects an interruption had on subjects performance, when reading prose. The results showed that when reading organized text (a sequence of sentences having dependencies between them) an interruption (requiring a different task to be performed) caused information on the last two sentences to be lost from working memory. This loss of information caused a reduced subjects performance in reading the remaining sentences (unless they were able to reread the previous two sentences). An interruption did not cause a reduction in performance when the sentences were not organized (i.e., they were not related to each other).
- A study by Gibson and Thomas[486] found that subjects were likely to perceive complex ungrammatical sentences as being grammatical. Subjects handling complex sentence that exceeded working memory capacity by *forgetting* parts of the syntactic structure of the sentence, resulting in a grammatically correct sentence.
- Text inference often involve more than integrating information between sentences. Knowledge about the real world is often required. A study by Singer and Ritchot[1245] showed subjects pairs of sentences and asked them to answer questions about inferences that could be drawn from these sentences. For instance, the two sentences "Valerie left early for the birthday party. She spent an hour shopping in the mall." would be expected to activate reader's knowledge of bringing birthday presents to parties, while the sentences "Valerie left the birthday party early. She spent an hour shopping in the mall." would not be expected to activate such knowledge. The results showed that there was no correlation between reading span and knowledge access when making such bridging inferences. The result of this study implies that while reading span provides a good measure of a person's ability to integrate information between sentences, it does not provide a measure of their ability to integrate information they have just read with information held in long-term memory.

A study by Ehrlich and Johnson-Laird[380] asked subjects to draw diagrams depicting the spatial layout of everyday items specified by a sequence of sentences. The sentences varied in the extent to which an item appearing as the object (or subject, or not at all) in one sentence appeared as the subject (or object, or not at all) in the immediately following sentence. For instance, there is referential continuity in the sentence sequence "The knife is in front of the pot. The pot is on the left of the glass. The glass is behind the dish.",

but not in the sequence "The knife is in front of the pot. The glass is behind the dish. The pot is on the left of the glass.".

The results found that when the items in the sentence sequences had referential continuity 57% of the diagrams were correct, compared to 33% when there was no continuity. Most of the errors for the non-continuity sentences were items missing from the diagram drawn and subjects reported finding it difficult to remember the items as well as the relation between them.

A study by Frase[446] found that the kind of deduction subjects had to perform (e.g., forward to backward chaining) also affects their performance. For instance, verifying the correctness of the deduction in "Some X are Y. Some Z are X. Therefore, some Z are Y." requires forward chaining, while verification of "Some Y are X. Some X are Z. Therefore, some Z are Y." requires backward chaining. The results showed that subjects were slower and more error prone when performing backward chaining.

statement visual layout

Visual layout of statements

Source code statements are generally written one per line, a practice that is different from prose sentences (which generally appear as a continuous stream of characters, with one sentence immediately following another on the same line, with line breaks decided by the space available for the next word). Statements are usually indented on the left to show block nesting level (this issue is discussed elsewhere).

reading 770 kinds of visual 792 skimming

```
1  #include <string.h>
2  #define v1 13
3  #define v2 0
4  #define v3 1
5  int v4(char v5[], int *v6) { int v7, v8; *v6=v2; v8=strlen(v5); if
6  (v8 > v1) { *v6=v3; } else { for (v7=0; v7 < v8; v7++) { if ((v5[v7]
7  < '0') || (v5[v7] > '9')) { *v6=v3; } } } }
```

The two cases discussed here are the practice of writing two or more statements on the same line and what to do when a statement will not fit on a single line. These cases are only issues that need discussion because source is not always read in detail, it is sometimes rapidly scanned visually. During rapid visual scanning of the source its left edge is often used as a reference point for the start of individual statements. This usage suggests the following:

reading 770 kinds of

- If multiple statements appears on the same line, readers using rapid visual scanning may only the first one may be noticed. For this reason some coding guideline documents recommend that a line contain at most one statement. However, there can be benefits to placing more than one statement on the same line. For instance, in the following fragment assigns values representing the four corners of a square:

  ```
  1  x1=1.0; y1=4.0; x2=3.0; y2=4.0;
  2  x3=1.0; y3=2.0; x4=3.0; y4=2.0;
  ```

  and the layout of the statements is suggestive of what they represent (other combinations are possible), and has the possibly benefits of reducing comprehension effort and being able to have more statements simultaneously visible on the screen. These benefits need to be balanced against the potential cost of readers failing to notice the assignment to other objects on the same line. Within a **`switch`** statement some of the labeled statements may only perform a single operation. It is possible to visually highlight this operation and contrast it with operations performed by other labeled statements by placing the *uninteresting* termination statement to the right of the statement, rather than underneath it.

  ```
  1  case 1: i--;            break;
  2  case 2: k++;            break;
  3  case 3: ++expr;ssion--; return;
  4  case 4: func();         break;
  ```

  These benefit need to be balanced against the potential cost of readers failing to notice a difference in termination statements, or treating two statement as one statement. The following guideline recommendation allows for some degree of flexibility.

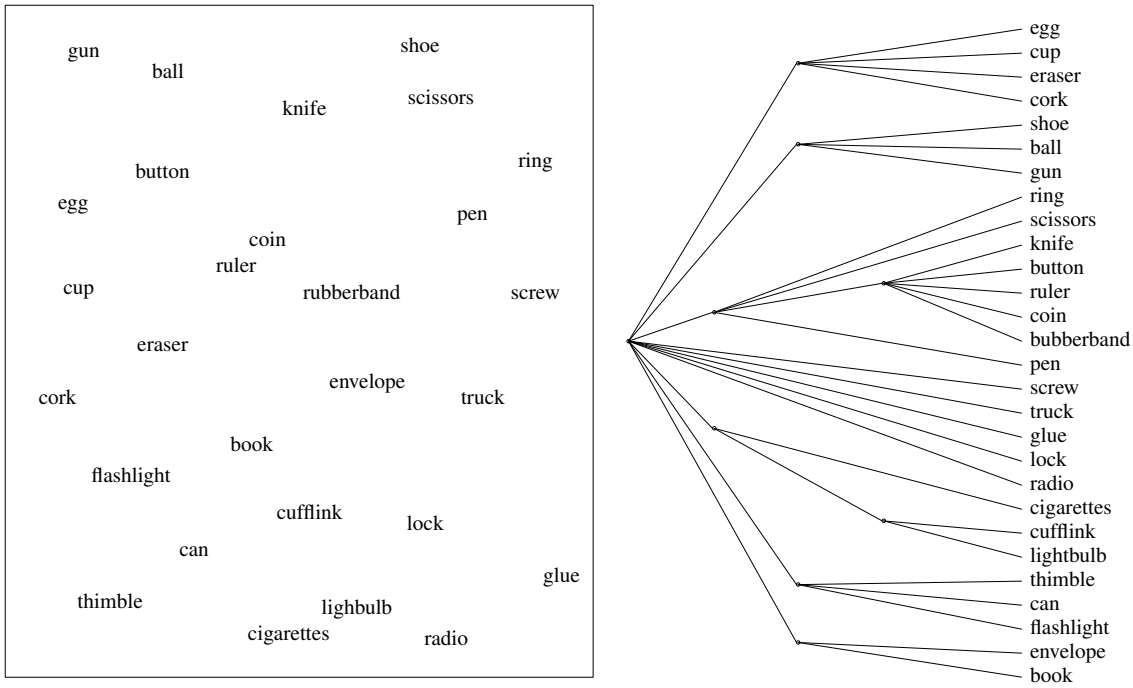

Figure 1707.6: Example of an object layout and the corresponding ordered tree for one of the subjects. Based on McNamara, Hardy, and Hirtle.[923]

Rev 1707.1

Multiple statements shall only appear on the same line, in a visible form, when the probable reduction in reader comprehension costs is greater than the probable increase in costs caused by mistakes made when quickly scanning the source visually.

- Readers are likely to treat the start of every line that appears immediately above or below adjacent lines, in a sequence of statements, as the start of a different statement. One way of reducing this possibility is to use a significant amount of right indentation on the second and subsequent lines relative to the start of the first line (which is what developers appear to do).

grouping
spatial location

Studies have found that peoples memory for objects within their visual field of view is organized according to the relative positions of those objects. For instance, a study by McNamara, Hardy, and Hirtle[923] gave subjects two minutes to memorize the location of objects on the floor of a room (see Figure 1707.6). The objects were then placed in a box and subjects were asked to place the objects in their original position. The memorize/recall cycle was repeated, using the same layout, until the subject could place all objects in their correct position.

The order in which each subject recalled the location of objects was used to create a hierarchical tree (one for each subject). The resulting trees (see Figure 1707.6 for an example) showed how subjects' spatial memory of the objects seen had a hierarchical organization, with the spatial distance between items being a significant factor in its structure.

Source code statements usually have a one-dimensional organization, down the display (indentation does not change the one-dimensional organization; multiple statements on the same line is not really fully two-dimensional).

If developer memory of statement sequences is hierarchical, with visual distance between statements being a significant factor in the formation of clusters, then ordering statements so that related ones are close to each

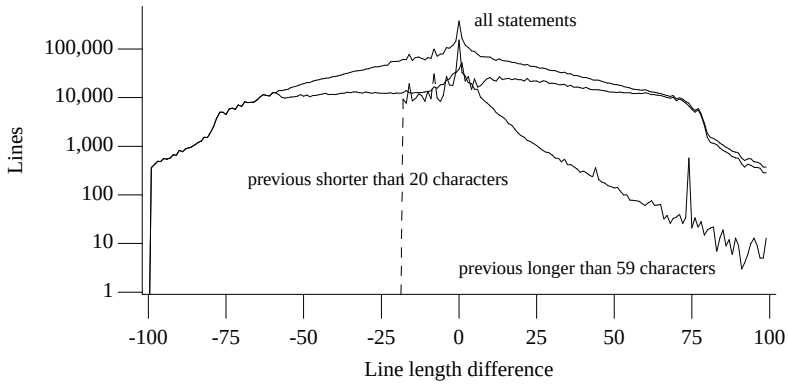

Figure 1707.7: Visible difference in offset of last non-space character on a line between successive lines, in the visible form of the `.c` files (horizontal tab characters were mapped to 8 space characters), for lines of various lengths, i.e., those whose previous line contained 60 or more characters, and those whose previous line contains less than 20 characters. There are ten times fewer lines sharing the same right offset as sharing the same left offset (see Figure 1707.8). Based on the visible form of the `.c` files.

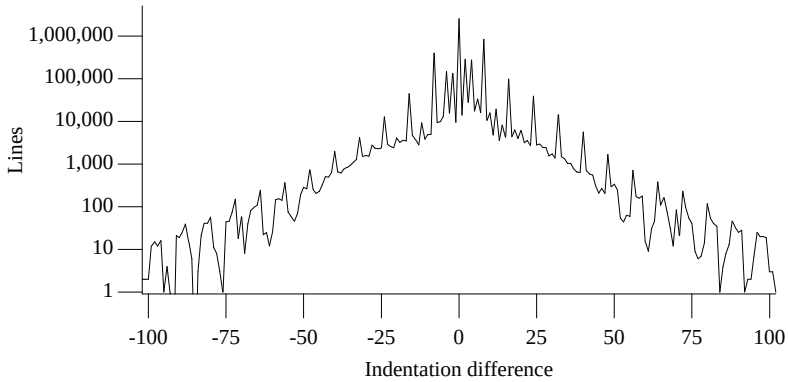

Figure 1707.8: Visible difference in relative indentation of first non-space character on a line between successive lines in the visible form of the `.c` files (horizontal tab characters were mapped to 8 space characters). The smaller peaks around zero are indentation differences of two characters. The wider spaced peaks have a separation of eight characters. Individual files had more pronounced peaks. Based on the visible form of the `.c` files.

other may improve recall performance. The extent to which statements can be reordered will depend on the relative order in which their side effects must occur.

metrics introduction 0

Many software engineering metrics use statements as the unit of measurement.

Usage

Of the approximately 2,204,000 statements in the visible form of the `.c` files 60.3% were *`expression-statement`*s, 21.3% *`selection-statement`*s, 15.0% *`jump-statement`*s, and 3.4% *`iteration-statement`*s. Of these 5.4% were *`labeled-statement`*s.

Semantics

---

statement

A *`statement`* specifies an action to be performed. 1708

Commentary

This defines the term *statement*. This definition might also be said to include those declarations that include initializers. However, *`statement`* is also a terminal of the C syntax. Like declarations, statements can also cause identifiers to be declared (e.g., the type of a cast operator). So the two do share some characteristics. In the case of the null statement no action is performed.

null statement 1733

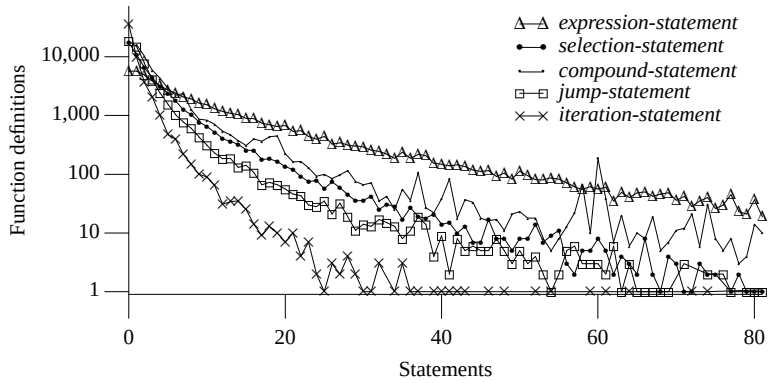

Figure 1707.9: Number of function definitions containing a given number of each kind of statement. Based on the translated form of this book's benchmark programs.

C++

The C++ Standard does not make this observation.

Other Languages

Some languages do not define things called *statement*s, everything is an expression. While other languages do define them, and always allow them to return values, just like C expressions. Programs written in logic programming languages (e.g., Prolog) contain a list of facts, not statements, to execute. The user of such programs states a goal and the implementation attempts to prove, or disprove it, using the available facts.

Coding Guidelines

It is possible to write statements whose action, when performed, does not affect the output of a program. This issue is discussed elsewhere. A sequence of one or more statements whose actions can never be performed is commonly known as *dead code*.

190 redundant code
190 dead code

1709 Except as indicated, statements are executed in sequence.

statement executed in sequence

Commentary

The sequence referred to here is that obtained by starting with the first token in a source file and parsing to the end of that file. The exceptions are caused by statements which change the flow of control, causing a statement at the start of another sequence to be executed. The terms *order of execution*, or *execution order* are sometimes used to describe the order in which statement sequences are executed. This specification has been interpreted as having a wider meaning by the C committee (see the response to DR #087). It is taken to imply that the execution of two functions cannot overlap (i.e., occur in parallel). For instance, in the expression `g() + h()` one of the functions is chosen to be executed and that function must execute a **`return`** statement before the other function can start execution.

Performing the actions specified by statements is what most programs spend most of their time doing (issues such as idling, waiting for an I/O to complete, and system resource management, such as page swapping, are not considered here). In some applications it is important to be able to make accurate estimates of the time needed to execute a given sequence of statements. For instance, in realtime applications there may be a fixed time window within which certain calculations must be carried out, either because new data is arriving or the result of the calculation is needed.

Accurately estimating the best and worst-case execution times (*BCET* and *WCET*) of a statement is not always as simple as summing the execution times of the sequence of machine instructions generated for that statement. Issues such as instruction pipelining, caching of data and instructions, and dependencies between instructions (that create interlocks) all complicate the calculation. Various tools have been developed for estimating the worst-case execution time of C source code. Engblom[391] reviews the available techniques

0 processor pipeline
0 cache

iteration statement 1763 syntax

and proposes worst-case execution time analysis method. The subproblem of estimating the number of iterations of a loop is discussed elsewhere.

Other Languages

Some languages (e.g., Algol 68) contain constructs that allow developers to specify that certain statements may be executed in parallel. Other languages (e.g., Java) support threads of execution where the function is the smallest unit of concurrent execution.

Common Implementations

Translators that perform little or no optimization usually generate machine code on a statement by statement basis. This severely restricts the savings that can be made and considering sequences of statements provides an opportunity to make greater savings (the actual unit considered is usually a basic block). The OpenMP C++ API specification[42] defines directives that can be included in source code to support symmetric multiprocessing (SMP).

basic block 1710

```
1  int f(void)
2  {
3  /* ... */
4     #pragma omp parallel
5     {
6     /*
7      * Code in this block potentially executed
8      * in another processor thread.
9      */
10    }
11 /* ... */
12 }
```

---

block

A *block* allows a set of declarations and statements to be grouped into one syntactic unit. 1710

Commentary

This defines the term *block*. The term *compound statement* and its association with block is discussed elsewhere. In various contexts a block might exist without there being a compound statement present.

compound statement 1729 syntax

block 1742 selection sub-statement

C90

A compound statement (also called a block) allows a set of statements to be grouped into one syntactic unit, which may have its own set of declarations and initializations (as discussed in 6.1.2.4).

compound statement 1729 syntax

The term *block* includes compound statements and other constructs, that need not be enclosed in braces, in C99. The differences associated with these constructs is called out in the sentences in which they occur.

C++

The C++ Standard does not make this observation.

Common Implementations

basic block

The term *basic block* is often used by compiler writers to refer to a sequence of instructions that has one entry point and one exit point. The basic block is often the region of code over which many optimizers operate. More sophisticated optimizers consider the effects of multiple basic blocks. A block may also be a basic block, but if it contains any statements or operators that have conditional flow of control it will be a sequence of basic blocks. The implementation of C operators such as function call, logical-AND, and the comma operator all terminate one basic block and start another; as do the statements **`goto`** and **`return`** and labeled statements.

Table 1710.1: Occurrence of constructs that terminated execution of a basic block during execution of PostgreSQL processing the TPC-D benchmark. Adapted from Ramirez, Larriba-Pey, Navarro, Serrano, Torrellas, and Valero.[1141]

Basic Block Type	Static Count (thousand)	Dynamic Count (billion)
Branch	54.026 (42.4%)	4.0 (50.2%)
Fall-through	31.120 (24.4%)	1.8 (22.4%)
Function return	32.052 (25.2%)	1.1 (13.7%)
Function call	10.228 (8 %)	1.1 (13.7%)

Writers of translators and processor designers want the average number of machine instructions executed in a basic block to be as large as possible. For translators long sequences of code with continuous flow of control increases the probability of common subexpressions occurring and the consequent reuse, rather than recalculation, of values. For processors large basic blocks enable them to keep their pipelines full, minimizing average instruction execution time. Function inlining can remove one of the constructs that cause basic blocks to end, function calls (see Table 1710.1), increasing the length of some basic blocks. Table 1710.2 lists average basic block lengths for some complete programs. The special case of iteration statements is discussed elsewhere.

0 processor pipeline
1529 inline suggests fast calls
1774 for statement

Table 1710.2: Mean number of machine instructions executed per basic block (i.e., total number of instructions executed in a function divided by the total number of basic blocks executed in that function) for a variety of SPEC benchmark programs. *Leaf* refers to functions that do not call any other functions, while *Non-Leaf* refers to functions that contain calls to other functions. Based on Calder, Grunwald, and Zorn.[192]

Program	Leaf	Non-Leaf	Program	Leaf	Non-Leaf
burg	6.8	4.9	eqntott	9.1	5.4
ditroff	6.8	4.7	espresso	5.0	5.1
tex	10.4	8.5	gcc	5.2	5.7
xfig	4.8	5.3	li	2.9	5.7
xtex	7.3	5.8	sc	3.5	4.2
compress	18.4	5.7	Mean	7.3	5.5

Just as optimizers moved up from working at the single statement level, they eventually moved up from working at the single basic block level (the issue of whole function optimization is discussed elsewhere). Translator output (machine code) for each block often occurs in the program image in the same sequential order as the basic blocks in the source code. However, processors can have a number of characteristics that can cause this ordering to be sub-optimal, including:

1821 function definition syntax

- *Span dependent branch instructions.* This issue is discussed elsewhere.
- *Instruction caches.* The size of a function or basic block, the total size of the cache and the size of a cache line all need to be considered when working out the optimal layout of instruction sequences in memory.[547]
- *Instruction pipelines*. Basic blocks can be reordered to ensure that they start on alignments best suited to a processor.[1495]
- *Storage organized in fixed sized pages.* Having infrequently executed instructions in the same page as frequently executed instructions can increase execution overheads (through increased swapping of pages). Storing infrequently executed instructions together in different pages can increase overall performance (the overhead of the extra instruction to jump back, at the end of an else arm, is offset by the removal of the instruction that would otherwise be needed, in the if arm, to jump around the else).

1783 jump statement causes jump to
0 cache
0 processor pipeline
1710 basic block
0 storage dividing up

The memory manager prefetches sequences of instructions to fill a complete cache line. Optimal use of this prefetching occurs if all instructions in a cache line are executed. In the example below, whichever arm of the **`if`** statement is executed, it is likely that some instructions from the non-executed arm will be fetched into a cache line.

```
if (x == 2)
   {
   /* Frequently executed code. */
   }
else
   {
   /* Infrequently executed code. */
   }
/* other code */
```

If it is known (for instance, through dynamic profiling information[986]) that one of the arms is executed more frequently than the other, it may be worthwhile reordering basic blocks in the program image. One technique is to place infrequently executed blocks in an area of storage reserved for such cases. The generated code being rewritten to jump to the infrequent block, and back again (the rewritten form of the above example is in C form below). This reorganization is likely to result in a higher percentage of the instructions contained in a cache line being executed.

```
if (x != 2)
   goto INFREQ_15_s;

   {
   /* Frequently executed code. */
   }
INFREQ_15_e:
/* other code */

/* ... */
goto INFREQ_14_e;
INFREQ_15_s:
   {
   /* Infrequently executed code. */
   }
goto INFREQ_15_e;
INFREQ_16_s:
/* ... */
```

The major problem associated with optimizing code layout at translation time is that information on frequency of basic block execution usage is needed. Developers may be unwilling or unable to gather this information, or it may be very difficult to obtain reliable information because of different end user usage patterns.

One solution to this problem is to perform what has been called *just in time code layout*.[220] The usage patterns of an executing program were monitored to decide when it is worthwhile moving code within the executing program image, to improve the instruction cache hit rate. Performance results comparable to those obtained for profile based methods have been obtained for programs running under Unix, but results for programs running under Windows NT were mixed (as they were for profile based code layout).

As processor power and available storage capacity has increased, the ability to consider code layout from more global perspectives has become possible. At first researchers built translators that reordered statements within basic blocks, and then moved on to reordering basic blocks within individual functions.[9] The break has now been made with source level constructs and the latest code layout algorithms are based purely on frequency of basic block execution over the entire program[539] (the function definitions to which the basic blocks might be said to belong have become irrelevant).

Usage

limit 277
block nesting

Usage information on block nesting is discussed elsewhere.

object initializer evaluated when

The initializers of objects that have automatic storage duration, and the variable length array declarators of 1711

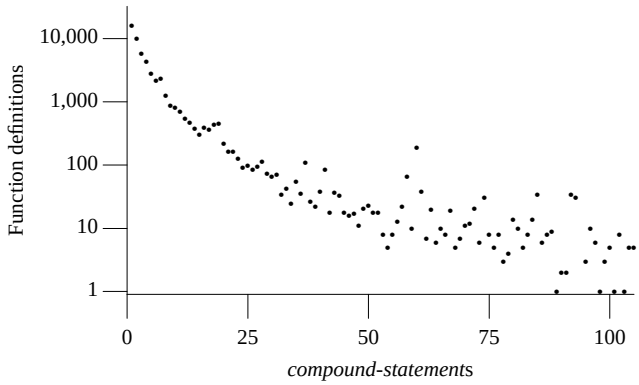

Figure 1710.1: Number of function definitions containing a given number of `compound-statement`s. Based on the translated form of this book's benchmark programs.

ordinary identifiers with block scope, are evaluated and the values are stored in the objects (including storing an indeterminate value in objects without an initializer) each time the declaration is reached in the order of execution, as if it were a statement, and within each declaration in the order that declarators appear.

Commentary

Both declarations and compound literals can create objects having automatic storage duration and an initializer. Storage for objects that have automatic storage duration, and non VLA type, will have been created at the start of their lifetime (when the block that declares them was entered). As well as performing initialization, the evaluation of a declaration for an object having a variable length array type also allocates storage for it.

457 automatic storage duration
464 VLA lifetime starts/ends

The indeterminate value stored in an object is a conceptual value in the sense that no pattern of bits need be stored in the object by an implementation (because no predictable behavior is required to occur, should this value be accessed).

75 indeterminate value

In one particular case, overlapping initializers, the evaluation of the initializers need not occur as if they were a sequence of assignment statements.

1676 initialization in list order

C90

Support for variable length array types is new in C99.

C++

Support for variable length array types is new in C99 and they are not specified in the C++ Standard.

Other Languages

This initialization behavior is found in the majority of programming languages (although many do not support the mixing of statements are declarations).

Common Implementations

The indeterminate value stored in an object may be affected by the initialization of other objects defined in the same block. For instance, if a several objects are initialized to the same value it may be more efficient to initialize a block of storage, which may include space allocated to uninitialized objects, using a loop rather than individual stores.

Coding Guidelines

The evaluation of variable length array declarators can generate side effects. However, because the expression appearing between **[** and **]** is not a full expression there is no sequence point after its evaluation (there is a sequence point at the end of the full declarator that contains it). For this reason the guideline given for the evaluation of full expressions is not applicable here. However, until the use of variable length arrays becomes more common and the ordering of side effects in their evaluation becomes an issue worth addressing a guideline recommendation is not cost effective.

1712 full expression
187 sequence points
1550 full declarator sequence point
187.1 sequence points all orderings give same value

```
#include <stdio.h>

int glob;

void f(void)
{
int
    /*
     * Unspecified order of evaluation of expressions in a full declarator.
     */
    a_1[printf("Hello ")][printf("world\n")],

    /*
     * Same object modified more than once between sequence
     * points -> undefined behavior.
     */
    a_2[glob++][glob++];
}
```

string literal 903
static storage duration

The extent to which developers might draw an, incorrect, parallel between a compound literal containing constant expressions only and string literals (which have static storage duration) is not known. One important difference is that any modification of the unnamed object, denoting the compound literal, will be overwritten when the original definition is executed again. Until more experience in developer use of compound literals has been gained there is no point in discussing this issue further.

Example

```
#include <stdio.h>

extern int glob;
struct T {
          int mem;
         };

void f(void)
{
int i = 0;

START_LOOP:
if (i == 10)
   goto END_LOOP;

i++;
   int      loc_1 = glob;
   struct T loc_2 = { 1 },             loc_3 = { glob },
           *ploc_a = (struct T){ 1 }, *ploc_b = (struct T){ glob };

            loc_1++;
            loc_2.mem++;               loc_3.mem++;
            ploc_a->mem++;             ploc_b->mem++;

goto START_LOOP;
END_LOOP:;

if (       (loc_1 != (glob+1))  ||
           (loc_2.mem != 1+1)   ||    (loc_3.mem != (glob+1)) ||
           (ploc_a->mem != 1+1) ||    (ploc_b->mem != (glob+1)))
   printf("This is not a conforming implementation\n");
}
```

1712 A *full expression* is an expression that is not part of another expression or of a declarator.

full expression

Commentary

281 parenthesized expression nesting levels

This defines the term *full expression*. While the term may only be used once outside of this C paragraph, it can be of use in disambiguating what is meant during conversations between developers. Developers often use the shorter term *expression*. However, this term might also be applied to individual arguments in a function call, or an array index. The terms *top-level expression* or *outer most expression* are sometimes used to refer to what the C Standard calls a full expression. A component of an expression is often referred to as a *subexpression*. An expression that is part of a declarator is included within the definition of a full declarator. 1549 full declarator

The subexpression `x+y` is said to be a *common subexpression* of `x+y + a[x+y]` (it may also be a CSE of other expressions, provided the values of `x` and `y` are unchanged).

common subexpression

C++

A full-expression is an expression that is not a subexpression of another expression. 1.9p12

The C++ Standard does not include declarators in the definition of a full expression. Source developed using a C++ translator may contain declarations whose behavior is undefined in C.

```
1  int i;
2
3  void f(void)
4  {
5  int a[i++][i++]; /* undefined behavior */
6                   // a sequence point between modifications to i
7  }
```

1713 Each of the following is a full expression:

Commentary

These are all of the contexts in which an expression, that needs to be evaluated during program execution, can occur.

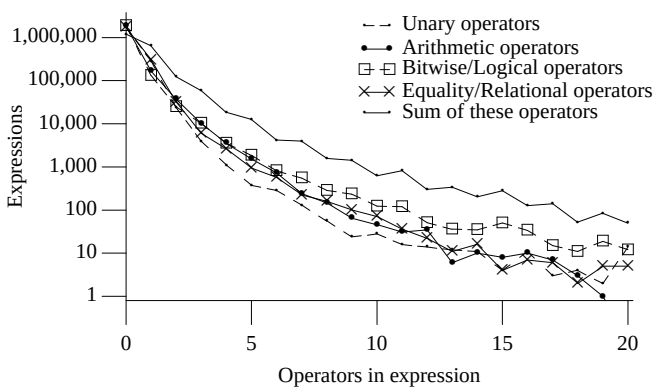

Figure 1712.1: Number of expressions containing a given number of various kinds of operator, plus a given number of all of these kinds of operators. Based on the visible form of the `.c` files.

C++

The C++ Standard does not enumerate the constructs that are full expressions.

Table 1713.1: Occurrence of full expressions in various contexts (as a percentage of all full expressions). Based on the translated form of this book's benchmark programs.

Context of Full Expression	Occurrence	Context of Full Expression	Occurrence
expression statement	65.9	**for** *expr-1*	1.6
if controlling expression	16.4	**for** controlling expression	1.5
return expression	6.2	**for** *clause-1*	1.5
object declaration initializer	4.2	**switch** controlling expression	0.6
while controlling expression	2.1		

---

full expression initializer

an initializer; 1714

Commentary

This is the complete expression appearing between braces, not the individual comma-separated expressions.

---

full expression expression statement

expression statement syntax 1731

the expression in an expression statement; 1715

Commentary

In an expression statement the entire statement is an expression.

C++

The following is not the same as saying that an expression statement is a full expression, but it shows the effect is the same:

6.2p1 *All side effects from an expression statement are completed before the next statement is executed.*

Other Languages

In many languages C's most common form of expression statement (i.e., simple assignment) consists of two expressions. These are the expressions appearing to the left and right of the assignment token, which are considered to be separate expressions.

---

full expression controlling expression

the controlling expression of a selection statement (**if** or **switch**); 1716

Commentary

This ensures consistent behavior for all control flows leading from the evaluation of the controlling expression. For instance, in the following sequence of statements:

```
1  if (i++)
2     j++;
3  k=i;
```

the value of `i` assigned to `k` does not depend on the sequence point contained within the arm of the **if** statement.

---

the controlling expression of a **while** or **do** statement; 1717

full expression controlling expression 1716

Commentary

The rationale here is the same as for selection statements.

---

each of the (optional) expressions of a **for** statement; 1718

Commentary

In C90 the semantics of the **for** statement were expressed in terms of an equivalent **while** statement. This equivalence required that each of the (optional) expressions be equivalent to a full expression.

1774 for statement

Other Languages

In many languages the expressions in a **for** statement are evaluated once, prior to the first iteration of the loop, every time the statement is encountered during program execution.

1719 the (optional) expression in a **return** statement.

return expression sequence point

Commentary

A sequence point occurs just before a function is called. Having one occur just before the called function returns allows the execution of a function call to be treated as an indivisible operation (from the point of view of the code containing the call).

1025 function call sequence point

1720 The end of a full expression is a sequence point.

full expression sequence point

Commentary

The order in which the sequence points at the end of full expressions occur is fully defined by a programs flow of control. Unlike the ordering of sequence points within a full expression (assuming there is more than one), which occur in one of several possible orderings.

187 sequence points

Coding Guidelines

The guideline recommendation dealing with sequence point evaluation ordering applies to sequence points within a full expression. The sequence point at the end of full expressions occurs in the same order for all implementations.

187.1 sequence points all orderings give same value

1721 **Forward references:** expression and null statements (6.8.3), selection statements (6.8.4), iteration statements (6.8.5), the **return** statement (6.8.6.4).

6.8.1 Labeled statements

1722

labeled statements syntax

labeled-statement:
identifier **:** *statement*
case *constant-expression* **:** *statement*
default **:** *statement*

Commentary

Rationale

Case ranges of the form, *lo .. hi*, were seriously considered, but ultimately not adopted in the Standard on the grounds that it added no new capability, just a problematic coding convenience. The construct seems to promise more than it could be mandated to deliver:

- A great deal of code or jump table space might be generated for an innocent-looking case range such as `0 .. 65535`.
- The range `'A' .. 'Z'` would specify all the integers between the character code for "upper-case-A" and that for "upper-case-Z". In some common character sets this range would include non-alphabetic characters, and in others it might not include all the alphabetic characters, especially in non-English character sets.

No serious consideration was given to making switch more structured, as in Pascal, out of fear of invalidating working code.

When source code oriented symbolic debuggers (i.e., the ability to refer to lines in the source) are not available labels are sometimes used as a means of associating a symbol with a known point in the code.

Other Languages

Some languages (e.g., Fortran and Pascal) require that labels be digit, rather than alphabetic, character sequences.

Languages in the Pascal family do not classify **case**, or any equivalent to **default**, as a label. They are usually defined as part of the syntax of the selection statement in which they appear. Ada intentionally[619] differentiates visually between statement labels and case labels. An identifier that is a statement label is required to appear between the tokens << and >>. Some languages use **else** or **otherwise** rather than **default** in their selection statements.

Common Implementations

Some implementations (e.g., `gcc` and Code Warrior[927]) support case ranges as an extension.

Coding Guidelines

Many coding guideline documents recommend against the use of **goto** statements. However, in the case of C language, prohibiting labels (except **case** and **default**) would be more encompassing. For instance, a mistyped label in a **switch** statement may turn it into another kind of label (e.g., misspelling **default**, `defolt` is often seen for non-English speakers, creates a different kind of label). The issues associated with the use of jump statements are discussed elsewhere.

jump statement 1782 syntax

Usage

In the translated form of this book's benchmark programs 2% of labels were not the destination of any **goto** statement. Usage information on **goto** statements is given elsewhere.

jump statement 1783 causes jump to

Table 1722.1: Percentage of function definitions containing a given number of labeled statements (other than a **case** or **default** label). Based on the visible form of the `.c` files.

Labels	% Functions	Labels	% Functions
1	3.5	3	0.3
2	0.9	4	0.1

Constraints

case label appear within switch

A **case** or **default** label shall appear only in a **switch** statement. 1723

Commentary

This constraint is necessary because these constructs are not distinguished syntactically from other kinds of labels.

Other Languages

In other languages these kinds of labels are usually distinguished in the language syntax.

Coding Guidelines

This constraint does not prohibit **case** or **default** labels occurring in a variety of potentially surprising, to a reader, contexts within a **switch** statement. For instance, within a nested compound statement.

```
1  extern int glob;
2
3  void f(int valu)
4  {
5  switch (valu)
6     {
7     case 0: if (glob == 3)
```

```
8                   {
9                   case 2: value--;
10                  }
11              break;
12      }
13  }
```

In practice this usage is rare. Some practical applications of this usage are discussed elsewhere. 1766 Duff's Device

---

1724 Further constraints on such labels are discussed under the **switch** statement.

Commentary

This is essentially a forward reference. 66 forward reference

---

1725 Label names shall be unique within a function. label name unique

Commentary

Label names have function scope, which means they are visible anywhere within the function definition that contains them. 404 scope function

C90

This wording occurred in Clause 6.1.2.1 Scope of identifiers in the C90 Standard. As such a program that contained non unique labels exhibited undefined behavior.

A function definition containing a non-unique label name that was accepted by some C90 translator (a very rare situation) will cause a C99 translator to generate a diagnostic.

Other Languages

This requirement is common to most languages, although a few (e.g., Algol 68) give labels block scope. Some assembly languages supported duplicate label names. A jump instruction usually being defined, in these cases, to jump to the closest label with a given name.

Common Implementations

Although this was not a requirement that appeared within a Constraints clause in C90, all implementations known to your author issued a diagnostic if a label name was not unique within a function definition.

Coding Guidelines

Label names that are not referenced might be classified as redundant code. However, labels have uses other than as the destination of **goto** statements. They may also be used as breakpoints when stepping through code using a symbolic debugger. Automatically generated code may also contain labels that are not jumped to. Given that labels are relatively uncommon, and the only nontrivial cost involved in a redundant label name is likely to be a small increase in reader comprehension time, a recommendation that all defined labels be jumped to from somewhere does not appear to have a worthwhile benefit. 190 redundant code

The issues relating to the spelling of label names are discussed elsewhere. 792 label naming conventions

Semantics

1726 Any statement may be preceded by a prefix that declares an identifier as a label name.

Commentary

It is not possible to prefix a declaration with a label (although a preceding null statement could be labeled).

C does not provide any mechanism for declaring labels before they appear as a prefix on a statement. Labels may be referenced before they are declared. That is it is possible to **goto** a label that has not yet been seen within the current function.

Other Languages

Some languages (e.g., those in the Pascal family) provide declaration syntax for label names. Their appearance as a statement prefix is simply a use of a name that has been previously defined. Some languages (e.g., Fortran) allow all lines to be prefixed by a line number. These line numbers can also be used as the destination in **goto** statements.

---

case fall through

Labels in themselves do not alter the flow of control, which continues unimpeded across them. 1727

Commentary

EXAMPLE 1762 case fall through

An example of this is given elsewhere.

C++

The C++ Standard only explicitly states this behavior for **case** and **default** labels (6.4.2p6). It does not specify any alternative semantics for 'ordinary' labels.

Other Languages

In some languages certain kinds of labels alter the flow of control. For instance, in Pascal encountering a **case** label cases flow of control to jump to the end of the **switch** statement (the following using Pascal syntax and keywords).

```
1  case expr of
2     1: begin
3        x:=88;
4        y:=99;
5        end;
6
7     2: z:=77;
8     end;
```

Common Implementations

Labels may not alter the flow of control but they are usually the destination of a change of flow of control. As such they are bad news for code optimization, because accumulated information on the values of objects either has to be reset to nothing (worst-case assumption made by a simple optimizer), or merged with information obtained along other paths (more sophisticated optimizer).

Coding Guidelines

Most C coding guideline documents recommend against *falling through* to a statement prefixed by a **case** or **default** label. For instance, in the following fragment it is likely that the author had forgotten to place a **break** statement after the assignment to y.

```
1  case 1: x=88;
2          y=99;
3
4  case 2: z=77;
```

Duff's Device 1766

There are occasions where falling through to a statement prefixed by a **case** label is the intended behavior. A convention sometimes adopted is to place a comment containing the words FALL THROUGH on the line before the statement that is fallen into (some static analysis tools recognize this usage and don't issue a diagnostic for the fall through that it comments).

Experience suggests that code containing a statement prefixed by a **case** label whose flow of control *falls through* to another statement prefixed by a **case** label causes readers to spend significant effort in verifying whether the usage is intended or a fault in the code. Commenting such usage has a cost that is likely to be significantly smaller than the benefit.

Cg 1727.1

If the flow of control can reach a statement prefixed by one or more **case** labels, other than by a direct jump from the controlling expression of a **switch** statement, the source line immediately before that statement shall contain the words "FALL THROUGH" in a comment.

Table 1727.1: Common token pairs involving a **case** or **default** label. Based on the visible form of the `.c` files. Almost all of the sequences { case occur immediately after the controlling expression of the **switch** statement.

Token Sequence	% Occurrence First Token	% Occurrence of Second Token
; default	0.4	81.4
; case	2.1	52.1
: case	15.5	22.1
{ case	2.6	15.0
} case	1.3	7.3
: default	0.5	5.7
#endif default	0.8	4.4

1728 **Forward references:** the **goto** statement (6.8.6.1), the **switch** statement (6.8.4.2).

6.8.2 Compound statement

compound statement syntax

1729

compound-statement:
{ *block-item-list*$_{opt}$ **}**
block-item-list:
block-item
block-item-list block-item
block-item:
declaration
statement

Commentary

Compound statements are commonly used to group together a sequence of statements that are required to be executed under the same set of conditions. While compound statements also provide a mechanism to limit the scope of declared identifiers and the lifetime of objects, developers do not often make use of this functionality (see Figure 408.1).

C90

The C90 syntax required that declarations occur before statements and the two not be intermixed.

compound-statement:
{ *declaration-list*$_{opt}$ *statement-list*$_{opt}$ **}**
declaration-list:
declaration
declaration-list declaration
statement-list:
statement
statement-list statement

C++

The C++ Standard uses the C90 syntax. However, the interpretation is the same as the C99 syntax because C++ classifies a declaration as a statement.

Other Languages

Many languages use the keywords **begin/end** instead of a pair of braces. While Fortran, prior to the 1995 standard, did not provide any syntactic mechanism for grouping statements together in blocks. Subroutines were the only explicit statement grouping construct. Developers used conditional and unconditional jumps to create groups of statements.

Some languages (e.g., Pascal) do not allow declarations to occur within nested blocks.

In some languages (e.g., Pascal) the semicolon is a statement separator, not a terminator as in other languages (e.g., Ada). So it need not occur after the last statement in a compound statement. But it may need to occur after the compound statement.

```
1  A := B;
2  begin C := D end;
3  E := F
```

In C the semicolon is part of the syntax of certain statements. The syntax for compound statement does not include a semicolon.

```
1  a = b;
2  { c = d; }
3  e = f;
```

Ada supports the optional occurrence of a token between the **end** and **;**, echoing the corresponding opening header. For instance, `end if;` terminating an **if** statement.

Common Implementations

A compound statement could be translated into a sequence of machine code instructions making up a basic block, provided it contains no statements or operators that cause conditional execution to occur. For instance, an **if** statement, or the logical-AND operator.

Coding Guidelines

The issues of mixing declarations and statements, and whether to locate declarations at the start of a block or near the point of first use are discussed elsewhere.

mixing 1821 declarations and statements

Many of the visual layout schemes for source code can be differentiated by where they place opening brace, relative to other tokens. A more realistic analysis, compared to the glowing claims of readability made by the proponents authors of these schemes, is given elsewhere. Some layout schemes locate the open brace after non-white-space characters (e.g., `if (x < y) {`), rather than on a line by itself (and possibly other white-space characters). There are several reasons for believing that the former usage results in a larger number of mistakes being made than the latter. These include: (1) the **{** token not being visible during a visual scan of the left edge of the visible source, and (2) non-white-space characters appear along the visual line connecting the opening and closing brace characters (which require cognitive effort to search and are a possible cause of interference).

reading 770 practice

reading 770 kinds of

Given the lack of experimental measurements of reading performance for different layout schemes, there is no empirical evidence to support any guideline recommendation relating to the visual layout of blocks.

Usage

Usage information on the number of declarations occurring in nested blocks is given elsewhere (see Figure 408.1).

Semantics

---

compound statement is a block

A *compound statement* is a block. 1730

Commentary

block 1710

This defines the term *compound statement*.

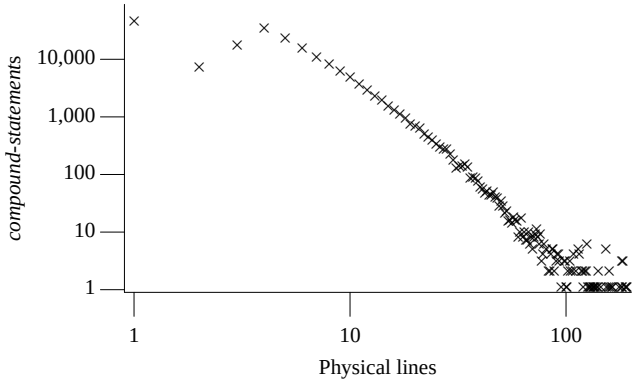

Figure 1729.1: Number of *compound-statement*s containing the given number of physical lines (including the opening and closing braces and any nested *compound-statement*s, but excluding the lines between the braces denoting the start/end of the function definition). Based on the translated form of this book's benchmark programs.

C90

The terms *compound statement* and *block* were interchangeable in the C90 Standard.

Coding Guidelines

The issue associated with enclosing the bodies associated with selection and iteration statements in a pair of matching braces is discussed in the C sentences for those statements. The term most commonly used by developers is *block*, rather than *compound statement*. In C99, but not C90, the term *block* includes constructs that are not compound statements. Authors of coding guideline documents need to ensure that their usage of terminology is consistent.

6.8.3 Expression and null statements

1731 null statement syntax expression statement syntax

expression-statement:
expression$_{opt}$ **;**

Commentary

Syntactically a sequence of two semicolons (e.g., `;;`) represents at least one null statement (and never a null declaration).

Other Languages

The syntax of many languages do not allow expressions to occur at the statement level. Assignment is often specified by placing an expression on either side of a token (such as `:=` or `=`) that is not defined to be an operator. Some languages (e.g., Fortran and PL/1) require that functions calls at the statement level be prefixed by the keyword **`call`**, while others (e.g., Ada and Pascal) support such calls (to *procedures*) without the use of any keyword. Perl supports what are known as statement modifiers, which provide a conditional or looping mechanism. For instance, `$i=$num if ($num < 50);` only performs the assignment if the controlling expression of the **`if`** is true (it is also possible to use **`unless`**, **`while`**, and **`until`** instead of **`if`**).

Table 1731.1: Occurrence of the most common forms of expression statement (as a percentage of all expression statements). Where *object* is a reference to a single object, which may be an identifier, a member (e.g., `s.m`, `s->m->n`, or `a[expr]`), *integer-constant* is an integer constant expression, and *expression* denotes expressions that contain arithmetic and shift operators. Based on the visible form of the `.c` files.

Form of *expression-statement*	%	Form of *expression-statement*	%
function-call	37	object = expression	4
object = object	16	object `v++`	2
object = function-call	10	expression	1
object = constant	7	other-expr-stmt	22

Semantics

expression statement evaluated as void expression

The expression in an expression statement is evaluated as a void expression for its side effects.[132)] 1732

Commentary

Treating an expression as a statement simplifies the C syntax. However, this specification is needed to handle the resulting value.

Other Languages

compound expression 1313

Some languages (e.g., Algol 68 and as an extension in `gcc`) allow some form of bracketed statement sequence to appear as the operand in an expression. In such languages the equivalent form of a C expression statement can return a value.

Coding Guidelines

EXAMPLE discard function return 1734

Some coding guideline documents recommend that function calls whose return value is not used (i.e., having a return type other than **`void`**) be explicitly cast to **`void`**. The rationale is that the cast provides an explicit indication of the authors intent to discard the functions return value (the return value presumably being used in other situations, otherwise a return type of **`void`** would be applicable). One of the costs of explicitly specifying that a functions return value is discarded is an increase in the cognitive effort needed to locate the name of the called function (which will appear between some tokens, rather than as the first token on a line). Given that the benefits do not appear to be significantly greater than the costs, no guideline recommendation is given here.

redundant code 190

The issue of expressions whose evaluation does not cause side effects is discussed elsewhere.

null statement

A *null statement* (consisting of just a semicolon) performs no operations. 1733

Commentary

This defines the term *null statement*. A null statement performs no operation in the sense that translators are unlikely to generate any machine code for it. It may perform a syntactic operation by allowing a label to be placed anywhere in the source.

EXAMPLE labeled null statement 1737

Other Languages

Some form of statement that performs no operation is common to most languages.

Coding Guidelines

Null statements are very easy to accidentally create and often go unnoticed by readers. Highlighting those cases where a null statement is intended can reduce a reader's effort deducing this fact (sometimes a semicolon as the only non-white-space character on a line is considered to be sufficient highlighting). Those cases where a null statement is not intended are faults and it is not the purpose of these coding guidelines to recommend against faults.

EXAMPLE null statement 1736

guidelines not faults 0

Example

```
1  extern int glob;
2
3  void f(void)
4  {
5  if (glob == 3);
6     ; /* A null statement that might be noticed while scanning the left edge. */
7
8  if (glob == 3);
9     /* A null statement unlikely to be noticed while scanning the left edge. */ ;
10
11 while (glob++ < 22);
12   ;  ;  ;  ;  ;  ; /* Conspicuous consumption of attention. */
13 }
```

1734 EXAMPLE 1 If a function call is evaluated as an expression statement for its side effects only, the discarding of its value may be made explicit by converting the expression to a void expression by means of a cast:

EXAMPLE discard function return

```
int p(int);
/* ... */
(void)p(0);
```

Other Languages

Some languages contain functions and procedures, the former always returns a value, while the latter never returns a value and is required to be used in expression statement contexts.

Coding Guidelines

The issues associated with this usage are discussed elsewhere.

1732 expression statement evaluated as void expression

1735 132) Such as assignments, and function calls which have side effects.

footnote 132

Commentary

Or accessing an object declared with the **volatile** type qualifier.

C++

The C++ Standard does not contain this observation.

1736 EXAMPLE 2 In the program fragment

EXAMPLE null statement

```
char *s;
/* ... */
while (*s++ != '\0')
        ;
```

a null statement is used to supply an empty loop body to the iteration statement.

Coding Guidelines

The issues associated with side affects appearing in a controlling expression are discussed elsewhere.

1740 controlling expression if statement

1737 EXAMPLE 3 A null statement may also be used to carry a label just before the closing } of a compound statement.

EXAMPLE labeled null statement

```
while (loop1) {
        /* ... */
        while (loop2) {
                /* ... */
                if (want_out)
                        goto end_loop1;
```

```
                /* ... */
        }
        /* ... */
end_loop1: ;
}
```

Commentary

A null statement may also be used to carry a label just after the opening **{** of a compound statement (which may contain declarations with initializers).

Forward references: iteration statements (6.8.5). 1738

6.8.4 Selection statements

---

selec-
tion statement
syntax 1739

selection-statement:
if (*expression*) *statement*
if (*expression*) *statement* else *statement*
switch (*expression*) *statement*

Commentary

This syntax is ambiguous in that it does not uniquely specify the parse for the token sequence `if (a) b; if (c) d; else e;`. This syntactic ambiguity is resolved by a semantic rule.

else 1747
binds to nearest if

Other Languages

There is a great deal of variety in the syntactic forms of selection statements used by different languages. Some languages (e.g., those in the Pascal family) require that the controlling expression be followed by the keyword **then**, while others require the **if** statement to be terminated by some keyword (e.g., **end** in Ada, or **fi** in Algol 68). Some languages support an **elif** form (e.g., Ada, Algol 68, and the C preprocessor). Fortran has what it calls an *arithmetic if* statement:

preprocessor 1854
directives
syntax

```
1       if (i) 10, 20, 30
2      C Jump to label 10 if i < 0
3      C Jump to label 20 if i == 0
4      C Jump to label 30 if i > 0
```

The Fortran equivalent of the **switch** statement is known as a *computed goto* (in the following code fragment the **goto** jumps to label 10 if I==1, 20 if I==2, and so on):

```
1       goto (10, 20, 30, 40), I
```

Algol 60 required the labels to be declared in a **switch** statement:

```
1  SWITCH x := label1, label2, label3;
2        ...
3  GOTO x[i];
```

The Algol 68 **case** statement essentially has Fortran semantics (it also supports a **default** form), but with a Pascal like syntax.

Most languages (including Java) unconditionally bracket, syntactically, the complete list of case labels and their associated statements that follow a **switch** header.

Java supports the occurrence of labels that do not label any statement, at the end of the sequence of statements in a **switch** statement (where they essentially act as a comment whose contents are syntactically and semantically checked).

Languages in the Pascal family use the keyword **case**, rather than **switch**, is used. The following example is a fragment of Ada:

```
case x is
   when 2 => y:=1;
   when 3 => y:=2;
end case;
```

A few languages supports a **switch** statement containing more than one dimension (e.g., CHILL supports an arbitrary number, while Cobol supports a maximum of two). The following example is a fragment of Cobol:

```
        EVALUATE price ALSO quantity
           WHEN ANY ALSO 0   PERFORM ABC
           WHEN 0   ALSO ANY PERFORM PQR
           WHEN 1   ALSO num PERFORM XYZ
        END-EVALUATE
```

Common Implementations

The availability of the **switch** statement does not mean that developers always use it. Uh[1385] gives the following example from the source of `grep`.

```
if ((c = *sp++) == 0)
   goto cerror;
if (c == '<') { ... }
if (c == '>') { ... }
if (c == '[') { ... }
if (c == ']') { ... }
if (c >= '1' && c <= '9') { ... }
```

Uh added optimizations to an existing compiler to detect and optimize linear sequences of **if** statements that compared the same variable against different constant values. Performance improvements varied between 0.67% to 5.56%, depending on the processor (see Table 1753.1).

Yang, Uh, and Whalley[1490] took a different approach to optimizing nested sequences of **if** statements. They used profile information to reorder the sequence in which the controlling expression tests were made, putting those that succeeded most often first. An average performance improvement of 4% was obtained (on a variety of Unix tools).

The implementation of the **if** statement (and some operators, e.g., logical-AND) usually uses a conditional branch machine instruction. Conditional branch instructions create a bottleneck for processors that have the ability to execute more than one instruction at the same time. Without knowing which sequence of instructions are going to be executed, after the branch instruction, the processor is unable to keep the execution pipeline full; execution stalls. Several methods have been used to help reduce the likelihood of stalls occurring, including:

1248 logical-AND-expression syntax

- *Speculative execution of the two flows of control.* Speculative execution of two flows of control is implemented by keeping the results of both execution paths in shadow registers. Once the result of the branch test is known the values in the appropriate set of shadow registers are copied into the actual registers. This approach requires a lot of hardware resources (it has been implemented on the IBM 360/91 and the Sun SuperSPARC[1498]).
- *Predicting the branch the instruction is likely to take*, so called *branch prediction*, and speculatively executing that flow of control. If the prediction turns out to be correct the processor has a full pipeline of instructions and can continue from the point it had speculatively executed to, otherwise the pipeline has to be flushed and filled with instructions from the start location of the other branch.
- *Conditional instructions.* An alternative to a conditional branch is to use instructions whose execution is conditional on the setting of various processor flags. These instructions are read from the instruction stream but are only executed if the condition specified, as part of the encoding of the instruction, is currently true. The current conditions being set by executing a compare instruction, much like that which might appear before a conditional branch instruction.

1739 conditional instructions

branch prediction

Branch prediction

jump statement syntax 1782

Most modern high-performance processors perform some kind of branch prediction followed by speculative execution of the predicted destination instructions (unconditional branches are discussed elsewhere). Processor based branch prediction can take the following two forms:

- Encoding the branch instruction to include a bit specifying whether the branch is likely to be taken or not (e.g., the IBM PowerPC). This branch probability decision bit is filled in by the translator when generating machine code.
- Using the history of an executing programs previous branch decisions (taken/not taken) is used to predict the probably outcome of the next branch decision. Studies have found that there is often a strong correlation between the branch decisions made by a particular instruction (i.e., the same decision is repeated), also the last branch decision (usually a completely different branch instruction) and the decision made by the following branch instruction may be correlated (some branch predictors maintain information on the history of the branch itself and the branch previous to it, in the dynamic execution flow). This branch history information is often held in a table (a few bits specifying the direction of the last few jump decisions), indexed by the branch instructions address (usually a few of the least significant address bits).

The following are two methods a translator can use to predict branch direction:

- *Static analysis of the translated source code* (i.e., the machine code making up the program image). Various heuristics have proven to be reliable indicators of branch direction. This technique is known as *program-based* branch prediction.
- *Gather data on the branch decisions made during program execution.* This profile of branch decisions is then used in a subsequent translation to build a program image whose branch instructions are encoded to specify the most frequent branch direction taken during the profiling executions. This technique is known as *profile-based* branch prediction.

Static analysis of branch direction

The quantity measured in branch prediction is the *miss rate* (predicted destination incorrect), expressed as a percentage. The *perfect* predictor selects the branch direction based on the most common direction actually chosen, for each branch, over a large number of executions of the program. A study by Ball and Larus[88] analyzed translator generated machine code to create a number of heuristics that could be used to predict branch behavior. The heuristics found to be worthwhile (see Table 1739.1) were:

- *Opcode heuristic.* A relational comparison against zero is assumed to fail if it tests for less than (or less than or equal) and assumed to succeed if it tests for greater than (or greater than or equal).
- *Loop heuristic.* The successor does not postdominate[1739.1] the branch and is either a loop head or a loop preheader (i.e., passes control unconditionally to a loop head which it dominates). If the heuristic applies, predict the successor with the property.
- *Call heuristic.* The successor block contains a call or unconditionally passes control to a block with a call that it dominates, and the successor block does not postdominate the branch (many conditional calls handle exceptional cases, which are rarely taken). If the heuristic applies, predict the successor without the property.
- *Return heuristic.* The successor block contains a return or unconditionally passes control to a block that contains a return. If the heuristic applies, predict the successor without the property.

[1739.1] A node y, of some flow graph, is said to *postdominate* the node x if every path from x to the end of the graph includes y.

- *Guard heuristic.* Register r is an operand of the branch instruction, register r is used in the successor block before it is defined, and the successor block does not postdominate the branch (this test can only be performed after code generation and assumes that a translator has performed some form of optimizing register assignment). If the heuristic applies, predict the successor with the property.
- *Store heuristic.* The successor block contains a store instruction and does not postdominate the branch. If the heuristic applies, predict the successor without the property,
- *Pointer heuristic.* A test for equality between two pointers (one of them possibly being the null pointer constant) is assumed to fail. A test for inequality between two pointers (one of them possibly being the null pointer constant) is assumed to succeed.

Table 1739.1: Dynamic breakdown of non-loop branches for programs in SPEC89. *% of All Branches* is the percentage of all branches that are non-loop branches. *Heuristics* are the results of using the heuristics for predicting the target successor of each non-loop branch, *Perfect* the results for the perfect predictor, *Random* the results for predicting each non-loop branch randomly. *Big* is the number of non-loop branches in the program contributing more than 5% of all dynamic non-loop branches (and in parenthesis as a percentage of non-loop branches). Based on Ball and Larus.[88]

Program	% of All Branches	Heuristics	Perfect	Random	Big (%)	Program	% of All Branches	Heuristics	Perfect	Random	Big (%)
gcc	73	37	11	50	0 (0)	poly	20	40	3	31	3 (54)

espresso	37	26	13	42	3 (24)	Std.Dev.		12	8	13	
awk	29	14	3	57	4 (29)						

A more detailed analysis of this heuristic approach can be found in Deitrich.[342] An approach that looked at source code was investigated by Sokolova,[1264] who reported some improvements. Calder[190] trained a neural network, using a corpus of programs, to infer the branching behavior of new programs (they called the approach *evidence-based* static prediction).

Conditional instructions

conditional instructions

The extent to which large sophisticated branch prediction circuitry can be incorporated into processors used in resource limited environments is limited by the significant amount of power it consumes (up to 10% of a processors total dynamic power dissipation,[1053] which drains batteries and heats up the device). An alternative solution to the bottleneck created by conditional branches is to do away with them. Some processors (e.g., ARM[56] and Intel Itanium[231,841,1342]) achieve this by making the execution of all instructions conditional. This is implemented by having a sequence of bits in the instruction encoding represent various conditions. During program execution fetched instructions are only executed if the condition encoded in their bit sequence is true. Conditional execution of instructions can be more efficient than using a conditional branch instruction when there are only a few *nulled* instructions (representing the unexecuted arm). Since the number of instructions in the arms of **if** statements is often small, use of such instructions can often be worthwhile ([231] gives empirical results).

The following discussion and example is based on one appearing in the Intel XScale Microarchitecture Programmers Reference Manual.[629]

```
1  int f(int x)
2  {
```

```
3  if (x > 10)    /* if-cond   */
4     return 0;   /* if-stmt   */
5  else
6     return 1;   /* else-stmt */
7  }
```

The unoptimized machine code generated, using branch instructions, for the **if** statement usually has the form:

```
    cmp  r0, 10
    ble  L1
    mov  r0,  0
    b    L2
L1: mov  r0,  1
L2:
```

while that generated using conditional instructions has the form:

```
    cmp   r0, 10
    movgt r0,  0
    movle r0,  1
```

Intel recommend[629] using the conditional instruction form when:

$$N1_C \times \frac{P1}{100} + N2_C \times \frac{100 - P1}{100} \leq N1_B \times \frac{P1}{100} + N2_B \frac{100 - P1}{100} + \frac{P2}{100} \times 4 \tag{1739.1}$$

where:

$N1_B$: Number of cycles to execute the *if_stmt* assuming the use of branch instructions.

$N2_B$: Number of cycles to execute the *else_stmt* assuming the use of branch instructions.

$P1$: Percentage of times the *if_stmt* is likely to be executed.

$P2$: Percentage of times a branch misprediction penalty is likely to be incurred.

$N1_C$: Number of cycles to execute the *if-else* portion using conditional instructions assuming *if-cond* to be true.

$N2_C$: Number of cycles to execute the *if-else* portion using conditional instructions assuming the *if-cond* to be false.

The code generated above requires three cycles to execute the *else-stmt* and four cycles for the *if-stmt*, assuming best-case conditions and no branch misprediction penalties.

Coding Guidelines

1 Introduction

conditional statement

Source code comprehension that involves a controlling expression of an **if** statement can have many facets. Some of these include the following:

- *Comprehending the conditional expression itself.* In particular the conditions under which it is true and false. These issues are discussed in detail in this subclause.
- *Interpreting the conditional expression within the application domain.* A conditional expression is used to make one of two choices and these may be driven by applications requirements (e.g., `line_len < MAX_LINE_LEN` might be the implementation of a requirement on the maximum number of characters that can appear on an output line). These application mapping comprehension issues are outside the scope of these coding guideline subsections and are not discussed further here.

- *Control flow dependencies.* An **if** statement may be nested within other **if** statements. The conditions represented by the additional controlling expressions may need to be taken into account,
- *Data dependencies.* When reading statements whose execution is directly affected by the flow of control of the conditional expression (e.g., an assignment statement in one of the arms of an **if** statement). These statements may need to be processed in the context of the conditions interpretation with the application or may involve operands that appear in the condition. For instance, in:

```
1  if ((x >= y) && (x <= z))
2     {
3     p++;
4     q=z-y;
5     ...
```

the reason for p being incremented is likely to be connected to what the condition represents within the application domain, while some information about the assignment to q can be obtained directly from the condition expression (e.g., it is always positive). A data dependency can also exist between an **if** statement and another such statement executed before it.

```
1  if (x == 2)
2     y = 45;
3
4  if (y != 45)
5     {
6     /* x does not equal 2 here */
7     }
```

Some coding guideline documents recommend a value for the maximum nesting of **if** statements (sometimes giving a rationale based on the limits of human short-term memory). Human short term memory does place constraints on the complexity of code than can be easily comprehended. However, while the time taken to comprehend a sequence of nested **if** statements may not feel like very long, it is much longer than the period of time over which short-term memory operates (a guideline recommendation based purely on human short-term memory capacity would probably need to limit nesting to a single level).

0 memory developer
0 Miller 7±2

Any guideline recommendation designed to deal with human cognitive capacity limits needs a reasonably accurate model of how the people involved are likely to process a given construct. Given that the controlling expressions of **if** statements can have significantly different complexities and couplings to other statements it is necessary to calculate how readers are likely to interpret and chunk the information present in them (i.e., simply counting nesting is much too simplistic). At the time of this writing it is not possible to perform this calculation. Like all guideline recommendation it is also necessary to consider what alternative constructs developers might use. In the case of **if** statements some of the issues include the following:

- Many *alternative* techniques don't remove the nesting, they simply rearrange the source. For instance, replacing the inner most nested **if** statements by a call to a function that contains them only reduces nesting depth because of the accounting practices used to measure depth (the measure is usually based on the contents of a single function; the contents of called functions are not examined).
- The implicit **if** statements implied by the use of the logical operators in a conditional expression. For instance, `if ((a < 1) && (b > 10))` is usually counted as a single **if** statement, while the equivalent form `if (a < 1) if (b > 10)` is counted as two (there have been few psychological studies comparing how people treat rephrasing of these two forms; one study[1163] found no psychological equivalence).

The rest of the discussion in this coding guideline subsection deals with the reader comprehension aspects of the dependencies between a controlling expression and the rest of the source code that contains it (other dependency issues are discussed elsewhere; while there has been a lot of talk about the software engineering

1821 function definition syntax

costs associated with dependencies there has been little experimental research on the topic). In particular it discusses studies of human performance in reasoning tasks. It is possible to draw many parallels between solving these tasks and comprehending the use of, and references to, conditional expressions. These coding guidelines make the assumption that the pattern of mistakes made by developers will be the same as those made by the subjects used in these studies and that the factors found to affect subjects performance will be the same as those that affect developers performance. This is a big assumption, because most studies of reasoning aim to uncover some aspect of *natural* human thinking and thus avoid using subjects who have had training in the formal (i.e., mathematical) use of logical. This contrasts with developers who will have had some training in the use of mathematical logic and a significant amount of reasoning experience through attempts to comprehend of code. The assumption stated above implies that the extent to which developers are more adept at deductive reasoning, compared to the general undergraduate population used in the studies (which may be different from the general population[1283]), is purely due to experience (formal training on its own does not usually affect performance; a study[224] of students who had taken a course in logic showed only a 3% improvement in performance, compared to those who had no formal logic training).

The three main topics discussed are:

memory 0
developer

1. use of working memory resources (for simplicity the use of long-term memory is not considered here),
2. the impact of the visual appearance of the source, and
3. the performance of humans when reasoning.

At the time of this writing the research results discussed raise questions, rather than providing answers. However, they do go a long way towards dispelling the notion that developer reasoning performance is independent of the logical form of a problem.

2 Remembering conditional information

How is the information denoted by a conditional expression represented in a readers mind? There are a number of possibilities, including:

- It is not represented at all. The source containing the controlling expression is reread on an as-needed basis.
- As some representation of the conditional expression appearing in the visible source. For instance, the spoken form of the expression (in which case the use of identifiers having shorter spoken forms would be an advantage).

```
1  if (character_count > 20)
2
3  if (char_count > 20) /* Contains fewer syllables, in spoken form, than above. */
```

- as what it represents internally, in the program, or what it represents within the application. For instance, the following two conditional expressions may both be represented in a readers mind using the same information.

```
1  if (character_count > MARGIN_WIDTH)
2
3  if (SKIPPED_PAST_MARGIN)
```

- some combination of the above. For instance, the conditional expression:

```
1  if ((ch >= MIN_PRINTABLE) && (ch <= MAX_PRINTABLE) &&
2      (ch != 'Q'))
```

might be represented, in a readers mind, as “a printable character that is not equal to the letter Q”.

3 Visual appearance

The bodies of **if** statements are commonly indented, visually, to the right of the **if** keyword. The greater the nesting of **if** statements the greater the indentation. This indenting practice has a cost impact that is separate from the cost of comprehending any relationship between the controlling expressions; the cost factors include:

- Reducing the visible line length reduces the probability that individual statements will fit on a single line. The issue of the readability of statements split over more than one line is discussed elsewhere. 1707 statement visual layout
- Each indentation creates a visually discriminable location that needs to be temporarily remembered by readers. Your author could not find any studies relating to this problem (the study by Hake[533] asked subjects to judge discriminate the position of a pointer on a scale, relative to two end points, using 5, 10, 20 and 50 different locations).

Situations requiring many that levels of nested **if** statements be written also often involve relatively large numbers of statements. Separating out the individual contributions made by indentation and number of lines (the issue of function size is discussed elsewhere) to the total comprehension effort, and being able to calculate the cost/benefit of the various possible source code organizations, requires a significantly greater amount of expertise than is currently available. For this reason these coding guidelines do not discuss these issues further. The issue of the visual layout of conditional expressions is discussed elsewhere. 1821 function definition syntax 940 expressions

4 Reasoning

It has been claimed that the ability to reason is what separates humans from the rest of the animal kingdom. However, studies[1209] of reasoning using illiterate subjects from remote parts of the world obtained answers to verbal reasoning problems that were based on personal experience and social norms, rather than the western ideal of logic. The answers given by subjects, in the same location, who had received several years of schooling were much more likely to match those demanded by mathematical logic; the subjects had learned to *play the game*. Peng, Ames, and Knowles[1071] discuss styles of reasoning used in various cultures.

Until relatively recently (Wason's famous four card selection task[1445] was first published in 1966; he did not at first question whether logic was the correct normative theory and interpreted the results in terms of people being illogical or irrational) it was believed that mathematical logic formed the basis for human rational thought (a belief in line with the model of the human mind as a general purpose computer).

An example of how a reader's performance can be affected by the kind of question asked, about conditions, is provided by a study by Bell and Johnson-Laird.[111] They asked subjects to give yes/no responses to two kinds of questions, asking about what is possible or what is necessary. They predicted that subjects would find it easier to infer a 'yes' answer to a question about what is possible, compared to one about what is necessary, because only one instance needs to be found, whereas all instances need to be checked to answer 'yes' to a question about necessity (see Table 1739.2). For instance, in a game in which only two can play:

```
If Allan is in then Betsy is in.
If Carla is in then David is out.
```

answering 'yes' to the question "Can Betsy be in the game?" (a possibility) is easier than giving the same answer to "Must Betsy be in the game?" (a necessity).

However, subjects would find it easier to infer a 'no' answer to a question about what is necessary, compared to one about what is possible, because only one instance needs to be found, whereas they all instances need to be checked to answer 'no' to a question about possibility. For instance, in another two person game:

```
If Allan is out then Betsy is out.
If Carla is out then David is in.
```

answering 'no' to the question "Must Betsy be in the game?" (a necessity) is easier than giving the same answer to "Can Betsy be in the game?" (a possibility).

Table 1739.2: Percentage of correct responses given to the four kinds of questions. Adapted from Bell and Johnson-Laird.[111]

Kind of Question	Correct 'yes' Response	Correct 'no' Response
is possible	91%	65%
is necessary	71%	81%

The study of reading and representing natural language sentences has to deal with the fact that such sentences in such languages are often syntactically and semantically ambiguous. Conditional statements written in the C language have a well defined syntactic and semantic meaning (we ignore the ill-formed cases here). However, the existence of a well defined meaning does not imply that all readers will find and use it.

5 Deductive reasoning

deductive reasoning

Heuristics and Biases

conjunction fallacy

pragmatic interpretation

A number of reasons for people's failure to give answers that matched those required by one of the mathematical logics (e.g., propositional or predicate calculus) have been proposed. These include the use of heuristics as a means of overcoming cognitive limits, interpreting the wording of questions in a pragmatic way based on how natural language are used rather than as logical formula, and interpreting the questions in a social context.[575] The following are some of the factors that have been found to affect peoples performance in solving deductive reasoning problems:

- *age of reasoner*— Performance in reasoning tasks declines with age.[427] Contributing factors for this decline include a reduction in working memory capacity with age[491] and a slowing down of cognitive processing speed.[1192]
- *Belief bias*— people have been found to be more willing to accept a conclusion, derived from given premises, that they believe to be true than one that they believe to be false. A study by Evans, Barston, and Pollard[402] gave subjects two premises and a conclusion and asked them to state whether the conclusion was true or false (based on the premises given). The conclusions were rated as either believable or unbelievable (this status was checked by asking a separate group of subjects to rate the believability of the conclusions on a seven point scale). The results showed (see Table 1739.3) that belief did affect performance, particularly when the conclusion was invalid.

Table 1739.3: Percentage of subjects accepting that the stated conclusion could be logically deduced from the given premises. Based on Evans, Barston, and Pollard.[402]

Status-context	Example	Conclusion Accepted
Valid-believable		
	No Police dogs are vicious Some highly trained dogs are vicious Therefore, some highly trained dogs are not police dogs	88%
Valid-unbelievable		
	No nutritional things are inexpensive Some vitamin tablets are inexpensive Therefore, some vitamin tablets are not nutritional things	56%
Invalid-believable		
	No addictive things are inexpensive Some cigarettes are inexpensive Therefore, some addictive things are not cigarettes	72%
Invalid-unbelievable		
	No millionaires are hard workers Some rich people are hard workers Therefore, some millionaires are not rich people	13%

- *Form of premise*— a study by Dickstein[354] measured subjects performance on the 64 possible two premise syllogisms (a premise being one of the propositions: *All S are P*, *No S are P*, *Some S are P*, and *Some S are not P*). For instance, the following syllogisms show the four possible permutations of three terms (the use of S and P is interchangeable):

```
All M are S      All S are M    All M are S     All S are M
No P are M       No P are M     No M are P      No M are P
```

  The results showed that performance was affected by the order in which the terms occurred (known as the *figure*) in the two premises of the syllogism. The order in which the premises are processed may affect the amount of working memory needed to reason about the syllogism, which in turn can affect human performance.[494]

- *Individual preferences*— different people have been found to prefer the use of different strategies when solving a deductive problem.

1739 reasoning strategy choice

Whatever the reason for people giving the answers they do, studies have shown that there are patterns to the *mistakes* made and that these patterns are found in a large number of people. A variety of theories and models have been proposed to explain these patterns of behavior. The following is a brief description of some of the different theories that have been proposed (the *mental model* theory currently enjoys general acclaim, based on its ability to predict the behavior seen in a large number of studies and the number of researchers currently publishing papers based on some form of it):

- *Mental logic.*[151, 1167] People perform logical reasoning by the application of formal (syntactic) rules. The larger the number of rules that are applied to infer a conclusion the more difficult the problem is.
- *Mental models.*[677, 678] Readers construct a mental model (or set of models) from the given premises (this is a two-stage process that involves comprehending a premise, followed by combining the information contained in each premise to form the model). This model is used to draw possible conclusions (i.e., people reason from the content of a problem, unlike mental logic where reasoning is based on the syntactic form) which are then subject to a process of validation. Validation involves searching for alternative models, or counter examples, that are consistent with the premises, but which refute the conclusion. A conclusion is considered to be valid if no counter example can be found. Errors in reasoning are the result of limitations in the processing ability of the mind, in particular:

  1. one model is better than many. That is, the fewer models needed for an inference, and the simpler they are, the easier the inference,
  2. reasoners sometimes fail to consider all models in multiple-model problems. This results in them drawing conclusions that are possible rather than necessary,
  3. reasoners focus on what is true and neglect what is false. This can result in illusionary inferences,
  4. premise contents and background knowledge can affect the interpretation of assertions made in a premise and the process of reasoning, and
  5. with experience, reasoners develop tailor-made strategies for particular sorts of problems. To refute invalid conclusions, they can search for counter-examples.

- *Darwinian algorithms.*[285] It is argued that being able to perform certain kinds of conditional reasoning offers an evolutionary advantage and that the human mind has innate rule structures for dealing with these kinds of problems. For instance, one of the basis for social exchange is the generic rule *If you take a benefit, you pay a cost.*
- *Information gain.*[1021] Here reasoners are said to have the goal of gaining information or reducing uncertainty (an adaption to the environment in which people traditionally have use reasoning). Conclusions are informative to the extent that they are improbable, or surprising.

- *Pragmatic reasoning schemas.*[223] These schemas are packages of knowledge about specific domains, containing rules for thought and action. Solving a particular problem requires matching production rules that evoke the appropriate schema.
- *Dual process theories.*[1257, 1283] People use two systems of reasoning (see Table 1739.4). Stanovich[1283] has shown a strong correlation between students performance on SAT tests (as well as intelligence tests) and the extent to which they are likely to use System 2 in reasoning tasks. The results of some studies[401] have suggested that people sometimes use both systems of reasoning when reasoning about a problem.

Table 1739.4: Properties of the two systems of thinking. Based on Stanovich.[1283]

System 1	System 2
Unconscious	Conscious
Automatic	Controlled
Associative	Rule-based
Heuristic processing	Analytic processing
Undemanding of cognitive capacity	Demanding of cognitive capacity
Relatively fast	Relatively slow
Acquisition by biology, exposure, and personal experience	Acquisition by cultural and formal training
Highly contextualized	Decontextualized
Conversational and socialized	Asocial
Independent of general intelligence	Correlated with general intelligence

Deductive reasoning problems can take many forms and this discussion limits itself to syllogisms (the simplest form and the one used by most studies). A syllogism consists of two premises and a conclusion. The two premises are usually given and the conclusion has to be deduced from them. The following are some of the different forms of syllogism:

- *Categorical syllogisms* use relations of inclusion. For instance, from

```
All A are B
All B are C
```

  we can deduce that "All A are C".

- *Linear syllogisms* use relations of order. For instance, from

```
A is taller than B
B is taller than C
```

  we can deduce that "A is taller than C".

- *Conditional syllogisms* use relations of implication. For instance, from

```
if A, then B
A is true
```

  we can deduce that "B is true".

These coding guidelines are aimed at the C programming language, which does not directly support operators for the operations that occur in categorical syllogisms (e.g., *all* or *some*). While developers may implement functions that perform equivalent operations these coding guidelines do not attempt to address developer defined operations. For this reason categorical syllogisms are not discussed further.

5.1 Linear reasoning

linear reasoning
1197 relational operators
syntax

The use of relational operators have an obvious interpretation in terms of linear syllogisms. A study by De Soto, London, and Handel[333] provides a good example. The task they used was based on what they called *social reasoning*, using the relations *better* and *worse*. Subjects were shown two premises, involving three people, and a possible conclusion (e.g., "Is Mantle worse than Moskowitz?"). They had 10 seconds to answer *yes*, *no*, or *don't know*. All four possible combinations of conclusions were used.

Table 1739.5: Eight sets of premises describing the same relative ordering between A, B, and C (peoples names were used in the study) in different ways, followed by the percentage of subjects giving the correct answer. Adapted from De Soto, London, and Handel.[333]

	Premises	Percentage Correct Response		Premises	Percentage Correct Response
1	A is better than B B is better than C	60.5	5	A is better than B C is worse than B	61.8
2	B is better than C A is better than B	52.8	6	C is worse than B A is better than B	57.0
3	B is worse than A C is worse than B	50.0	7	B is worse than A B is better than C	41.5
4	C is worse than B B is worse than A	42.5	8	B is better than C B is worse than A	38.3

Based on the results (see Table 1739.5) De Soto et al made two observations (which they called *paralogical principles*; cases 5 and 6 possess both, while cases 7 and 8 possess neither):

1. People learn orderings better in one direction than another. In this study people gave more correct answers when the direction was better-to-worse (case 1), than mixed direction (case 2, 3), and were least correct in the direction worse-to-better (case 4). This suggests that use of the word *better* should be preferred over *worse* (the British National Corpus[823] lists *better* as appearing 143 times per million words, while *worse* appears under 10 times per million words and is not listed in the top 124,000 most used words).
2. People end-anchor orderings. That is, they focus on the two extremes of the ordering. In this study people gave more correct answers when the premises stated an end term (better or worse) followed by the middle term, than a middle term followed by an end term.

A second experiment in the same study gave subjects printed statements about people. For instance, "Tom is better than Bill". The relations used were *better*, *worse*, *has lighter hair*, and *has darker hair*. The subjects had to write the peoples names in two of four possible boxes; two arranged horizontally and two arranged vertically.

The results showed 84% of subjects selecting a vertical direction for better/worse, with better at the top (which is consistent with the *up is good* usage found in English metaphors[797]). In the case of lighter/darker 66% of subjects used a horizontal direction, with no significant preference for left-to-right or right-to left.

A third experiment in the same study used the relations *to-the-left* and *to-the-right*, and *above* and *below*. The above/below results were very similar to those for better/worse. The left-right results showed that subjects learned a left-to-right ordering better than a right-to-left ordering.

The results of this study show the affect that operand order has on the accuracy of peoples responses. However, the interpretation placed on the operator also plays a significant role. It appears that without knowing what interpretation a reader is likely to give to the operands and operators in the following two (logically equivalent) conditional expressions, for instance, it is not possible to select the one that is most likely to minimize incorrect reasoning on the part of readers.

```
1  if ((x <= y) && (x => z))
2  if ((x >= z) && (x <= y))
```

Since the De Soto, et al. study additional factors have been discovered and a number of models have been proposed to explain the strategies used by people in solving linear reasoning problems. These include:

- *The spatial model*[333, 609]— people integrate information from each premise into a spatial array representing all known relationships.
- *The linguistic model*[241]— people represent each premise using linguistic propositions (the individual premises are not integrated).
- *The algorithmic model*[1133]— people apply some algorithm to the structure of the linguistic representation of the premises. For instance, given "Reg is taller than Jason; Keith is shorter than Jason" and the question "Who is the shortest?", a so called *elimination strategy* was used by some subjects in the study. (The answer for the first premise is Jason, which eliminates Reg; the answer to the second premise is Keith which eliminates Jason, so Keith is the answer).
- *The mixed model*[1292]— the information in the premise is first decoded into a linguistic form and then encoded into a spatial form.

reasoning strategy choice

The strategy used to solve a given problem has been found to vary between people. A study by Sternberg and Weil[1293] found a significant interaction between a subjects' aptitude (as measured by verbal and spatial ability tests) and the strategy they used to solve linear reasoning problems. However, a person having high spatial ability, for instance, does not necessarily use a spatial strategy. A study by Roberts, Gilmore, and Wood[1173] asked subjects to solve what appeared to be a spatial problem (requiring the use of a very inefficient spatial strategy to solve). Subjects with high spatial ability used non-spatial strategies, while those with low spatial ability used a spatial strategy. The conclusion made was that those with high spatial ability were able to see that the spatial strategy was inefficient to select as alternative strategy, while those with less spatial ability were unable to perform this evaluation.

A study by Mayer[905] asked subjects to learn a sequence of facts expressed as a relationship, such as $B > C$, $A > B$, and $A > C$ (the ordering $A > B > C > D > E > F$ was true for all facts the subjects were asked to learn). One group of subjects were told to think of the operands as boys names and the relation as representing *taller than*, while the other group were given no such instruction. Once the subjects had learned the facts presented to them, they were tested by having to answer questions about them. The results suggested that subjects who had been told to think about the relationship as representing *taller than* had integrated the separately presented facts into a single linear-encoding. While the other subjects did not integrate the separate facts and unencoded each fact using a single association.

The information encoding used by people can affect how well they later recall that information and also their performance when making comparisons about objects or symbols having some attribute that varies along a continuem. For instance, studies[1114] have found that subjects performance improves the further apart the two objects being compared are perceived to be.

symbolic distance effect 1197

5.2 Causal reasoning

A question often asked by developers, while reading source, is "what causes this event/situation to occur?" Causal questions such as this are also common in everyday life. However, there has been little mathematical research (statistics deals with correlation) on causality (Pearl[1067] is an exception) and little psychological research on causal reasoning. It is often possible to express a problem in either a causal or conditional form. A study by Sloman, and Lagnado[1256] gave subjects one of the following two reasoning problems and associated questions:

- *Causal argument* form:

```
A causes B
A causes C
B causes D
C causes D
D definitely occurred
```

with the questions: "If B had not occurred, would D still have occurred?", or "If B had not occurred, would A have occurred?".

- *Conditional argument* form:

```
If A then B
If A then C
If B then D
If C then D
D is true
```

with the questions: "If B were false, would D still be true?", or "If B were false, would A be true?".

The results (see Table 1739.6) showed that subject performance depended on the form in which the problem was expression.

Table 1739.6: Percentage *yes* responses to various forms of questions (based on 238 responses). Based on Sloman, and Lagnado.[1256]

Question	Causal	Conditional
D holds?	80%	57%
A holds?	79%	36%

There has been relatively little psychological research into causality and counter factual reasoning, although this is starting to change. This subsection is intended to show that human performance with this kind of reasoning may not be the same as that when using conditional reasoning.

5.3 Conditionals in English

In all natural languages, the conditional clause generally precedes the conclusion, in a conditional statement.[264] An example where the conditional follows the conclusion is "I will leave, if you pay me" given as the answer to the question "Under what circumstances will you leave?". In one study of English[435] the conditional preceded the conclusion in 77% of written material and 82% of spoken material.

Table 1739.7: Occurrence of the most common conditional sentence types in speech (266 conditionals from a 63,746 word corpus) and writing (948 conditionals from 357,249 word corpus). In the notation *if* + *x*, *y*: *x* is the condition (which might, for instance, be in the past tense) and *y* can be thought of as the *then part* (which might, for instance, use one of the words would/could/might, or be in the present tense). Adapted from Celce-Murcia.[213]

Structure	Speech	Writing
If + present, present	19.2	16.5
If + present, (will/be going to)	10.9	12.5
If + past, (would/might/could)	10.2	10.0
If + present, (should/must/can/may)	9.0	12.1
If + (were/were to), (would/could/might)	8.6	6.0
If + (had/have +en), (would/could/might) have	3.8	3.3
If + present, (would/could/might)	2.6	6.1

Table 1739.8: Occurrence of various kinds of **if** statement controlling expressions (as a percentage of all **if** statements). Where *object* is a reference to a single object, which may be an identifier, a member (e.g., `s.m`, `s->m->n`, or `a[expr]`), *integer-constant* is an integer constant expression, and *expression* represents all other expressions. Based on the visible form of the `.c` files.

Abstract Form of Control Expression	%	Abstract Form of Control Expression	%
others	32.4	! function-call	3.8
object	15.5	object < *integer-constant*	2.2
object == object	8.9	object > *integer-constant*	1.8
! object	7.4	function-call == object	1.6
function-call	7.4	object > object	1.4
expression	5.7	object != *integer-constant*	1.3
object != object	4.2	function-call == *integer-constant*	1.2
object == *integer-constant*	4.0	object < object	1.1

Table 1739.9: Occurrence of various kinds of **switch** statement controlling expressions (as a percentage of all **switch** statements). Where *object* is a reference to a single object, which may be an identifier, a member (e.g., `s.m`, `s->m->n`, or `a[expr]`), *integer-constant* is an integer constant expression, and *expression* denotes expressions that contain arithmetic and shift operators. Based on the visible form of the `.c` files.

Abstract Form of Control Expression	%
object	75.3
function-call	14.2
expression	5.2
others	3.3
*v object	2.0

Table 1739.10: Occurrence of equality, relational, and logical operators in the conditional expression of an **if** statement (as a percentage of all such controlling expressions and as a percentage of all occurrences each operator in the source). Based on the visible form of the `.c` files. The percentage of controlling expressions may not sum to 100% because more than one of the operators occurs in the same expression.

Operator	% Controlling Expression	% Occurrence of Operator	Operator	% Controlling Expression	% Occurrence of Operator
==	31.7	88.6	>=	3.5	76.8
!=	14.1	79.7	no relational/equality	47.5	—
<	6.9	45.6	||	9.6	85.9
<=	1.9	68.6	&&	14.5	82.3
>	3.5	84.9	no logical operators	84.2	—

Semantics

controlling expression
if statement

A selection statement selects among a set of statements depending on the value of a controlling expression. 1740

Commentary

terms 31 defined where

The term *controlling expression* does not appear in italic type in the Standard. This C sentence might be considered to be its first definition.

C++

The C++ Standard omits to specify how the flows of control are selected:

6.4p1

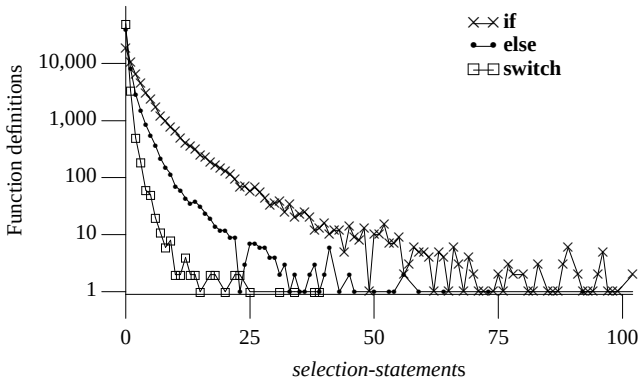

Figure 1739.1: Number of function definitions containing a given number of `selection-statement`s. Based on the translated form of this book's benchmark programs.

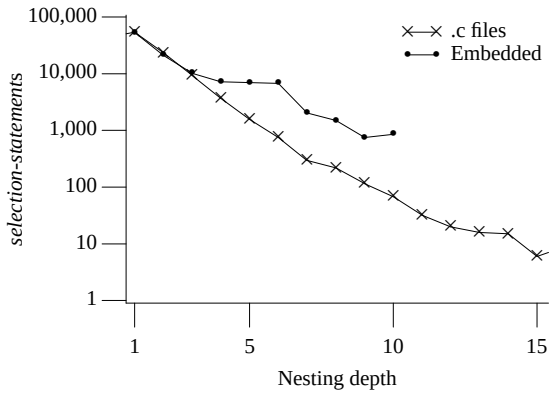

Figure 1739.2: Number of `selection-statement`s having a given maximum nesting level for embedded C[389] (whose data was multiplied by a constant to allow comparison; the data for nesting depth 5 was interpolated from the adjacent points). Based on the visible form of the `.c` files.

Selection statements choose one of several flows of control.

Coding Guidelines

The evaluation of a controlling expression is used to select the flow of control. The issue of side effects occurring during the evaluation is frequently discussed by developers and writers of coding guideline documents. Experience suggests that the following are the primary reasons for developers to write controlling expressions containing side effects:

- A belief that the resulting machine code is more efficient. In many cases this belief is false. For instance, most translators generate the same machine code generated for:

```
1   if (x = y)
```

  and:

```
1   x=y;
2   if (x != 0)
```

- Reducing the effort needed to organize the layout of the visible source, when writing it. For instance, an assignment inside a series of nested **`if`** statements would require the use of braces:

```
if (x = y)
   /* ... */
```

might have to be written as:

```
{
x=y;
if (x != 0)
   /* ... */
}
```

Neither of these reasons could be said to contain an actual benefit. The cost associated with side effects in controlling expressions is the possibility that they will go unnoticed by a reader of the source (especially if scanning along the left edge looking for assignments).

reading 770 kinds of

The most common form of side effect in a controlling expression is assignment, in particular simple assignment. The case where the author of the code intended to type an equality operator, rather than a simple assignment operator is a fault and these coding guidelines are not intended to recommend against the use of constructs that are obviously faults. However, it is possible that a reader of the visible source will mistake a simple assignment for an equality operator (the token **==** is much more likely than **=** in the context of a controlling expression) and reducing the likelihood of such a mistake occurring is also a cost reduction.

guidelines 0 not faults

controlling 1740 expression if statement

This discussion has referred to controlling expressions as if these costs and benefits apply to their use in all contexts (i.e., selection and iteration statements). The following example shows that writing code to avoid the occurrence of side effects in controlling expressions contained with iteration statements requires two, rather than one, assignments to be used.

```
extern int glob_1,
           glob_2;

void f_1(void)
{
if (glob_1 = glob_2)
   ;
while ((glob_1 = glob_2 + 1) != 3)
   { /* ... */ }
}

void f_2(void)
{
   {
   glob_1 = glob_2;     /* Single statement. */
   if (glob_1 != 0)
      ;
   }

glob_1 = glob_2 + 1;    /* Statement 1: always occurs. */
while (glob_1 != 3)
   {
   /* ... */
   glob_1 = glob_2 + 1; /* Statement 2: occurs after every iteration. */
   }
}
```

Duplicating the assignment to `glob_1` creates a maintenance dependency (any changes to one statement need to be reflected in the other). The increase in cost caused by this maintenance dependency is assumed to be greater than the cost reduction achieved from reducing the likelihood of a simple assignment operator being mistaken treated as an equality operator.

Cg 1740.1 The simple assignment operator shall not occur in the controlling expression of an **if** statement.

Experience has shown that there are a variety of other constructs, appearing in a controlling expression, that developer have difficulty comprehending, or simply miscomprehend when scanning the source. However, no other constructs are discussed here. The guideline recommendation dealing with the use of the assignment operator has the benefit of simplicity and frequency of occurrence. It was difficult enough analyzing the cost/benefit case for simple assignment and others are welcome to address more complicated cases.

Experience shows that many developers use the verbal form "if expression is not true then" when thinking about the condition under which an **else** form is executed. This use of *not* can lead to double negatives when reading some expressions. For instance, possible verbal forms of expressing the conditions under which the arms of an **if** statement are executed include:

```
1  if (!x)
2     a(); /* Executed if not x.               */
3  else
4     b(); /* Executed if not x is not true.   */
5          /* Executed if not x is equal to 0. */
6          /* Executed if x is not equal to 0. */
7
8  if (x != y)
9     c(); /* Executed if x is not equal to y.             */
10 else
11    d(); /* Executed if x is not equal to y is not true. */
```

The possible on linguistic impact of the ! operator on expression comprehension is discussed elsewhere. 1103 ! operand type

Cg 1740.2

The top-level operator in the controlling expression of an **if** statement shall not be ! or != when that statement also contains an **else** arm.

If the value of the controlling expression is known a translation time, the selection statement may contain dead code and the controlling expression is redundant. These issues are discussed elsewhere. 190 dead code 190 redundant code

Usage

In the translated form of this book's benchmark programs 1.3% of *selection-statement*s and 4% of *iteration-statement*s have a controlling expression that is a constant expression. Use of simple, non-iterative, flow analysis enables a further 0.6% of all controlling expressions to be evaluated to a constant expression at translation time.

1741 A selection statement is a block whose scope is a strict subset of the scope of its enclosing block. block selection statement

Commentary

```
enum {a, b};

int different(void)
{
    if (sizeof(enum {b, a}) != sizeof(int))
        return a;  // a == 1
    return b;  // which b?
}
```

Rationale

In C89, the declaration enum {b, a} persists after the if-statement terminates; but in C99, the implied block that encloses the entire **if** statement limits the scope of that declaration; therefore the different function returns different values in C89 and C99. The Committee views such cases as unintended artifacts of allowing declarations as operands of cast and **sizeof** operators; and this change is not viewed as a serious problem.

See the following C sentence for a further discussion on the rationale. 1742 block selection sub-statement

C90

See Commentary.

C++

The C++ behavior is the same as C90. See Commentary.

Coding Guidelines

Developers are more likely to be tripped up by the lifetime issues associated with compound literals than enumeration constants. For instance in:

```
1  if (f(p=&(struct S){1, 2}))
2     /* ... */
3  val=p->mem_1;
```

the lifetime of the storage whose address is assigned to `p` ends when the execution of the **`if`** statement terminates. Ensuring that developers are aware of this behavior is an educational issue. However, developers intentionally relying on the pointed-to storage continuing to exist (which it is likely to, at least until storage needs to be allocated to another object) is a potential guideline issue. However, until experience has been gained on how developers use compound literals it is not known whether this issue is simply an interesting theoretical idea of a real practical problem.

---

block selection sub-statement

Each associated substatement is also a block whose scope is a strict subset of the scope of the selection statement. 1742

Commentary

Rationale

A new feature of C99: A common coding practice is always to use compound statements for every selection and iteration statement because this guards against inadvertent problems when changes are made in the future. Because this can lead to surprising behavior in connection with certain uses of compound literals (§6.5.2.5), the concept of a block has been expanded in C99.

Given the following example involving three different compound literals:

```
extern void fn(int*, int*);

int examp(int i, int j)
{
    int *p, *q;

    if (*(q = (int[2]){i, j}))
        fn(p = (int[5]){9, 8, 7, 6, 5}, q);
    else
        fn(p = (int[5]){4, 3, 2, 1, 0}, q + 1);

    return *p;
}
```

it seemed surprising that just introducing compound statements also introduced undefined behavior:

```
extern void fn(int*, int*);

int examp(int i, int j)
{
    int *p, *q;
```

```
    if (*(q = (int[2]){i, j})) {
        fn(p = (int[5]){9, 8, 7, 6, 5}, q);
    } else {
        fn(p = (int[5]){4, 3, 2, 1, 0}, q + 1);
    }

    return *p;  // undefined--no guarantee *p designates an object
}
```

Therefore, the substatements associated with all selection and iteration statements are now defined to be blocks, even if they are not also compound statements. A compound statement remains a block, but is no longer the only kind of block. Furthermore, all selection and iteration statements themselves are also blocks, implying no guarantee that `*q` in the previous example designates an object, since the above example behaves as if written:

```
extern void fn(int*, int*);

int examp(int i, int j)
{
    int *p, *q;

    {
        if (*(q = (int[2]){i, j})) {
            // *q is guaranteed to designate an object
            fn(p = (int[5]){9, 8, 7, 6, 5}, q);
        } else {
            // *q is guaranteed to designate an object
            fn(p = (int[5]){4, 3, 2, 1, 0}, q + 1);
        }
    }

    // *q is not guaranteed to designate an object

    return *p;  // *p is not guaranteed to designate an object
}
```

If compound literals are defined in selection or iteration statements, their lifetimes are limited to the implied enclosing block; therefore the definition of “block” has been moved to this section. This change is compatible with similar C++ rules.

C90

The following example illustrates the rather unusual combination of circumstances needed for the specification change, introduced in C99, to result in a change of behavior.

```
1  extern void f(int);
2  enum {a, b} glob;
3
4  int different(void)
5  {
6  if (glob == a)
7                        /* No braces.                                          */
8     f((enum {b, a})1); /* Declare identifiers with same name and compatible type. */
9
10 return b;  /* C90: numeric value 1 */
11            /* C99: numeric value 0 */
12 }
```

C++

The C++ behavior is the same as C90.

Coding Guidelines

using braces
block
compound 1729
statement
syntax

Some coding guideline documents recommend that the block associated with both selection and iteration statements always be bracketed with braces (i.e., that it is always a compound statement). When the compound statement contains a single statement the use of braces is redundant and their presence decreases the amount of information visible on a display (the number of available lines is fixed and each brace usually occupies one line). However, experience has shown that in some cases the presence of these braces can:

- Provide additional visual cues that can reduce the effort needed, by readers, to comprehend a sequence of statements. However, the presence of these redundant braces reduces the total amount of information immediately visible, to a reader, on a single display (i.e., the amount of source code that can be seen without expending motor effort giving editor commands to change the display contents). The way in which these costs and benefits trade-off against each other is not known.

cost/accuracy 0
trade-off

- Help prevent faults being introduced when code is modified (i.e., where a modification results in unintended changes to the syntactic bindings of blocks to statement headers). Experience shows that nested **if** statements are the most common construct whose modification results in unintended changes to the syntactic bindings of blocks.

statement 1707
header

In the following example the presence of braces provides both visual cues that the **else** does not bind to the outer **if** and additional evidence (its indentation provides counter evidence because it provides an interpretation that the intent is to bind to the inner **if**.

```
1  void f(int i)
2  {
3  if (i > 8)
4     if (i < 20)
5        i++;
6  else
7     i--;
8
9  if (i > 8)
10    {
11    if (i < 20)
12       i++;
13 else
14    i--;
15    }
16 }
```

Blocks occur in a number of statements, is there a worthwhile cost/benefit in guideline recommendation specifying that these blocks always be a compound statement?

The block associated with a **switch** statement is invariably a compound statement. A guideline recommendation that braces be used is very likely to be redundant in this case. Iteration statements are not as common as selection statements and much less likely to be nested (in other iteration statements) than selection statements (compare Figure 1739.2 and Figure 1763.2), and experience suggests developer comprehension of such constructs is significantly affected by the use of braces. Experience suggests that the nested **if** statement is the only construct where the benefit of the use of braces is usually greater than the cost.

Cg 1742.1

The statement forming the block associated with either arm of an **if** statement shall not be an **if** statement.

6.8.4.1 The if statement

Constraints

1743 The controlling expression of an **if** statement shall have scalar type.

if statement controlling expression scalar type

Commentary

Although the type **_Bool** was introduced in C99 the Committee decided that there was too much existing code to change the specification for the controlling expression type.

C++

The value of a condition that is an expression is the value of the expression, implicitly converted to ***bool*** *for statements other than* ***switch****; if that conversion is ill-formed, the program is ill-formed.* 6.4p4

If only constructs that are available in C are used the set of possible expressions is the same.

Other Languages

In many languages the controlling expression is required to have a boolean type. Languages whose design has been influenced by C often allow the controlling expression to have scalar type.

Coding Guidelines

The broader contexts in which readers need to comprehend controlling expression are discussed elsewhere. This subsection concentrates on the form of the controlling expression. 1739 selection statement syntax

The value of a controlling expression is used to make one of two choices. Values used in this way are generally considered to have a boolean role. Some languages require the controlling expression to have a boolean type and their translators enforce this requirement. Some coding guideline documents contain recommendations that effectively try to duplicate this boolean type requirement found in other languages. Recommendations based on type not only faces technical problems in their wording and implementation (caused by the implicit promotions and conversions performed in C), but also fail to address the real issues of developer comprehension and performance.

In the context of an **if** statement do readers of the source distinguish between expressions that have two possible values (i.e., boolean roles), and expressions that may have more than two values being used in a context where an implicit test against zero is performed? Is the consideration of boolean roles a cultural baggage carried over to C by developers who have previously used them in other languages? Do readers who have only ever programmed in C make use of boolean roles, or do they think in terms of *a test against zero*? In the absence of studies of developer mental representations of algorithmic and source code constructs, it is not possible to reliably answer these questions. Instead the following discussion looks at the main issues involved in making use of boolean roles and making use of the implicit *a test against zero* special case.

A boolean role is not about the type of an expression (prior to the introduction of the type **_Bool** in C99, a character type was often used as a stand-in), but about the possible values an expression may have and how they are used. The following discussion applies whether a controlling expression has an integer, floating, or pointer type.

In some cases the top-level operator of a controlling expression returns a result that is either zero or one (e.g., the relational and equality operators). The visibility, in the source, of such an operator signals its boolean role to readers. However, in other cases (see Table 1763.2) developers write controlling expressions that do not contain explicit comparisons (the value of a controlling expression is implicitly compared against zero). What are the costs and benefits of omitting an explicit comparison? The following code fragment contains examples of various ways of writing a controlling expression:

```
1  if (flag)            /* 1 */
2     /* ... */
3
4  if (int_value)       /* 2 */
5     /* ... */
6
7  if (flag == TRUE)    /* 3 */
8     /* ... */
9
10 if (int_value != 0)  /* 4 */
11    /* ... */
```

Does the presence of an explicit visual (rather than an implicit, in the developers mind) comparison reduce either the cognitive effort needed to comprehend the **if** statement or the likelihood of readers making mistakes? Given sufficient practice readers can learn to automatically process `if (x)` as if it had been written as `if (x != 0)`. The amount of practice needed to attain an automatic level of performance is unknown. Another unknown is the extent to which the token sequence `!= 0` acts as a visual memory aid.

When the visible form of the controlling expression is denoted by a single object (which may be an ordinary identifier, or the member of a structure, or some other construct where a value is obtained from an object) that name may provide information on the values it represents. To obtain this information readers might make use of the following:

- *Software development conventions.* In the software development community (and other communities) the term *flag* is generally understood to refer to something that can be in one of two states. For instance, the identifier `mimbo_flag` is likely to be interpreted as having two possible values relating to a *mimbo*, rather than referring to the national flag of Mimbo. Some naming conventions contain a greater degree of uncertainty than others. For instance, identifiers whose names contain the character sequence *status* sometimes represent more than two values.
- *Natural language knowledge.* Speakers of English regard some prepositions as being capable of representing two states. For instance, a cat *is* or *is not* black. This natural language usage is often adopted when selecting identifier names. For instance, `is_flobber` is likely to be interpreted as representing one of two states (being a, or having the attribute of, *flobber* or not).
- *Real world knowledge.* A program sometimes needs to take account of information from the *real world*. For instance, height above the ground is an important piece of information in an airplane flight simulator, with zero height having a special status.
- *Application knowledge.* The design of a program invariably makes use of knowledge about the application domain it operates within. For instance, the term `ziffer` may be used within the application domain that a program is intended to operate. Readers of the source will need the appropriate application knowledge to interpret the role of this identifier.
- *Program implementation conventions.* The design of a program involves creating and using various conventions. For instance, a program dealing with book printing may perform special processing for books that don't contain any pages (e.g., `num_pages` being zero is a special case).
- *Conventions and knowledge from different may be mixed together.* For instance, the identifier name `current_color` suggests that it represents color information. This kind of information is not usually thought about in terms of numeric values and there are certainly more than two colors. However, assigning values to symbolic qualities is a common software development convention, as is assigning a special interpretation to certain values (e.g., using zero to represent no known color, a program implementation convention).

The likelihood of a reader assuming that an identifier name has a boolean role will depend on the cultural beliefs and conventions they share with the author of the source. There is also the possibility that rather than

using the identifier name to deduce a boolean role, readers may use the context in which it occurs to infer a boolean role. This is an example of trust based usage. Requiring that values always be compared (against true/false or zero/nonzero) leads to infinite regression, as in the sequence:

476 boolean role
792 trust based usage

```
1  if (flag)
2  if (flag == TRUE)
3  if ((flag == TRUE) == TRUE)
4  and so on...
```

At some point readers have to make a *final* comparison in their own mind. The inability to calculate (i.e., automatically enforceable) the form a controlling expression should take to minimize readers cognitive effort prevents any guideline recommendations being made here.

Semantics

1744 In both forms, the first substatement is executed if the expression compares unequal to 0.

if statement operand compare against 0

Commentary

Depending on the type of the other operand this 0 may be converted to an integer type of greater rank, a floating-point `0.0`, or a null pointer constant.

748 null pointer constant

C++

The C++ Standard expresses this behavior in terms of true and false (6.4.1p1). The effect is the same.

Other Languages

In languages that support a boolean type this test is usually expressed in terms of **`true`** and **`false`**.

Common Implementations

The machine code generation issues are similar to those that apply to the logical operators. The degree to which this comparison can be optimized away depends on the form of the controlling expression and the processor instruction set. If the controlling expressions top-level operator is one that always returns a value of zero or one (e.g., an equality or relational operator), it is possible to generate machine code that performs a branch rather than returning a value that is then compared. Some processors have a single instruction that performs a comparison and branch, while others have separate instructions (the comparison instruction setting processor condition flags that are then tested by a conditional branch instruction). On some processors simply loading a value into a register also results in a comparison against zero being made, with the appropriate processor condition flags being set. The use of conditional instructions is discussed elsewhere.

1111 logical negation result is
1250 && operand compare against 0
1739 conditional instructions

The machine code for the first substatement is often placed immediately after the code to evaluate the controlling expression. However, optimizers may reorder blocks of code in an attempt to maximize instruction cache utilization.

1710 basic block

1745 In the **`else`** form, the second substatement is executed if the expression compares equal to 0.

else

Commentary

Implementations are required to ensure that exactly one of the equality comparisons is true.

1221 equality operators exactly one relation is true

Coding Guidelines

Some coding guideline documents recommend that the **`else`** form always be present, even if it contains no executable statements. Such a recommendation has the benefit of ensuring that there are never any mismatching **`if`**/**`else`** pairs. However, then the same effect can be achieved by requiring nested **`if`** statements to be enclosed in braces (this issue is discussed elsewhere). The cost of adding empty **`else`** forms increases the amount of source code that may need to be read and in some cases decrease in the amount of non-null source that appears on a display device. Such a guideline recommendation does not appear worthwhile.

1742 using braces block

Usage

In the visible form of the .c files 21.5% of **if** statements have an **else** form. (Counting all forms of *if* supported by the preprocessor, with **#elif** counting as both an *if* and an *else*, there is an **#else** form in 25.0% of cases.)

If the first substatement is reached via a label, the second substatement is not executed. 1746

Commentary

The flow of control of a sequence of statements is not influenced by how they were initially reached, in the flow of control. The label may be reached as a result of executing a **switch** statement, or a **goto** statement. The issue of jumping into nested blocks or the body of iteration statements is discussed elsewhere.

switch 1753 statement causes jump
goto 1789 causes unconditional jump
jump 1783 statement causes jump to
iteration 1766 statement executed repeatedly

C++

The C++ Standard does not explicitly specify the behavior for this case.

Other Languages

This statement applies to all programming languages that support jumps into more deeply nested blocks.

---

else binds to nearest if

An **else** is associated with the lexically nearest preceding **if** that is allowed by the syntax. 1747

Commentary

selection 1739 statement syntax

As it appears in the standard the syntax for **if** statements is ambiguous on how an **else** should be associated in a nested **if** statement. This semantic rule resolves this ambiguity.

Other Languages

Languages that support nesting of conditional statements need a method of resolving which construct an **else** binds to. The rules used include the following:

- Not supporting in the language syntax unbracketed nesting (i.e., requiring braces or **begin**/**end** pairs) within the *then* arm. For instance, Algol 60 permits the usage `IF q1 THEN a1 ELSE IF q2 THEN a2 ELSE a3`, but the following is a syntax violation `IF q1 THEN IF q2 THEN a1 ELSE a2 ELSE a3`.
- Using a matching token to pair with the **if**. The keyword **fi** is a common choice (used by Ada, Algol 68, while the C preprocessor uses **endif**). In this case the bracketing formed by the **if**/**fi** prevents any ambiguity occurring.
- Like C— using the *nearest preceding* rule.

Coding Guidelines

if statement 1742.1 block not an if statement

If the guideline recommendation on using braces is followed there will only ever be one lexically preceding **if** that an **else** can be associated with. Some coding guideline documents recommend that an **if** statement always have an associated **else** form, even if it only contains the null statement.

null statement 1733

6.8.4.2 The switch statement

Constraints

---

switch statement

The controlling expression of a **switch** statement shall have integer type. 1748

Commentary

A **switch** statement uses the exact value of its controlling expression and it is not possible to guarantee the exact value of an expression having a floating type (there is a degree of unpredictability in the value between different implementations). For this reason implementations are not required to support controlling expressions having a floating type.

C++

> *The condition shall be of integral type, enumeration type, or of a class type for which a single conversion function to integral or enumeration type exists (12.3).* 6.4.2p2

If only constructs that are available in C are used the set of possible expressions is the same.

Common Implementations

The base document did not support the types **long** and **unsigned long**. Support for integer types with rank greater than **int** was added during the early evolution of C.[1180]

Other Languages

There are some relatively modern languages (e.g., Perl) that do not support a **switch** statement. Java does not support controlling expressions having type **long**. Some languages (e.g., PHP) support controlling expressions having a string type.

Coding Guidelines

A controlling expression, in a **switch** statement, having a boolean role might be thought to be unusual, an **if** statement being considered more appropriate. However, the designer may be expecting the type of the controlling expression to evolve to a non-boolean role, or the **switch** statement may have once contained more **case** labels.

Table 1748.1: Occurrence of **switch** statements having a controlling expression of the given type (as a percentage of all **switch** statements). Based on the translated form of this book's benchmark programs.

Type	%	Type	%
int	29.5	bit-field	3.1
unsigned long	18.7	**unsigned short**	2.8
enum	14.6	**short**	2.5
unsigned char	12.4	**long**	0.9
unsigned int	10.0	other-types	0.2
char	5.1		

1749 If a **switch** statement has an associated **case** or **default** label within the scope of an identifier with a variably modified type

switch past variably modified type

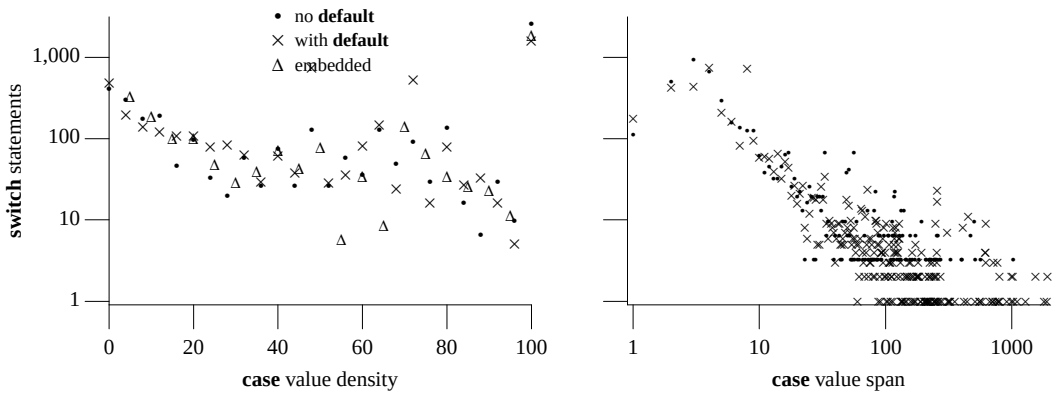

Figure 1748.1: *Density* of **case** label values (calculated as (maximum **case** label value minus minimum **case** label value minus one) divided by the number of **case** labels associated with a **switch** statement) and span of **case** label values (calculated as (maximum **case** label value minus minimum **case** label value minus one)). Based on the translated form of this book's benchmark programs and embedded results from Engblom[389] (which were scaled, i.e., multiplied by a constant, to allow comparison). The *no* ***default*** results were scaled so that the total count of **switch** statements matched those that included a **default** label.

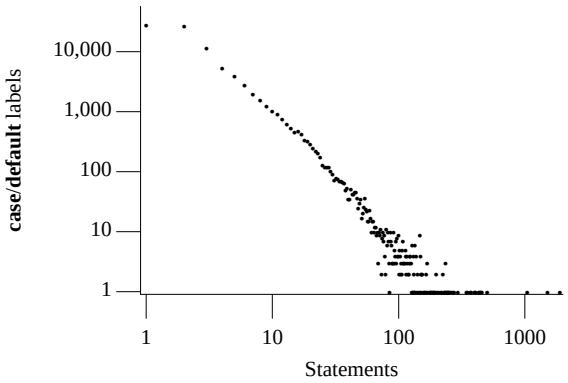

Figure 1748.2: Number of **case/default** labels having s given number of statements following them (statements from any nested **switch** statements did not contribute towards the count of a label). Based on the visible form of the `.c` files.

modified type, the entire **switch** statement shall be within the scope of that identifier.[133)]

Commentary

The declaration of an identifier having variable modified type can occur in one of the sequence of statements labeled by a **case** or **default**, provided it appears within a compound statement that does not contain any other **case** or **default** labels associated with that **switch** statement, or it appear after the last **case** or **default** label in the **switch** statement. In the compound statement case the variably modified type will not be within the scope of any **case** or **default** labels (its lifetime terminates at the end of the compound statement).

The wording of the requirement is overly strict in that it prohibits uses that might be considered well behaved. For instance:

```
1   switch (i)
2      {
3      case 1:
4            int x[n];
5            /* ... */
6            break;
7
8      case 2:
9            /* Statements that don't access x. */
10     }
```

Attempting to create wording to support such edge cases was considered to be a risk (various ambiguities may later be found in it) that was not worth the benefit. Additional rationale for this requirement is discussed elsewhere.

goto 1788 past variably modified type

C90

Support for variably modified types is new in C99.

C++

Support for variably modified types is new in C99 and is not specified in the C++ Standard.

The C++ Standard contains the additional requirement that (the wording in a subsequent example suggests that being visible rather than *in scope* is more accurate terminology):

6.7p3 *It is possible to transfer into a block, but not in a way that bypasses declarations with initialization. A program that jumps[77)] from a point where a local variable with automatic storage duration is not in scope to a point where it is in scope is ill-formed unless the variable has POD type (3.9) and is declared without an* `initializer` *(8.5).*

```
void f(void)
{
switch (2)
   {
   int loc = 99; /* strictly conforming */
                 // ill-formed

   case 2: return;
   }
}
```

Example

```
extern int glob;

void f(int p_loc)
{
switch (p_loc) /* This part of the switch statement is not within the scope of a_1. */
   {
   case 1: ;
           int a_1[glob]; /* This declaration causes a constraint violation. */

   case 2: a_1[2] = 4;
           break;

   case 3: {
           long a_2[glob]; /* Conforming: no case label within the scope of a_2. */
           /* ... */
           }
           break;
   }
}
```

1750 The expression of each **case** label shall be an integer constant expression and no two of the **case** constant expressions in the same **switch** statement shall have the same value after conversion.

case label unique in same switch

Commentary

Two case labels having the same value is effectively equivalent to declaring two labels, within the same function, having the same name.

Coding Guidelines

Some sequences of case label values might be considered to contain suspicious entries or omissions. For instance, a single value that is significantly larger or smaller than the other values (an island), or a value missing from the middle of a contiguous sequence of values (a hole). While some static analysis tools check for such *suspicious values*, it is not clear to your author what, if any, guideline recommendation would be worthwhile.

1751 There may be at most one **default** label in a **switch** statement.

default label at most one

Commentary

A **default** label is the destination of a jump for some, possible empty, set of values of the controlling expression. As such it is required to be unique (if it occurs) within a **switch** statement.

A bug in the terminology being used in the standard "may" ⇒ "shall".

Coding Guidelines

Some coding guideline documents recommend that all **switch** statements contain a **default** label. There does not appear to be an obvious benefit (as defined by these coding guideline subsections, although there may be benefits for other reasons) for such a guideline recommendation. To adhere to the guideline developers simply need to supply a **default** label and an associated null statement. There are a number of situations where adhering to such a guideline recommendation leads to the creation of redundant code (e.g., if all possible values are covered by the **case** labels, either because they handle all values that the controlling expression can take or because execution of the **switch** statement is conditional on an **if** statement that guarantees the controlling expression is within a known range).

redundant code 190

Usage

In the visible form of the `.c` files, 72.8% of **switch** statements contain a **default** label.

(Any enclosed **switch** statement may have a **default** label or **case** constant expressions with values that duplicate **case** constant expressions in the enclosing **switch** statement.) 1752

Commentary

This specification (semantics in a Constraints clause) clarifies the interpretation to be given to the phrase "in the same **switch** statement" appearing earlier in this Constraints clause.

case label unique in same switch 1750

Semantics

---

switch statement causes jump

A **switch** statement causes control to jump to, into, or past the statement that is the *switch body*, depending on the value of a controlling expression, and on the presence of a **default** label and the values of any **case** labels on or in the switch body. 1753

Commentary

This defines the term *switch body*. Developers also use the terminology *body of the switch*.

It is possible to write a **switch** statement as an equivalent sequence of **if** statements. However, experience shows that in some cases the **switch** statement appears to require less significantly less (cognitive) effort to comprehend than a sequence of **if** statements.

Common Implementations

Many processors include some form of instruction (often called an *indirect jump*) that indexes into a table (commonly known as a *jump table*) to obtain a location to jump to. The extent to which it is considered to be more efficient to use such an instruction, rather than a series of **if** statements varies between processors (whose behavior varies for the case where the index is out of range of the jump table) and implementations (the sophistication of the available optimizer). The presence of a **default** label creates additional complications in that all values of the controlling expression, not covered by a **case** label, need to be explicitly handled. Spuler[1275] discusses the general issues.

Some translators implement **switch** statements as a series of **if** statements. Knowledgeable developers know that, in such implementations, placing the most frequently executed **case** labels before the less frequently executed ones can provide a worthwhile performance improvement. Some translators[20,578] provide an option that allows the developer to specify whether a jump table or sequence of **if** statements should to be used.

Optimal execution time performance is not the only factor that implementations need to consider. The storage occupied by the jump table sometimes needs to be taken into account. In a simple implementation it is proportional to the difference between the maximum and minimum values appearing in the **case** labels (which may not be considered an efficient use of storage if there are only a few case labels used within this range). A more sophisticated technique than using a series of **if** statements is to create a binary tree of **case** label values and jump addresses. The value of the controlling expression being used to walk this tree to obtain the destination address. Some optimizers split the implementation into a jump table for those **case** label values that are contiguous and a binary tree for the out lying values.

Translator vendors targeting modern processors face an additional problem. Successful processors often contain a range of different implementations, creating a processor family, (e.g., the Intel Pentium series). These different processor implementations usually have different performance characteristics, and in the case of the **switch** statement different levels of sophistication in branch prediction. How does a translator make the decision on whether to use a jump table or **if** statements when the optimal code varies between different implementations of a particular processor?

A study by Uh and Whalley[1387] compared (see Table 1753.1) the performance of a series of **if** statements and the equivalent jump table implementation. For three of the processors it was worth using a jump table when there were more than two **if** statements were likely to be executed. In the case of the UltraSPARC-1 the figure was more than eight **if** statements executed (this was put down to the lack hardware support for branch prediction of indirect jumps).

Table 1753.1: Performance comparison (in seconds) of some implementation techniques for a series of **if** statements (contained in a loop that iterated 10,000,000 times) using (1) linear search (LS), or (2) indirect jump (IJ), for a variety of processors in the SPARC family. *br* is the average number of branches per loop iteration. Based on Uh and Whalley.[1387]

Processor Implementation	2.5br LS	4.5br LS	8.5br LS	2.5br IJ	4.5br IJ	8.5br IJ
SPARCstation-IPC	3.82	5.53	8.82	2.61	2.71	2.76
SPARCstation-5	1.03	1.65	2.74	0.63	0.76	0.76
SPARCstation-20	0.93	1.60	2.65	0.87	0.93	0.94
UltraSPARC-1	0.50	1.16	1.56	1.50	1.51	1.51

1754 A **case** or **default** label is accessible only within the closest enclosing **switch** statement.

Commentary

This requirement needs to be explicitly stated because there is no syntactic association between **case** labels and their controlling **switch** statement.

Coding Guidelines

The issue most likely to be associated with a nested **switch** statement is source layout (because the amount of indentation used is often greater than in nested **if** statements). However, nested **switch** statements are relatively uncommon. For this reason the issue of the comprehension effort needed for this form of nested construct is not discussed.

1707 statement visual layout

1755 The integer promotions are performed on the controlling expression.

Commentary

The rationale for performing the integer promotions is the same as that for the operands within expressions.

675 integer promotions

Common Implementations

When the controlling expression is denoted by an object having a character type the possible range of values is known to fit in a byte. Even relatively simple optimizers often check for, and make use of, this special case.

1756 The constant expression in each **case** label is converted to the promoted type of the controlling expression.

Commentary

Prior to this conversion the type of the constant expression associated with each **case** label is derived from the form of the literals and result type of the operators it contains. The relationship between the value of a **case** label and a controlling expression is not the same as that between the operands of an equality operator. The conversion may cause the rank of the case label value to be reduced. If the types of both expressions are unsigned it is possible for the **case** label value to change (e.g., a modulo reduction). Like all integer conversions undefined behavior may occur for some values and types.

Other Languages

Many languages have a single integer type, so there is no conversion to perform for **case** label values. Strongly typed languages usually require that the type of the **case** label value be compatible with the type of the controlling expression, there is not usually any implicit conversions. Enumerated constants are often defined to be separate types, that are not compatible with any integer type.

Coding Guidelines

This C sentence deals with the relationship between individual **case** label values and the controlling expression. The following points deal with the relationship between different **case** label values within a given **switch** statement:

- Mixing **case** labels whose values are represented using both character constants and integer constants is making use of representation information (in this context the macro `EOF` might be interpreted in its symbolic form of representing an end-of-file character, rather than an integer constant). There does not appear to be a worthwhile benefit in having a deviation that permits the use of the integer constant 0 rather than the character constant `'\0'`, on the grounds of improved reader recognition performance. The character constant `'\0'` is the most commonly occurring character constant (10% of all character constants in the visible form of the `.c` files, even if it only represents 1% of all constant tokens denoting the value 0).
- Mixing **case** labels whose values are represented using both enumeration constants and some other form of constant representation (e.g., an integer constant) is making use of the underlying representation of the enumerated constants. The same is also true if enumerated constants from different enumerations types are mixed.
- Mixing integer constants represented using decimal, hexadecimal, or octal lexical forms. The issue of visually mixing integer constants having different lexical forms is discussed elsewhere.

form of representation mixing 1875

equality operators not floating-point operands 1214.1

Floating point literals are very rarely seen in **case** labels. The guideline recommendation dealing with exact comparison of floating-point values is applicable to this usage.

Example

```
#include <limits.h>

enum {red, green, blue};

extern int glob;

void f(unsigned char ch)
{
switch (ch)
   {
   case 'a': glob++;
             break;

   case green: glob+=2;
               break;

   case (int)7.0: glob--;
                  break;

   case 99: glob -= 9;
            break;

   case ULONG_MAX: glob *= 3;
                   break;
   }
}
```

1757 If a converted value matches that of the promoted controlling expression, control jumps to the statement following the matched **case** label.

Commentary

A **case** label can appear on any statement in the **switch** body.

```
switch (x)
   default : if (prime(x))
                case 2: case 3: case 5: case 7:
                   process_prime(x);
             else
                case 4: case 6: case 8: case 10:
                   process_composite(x);
```

There can be more practical uses for this functionality. 1766 Duff's Device

Coding Guidelines

Experience suggests that developers treat the case label value as being the result of evaluating the expression appearing in the source (i.e., that no conversion, driven by the type of the controlling expression, takes place). A conversion that causes a change of value is very suspicious. However, no instances of such an event occur in the Usage `.c` files or have been experienced by your author. Given this apparent rarity no guideline recommendation is made here.

1758 Otherwise, if there is a **default** label, control jumps to the labeled statement.

Commentary

A **switch** statement may be thought of as a series of **if** statements with the **default** label representing the final **else** arm (although other **case** labels may label the same statement as a **default** label).

Common Implementations

Having a **default** label may not alter the execution time performance of the generated machine code. All of the tests necessary to determine that the default label should be jumped to are the same as those necessary to determine that no part of the switch should be executed (if there is no **default** label).

1759 If no converted **case** constant expression matches and there is no **default** label, no part of the switch body is executed.

Commentary

This behavior is the same as that of a series of nested **if** statements. If all of their controlling expressions are false and there is no final **else** arm, none of the statement bodies is executed.

Other Languages

Some languages require that there exist a **case** label value, or **default**, that matches the value of the controlling expression. If there is no such matching value the behavior may be undefined (e.g., Pascal specifies it is a *dynamic-violation*) or even defined to raise an exception (e.g., Ada).

Coding Guidelines

The coding guideline issue of always having a **default** label is discussed elsewhere. 1751 default label at most one

Implementation limits

1760 As discussed in 5.2.4.1, the implementation may limit the number of **case** values in a **switch** statement.

Commentary

This observation ought really to be a Further reference subclause. 296 limit case labels

footnote 133

133) That is, the declaration either precedes the **switch** statement, or it follows the last **case** or **default** label associated with the **switch** that is in the block containing the declaration. 1761

Commentary

If the declaration is not followed by any **case** or **default** labels, all references to the identifier it declares can only occur in the statements that follow it (which can only be reached via a jump to preceding **case** or **default** labels, unless a **goto** statement jumps to an ordinary label within the statement list occurs).

EXAMPLE case fall through

EXAMPLE In the artificial program fragment 1762

```
switch (expr)
{
        int i = 4;
        f(i);
case 0:
        i = 17;
        /* falls through into default code */
default:
        printf("%d\n", i);
}
```

the object whose identifier is **i** exists with automatic storage duration (within the block) but is never initialized, and thus if the controlling expression has a nonzero value, the call to the **printf** function will access an indeterminate value. Similarly, the call to the function **f** cannot be reached.

Commentary

static storage duration 151
initialized before startup

Objects with static storage duration are initialized on program startup.

```
1  switch (i)
2     {
3     static char message[] = "abc"; /* Not dependent on control flow. */
4     case 0:
5          f(message);
6          break;
7     case 1:
8          /* ... */
9     }
```

case 1727 fall through
switch 1749 past variably modified type

Other issues associated with constructs contained in this example are discussed elsewhere.

6.8.5 Iteration statements

iteration statement syntax

1763

iteration-statement:

while **(** *expression* **)** *statement*
do *statement* **while** **(** *expression* **)** **;**
for **(** $expression_{opt}$ **;** $expression_{opt}$ **;** $expression_{opt}$ **)** *statement*
for **(** *declaration* $expression_{opt}$ **;** $expression_{opt}$ **)** *statement*

Commentary

The terms *loop header* or *head of the loop* are sometimes used to refer to the source code location containing the controlling expression of a loop (in the case of a **for** statement it might be applied to all three components bracketed by parentheses).

It is often claimed that programs spend 90% of their time executing 10% of their code. This characteristic is only possible if the time is spent in a subset of the programs iteration statements, or a small number of functions called within those statements. While there is a large body of published research on program

performance, there is little evidence to back up this claim (one study[1316] found that 88% of the time was spent in 20% of the code, while analysis[1422] of some small embedded applications found that 90% of the time was spent in loops). It may be that researchers are attracted to applications which spend their time in loops because there are often opportunities for optimization. Most of existing, published, execution time measurements are based on engineering and scientific applications, for database oriented applications[1141] and operating systems[1358] loops have not been found to be so important.

The **;** specified as the last token of a **do** statement is not needed to reduce the difficulty of parsing C source. It is simply part of an adopted convention.

C90

Support for the form:

for (*declaration* $expr_{opt}$ **;** $expr_{opt}$ **)** *statement*

is new in C99.

C++

The C++ Standard allows local variable declarations to appear within all conditional expressions. These can occur in **if**, **while**, and **switch** statements.

Other Languages

Many languages require that the lower and upper bounds of a **for** statement be specified, rather than a termination condition. They usually use keywords to indicate the function of the various expressions (e.g., Modula-2, Pascal):

```
FOR I=start TO end BY step
```

Some languages (e.g., BCPL, Modula-2) require `step` to be a translation time constant. Both Ada or Pascal require **for** statements to have a step size of one. Ada uses the syntax:

```
for counter in 1..10
   loop
   ...
for counter in reverse 1..10
   loop
   ...
```

which also acts as the definition of `counter`.

Cobol supports a **PERFORM** statement, which is effectively a **while** statement.

```
        PERFORM UNTIL quantity > 1000
       * some code
        END-PERFORM
```

The equivalent looping constructs In Fortran is known as a **do** statement. A relatively new looping construct, at least in the Fortran Standard, is **FORALL**. This is used to express a looping computation in a form that can more easily be translated for parallel execution. Some languages (e.g., Modula-2, Pascal) use the keywords **repeat/until** instead of **do/while**, while other languages (e.g., Ada) do not support an iteration statement with a test at the end of the loop.

A few languages (e.g., Icon[234] which uses the term *generators*) have generalized the looping construct to provide what are commonly known as *iterators*. An iterator enumerates the members of a set (a mechanism for accessing each enumerated member is provided in the language), usually in some unspecified order, and has a loop termination condition.

Common Implementations

Many programs spend a significant percentage of their time executing iteration statements. The following are some of the ways in which processor and translator vendors have responded to this common usage characteristic:

Measuring implementations 0

translator optimizations 0

loop unrolling 1774

data dependency 988

cache 0

translator performance 0
vs. assembler
DSP processors 0

- Translator vendors wanting to optimize the quality of generated machine code have a number of optimization techniques available to them. A traditional loop optimization is strength reduction[277] (which replaces costly computations by less expensive ones), while more ambitious optimizers might perform hoisting of loop invariants and loop unrolling. Loop invariants are expressions whose value does not vary during the iteration of a loop; such expressions can be hoisted to a point just outside the start of the loop. Traditionally translators have only performed loop unrolling on **for** statements. (Translation time information on the number of loop iterations and step size is required; this information can often be obtained by from the expressions in the loop header, i.e., the loop body does not need to be analyzed.) More sophisticated optimizations include making use of data dependencies to order the accesses to storage. As might be expected with such a performance critical construct, a large number of other optimization techniques are also available.
- Processor vendors want to design processors that will execute programs as quickly as possible. Holding the executed instructions in a processor's cache saves the overhead of fetching them from storage and most processors cache both instructions and object values. Some processors (usually DSP) have what is known as a *zero overhead loop buffer* (effectively a software controlled instruction cache). The sequence of instructions in such a loop buffer can be repetitively executed with zero loop overhead (the total loop count may be encoded in the looping instruction or be contained in a register). Because of their small size (the Agere DSP16000[6] loop buffer has a limit of 31 instructions) and restrictions on instructions that may be executed (e.g., no instructions that change the flow of control) optimizers can have difficulty making good of such buffers.[1386] The characteristics of loop usage often means that successive array elements are accessed on successive loop interactions (i.e., storage accesses have spatial locality). McKinley and Temam[918] give empirical results on the effect of loops on cache behavior (based on Fortran source). Some CISC processors support a decrement/increment and branch on nonzero instruction;[319,615] ideal for implementing loops whose termination condition is the value zero (something that can be arranged in handwritten assembler, but which rarely happens in loops written in higher-level languages— Table 1763.1). The simplifications introduced by the RISC design philosophy did away with this kind of instruction; programs written in high-level languages did not contain enough loops of the right kind to make it cost effective supporting such an instruction. However, one application domain where a significant amount of code is still written in assembler (because of the comparatively poor performance of translator generated machine code) is that addressed by DSP processors, which often contain such decrement (and/or increment) branch instructions (the SC140 DSP core[972] includes hardware loop counters that support up to four levels of loop nesting). The C compiler for the Unisys e-@ction Application Development Solutions[1391] uses the `JGD` processor instruction to optimize the loop iteration test. However, this usage limits the maximum number of loop iterations to $2^{35} - 2$, a value that is very unlikely to be reached in a commercial program (a trade-off made by the compiler implementors between simplicity and investing effort to handle very rare situations).

Obtaining an estimate of the execution time of a sequence of statements may require estimating the number of times an iteration statement will iterate. Some implementations provide a mechanism for the developer to provide iteration count information to the translator. For instance, the translator for the TMS320C6000[1343] supports the following usage:

```
1   #pragma MUST_ITERATE (30) /* Will loop at least 30 times. */
```

Another approach is for the translator to deduce the information from the source.[557]

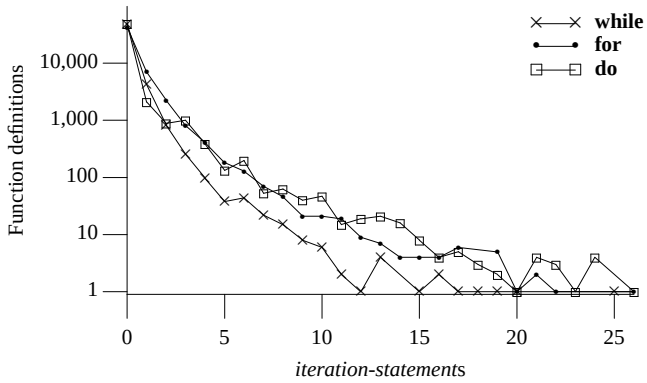

Figure 1763.1: Number of function definitions containing a given number of *iteration-statement*s. Based on the translated form of this book's benchmark programs.

Program loops may not always be expressed using an *iteration-statement* (for instance, they may be created using a **goto** statement). Ramalingam[1140] gives an algorithm for identifying loops in almost linear time.

Example

```
#include <stdio.h>

int f(unsigned char i, unsigned char j)
{
do
while (i++ < j)
   ;
while (i   > j++)
   ;

if (j != 0)
   printf("Initial value of i was greater than initial value of j\n");
}
```

Usage

A study by Bodík, Gupta, and Soffa[131] found that 11.3% of the expressions in SPEC95 were loop invariant.

Table 1763.1: Occurrence of various kinds of **for** statement controlling expressions (as a percentage of all such expressions). Where *object* is a reference to a single object, which may be an identifier, a member (e.g., `s.m`, `s->m->n`, or `a[expr]`); *assignment* is an assignment expression, *integer-constant* is an integer constant expression, and *expression* denotes expressions that contain arithmetic and shift operators. Based on the visible form of the `.c` files.

Abstract Form of **for** loop header	%
assignment ; identifier < identifier ; identifier **v++**	33.2
assignment ; identifier < *integer-constant* ; identifier **v++**	11.3
assignment ; identifier ; assignment	7.0
assignment ; identifier < expression ; identifier **v++**	3.3
assignment ; identifier < identifier ; **++v** identifier	2.7
; ;	2.5
assignment ; identifier != identifier ; assignment	2.5
assignment ; identifier <= identifier ; identifier **v++**	2.2
assignment ; identifier >= *integer-constant* ; identifier **v--**	1.6
assignment ; identifier < function-call ; identifier **v++**	1.4
assignment ; identifier < identifier ; identifier **v++** , identifier **v++**	1.4
others	31.1

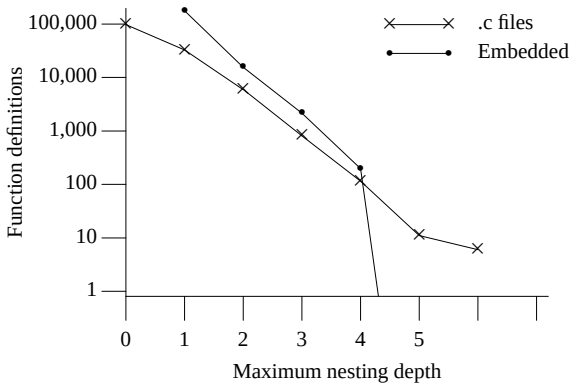

Figure 1763.2: Number of functions containing *iteration-statement*s nested to the given maximum nesting level; for embedded C[389] (whose data was multiplied by a constant to allow comparison) and the visible form of the `.c` files (zero nesting depth denotes functions not containing any *iteration-statement*s).

Table 1763.2: Occurrence of various kinds of **while** statement controlling expressions (as a percentage of all **while** statements). Where *object* is a reference to a single object, which may be an identifier, a member (e.g., `s.m`, `s->m->n`, or `a[expr]`); *assignment* is an assignment expression, *integer-constant* is an integer constant expression, and *expression* denotes expressions that contain arithmetic and shift operators. Based on the visible form of the `.c` files.

Abstract Form of Control Expression	%	Abstract Form of Control Expression	%
others	43.5	expression	2.2
object	12.2	`*v` object	2.0
object `!=` object	7.0	assignment	1.8
integer-constant	6.2	`!` object	1.6
object `<` object	4.7	`!` function-call	1.3
function-call	4.4	object `!=` *integer-constant*	1.2
object `>` *integer-constant*	4.0	object `v--` `>` *integer-constant*	1.1
object `v--`	3.2	`!` expression	1.0
assignment `!=` object	2.4		

Constraints

controlling expression iteration statement

The controlling expression of an iteration statement shall have scalar type. 1764

Commentary

if statement 1743 controlling expression scalar type

The issues here are the same as for controlling expressions in **if** statements.

Other Languages

Many languages do not support loop control variables having a pointer type (invariably because they do not support any form of pointer arithmetic).

Coding Guidelines

loop control variable 1774

The concept of *loop control variable* is discussed elsewhere.

for statement declaration part

The declaration part of a **for** statement shall only declare identifiers for objects having storage class **auto** or **register**. 1765

Commentary

loop control variable 1774

The intent is to support the declaration of an identifier that is used as a loop control variable. There are many people who believe that limiting the scope over which such control variables can be modified is a *good thing*. Another coding guideline related issue is that of declaration of identifiers occurring close to where they are used in statements (this issue is discussed elsewhere).

declaration 1348 syntax
statement 1707 syntax

Problem

Consider the code:

```
for (enum fred { jim, sheila = 10 } i = jim; i < sheila; i++)
     // loop body
```

Proposed Committee Response

The intent is clear enough; `fred`*,* `jim`*, and* `sheila` *are all identifiers which do not denote objects with* **`auto`** *or* **`register`** *storage classes, and are not allowed in this context.*

C90

Support for this functionality is new in C99.

C++

The `declarator` *shall not specify a function or an array. The* `type-specifier-seq` *shall not contain* **`typedef`** *and shall not declare a new class or enumeration.* 6.4p2

```
1  void f(void)
2  {
3  for (int la[10]; /* does not change the conformance status of the program */
4                   // ill-formed
5       ; ;)
6     ;
7  for (enum {E1, E2} le; /* does not change the conformance status of the program */
8                          // ill-formed
9       ; ;)
10    ;
11 for (static int ls; /* constraint violation */
12                     // does not change the conformance status of the program
13      ; ;)
14    ;
15 }
```

Other Languages

In some languages (e.g., Ada and Algol 68) the identifier used as a loop control variable in a **`for`** statement is implicitly declared to have the appropriate type (based on the type of the expressions denoting the start and end values).

Coding Guidelines

The ability to declare identifiers in this context is new in C99 and at the time of this writing there is insufficient experience with its use to know whether any guideline recommendation is worthwhile.

Semantics

1766 An iteration statement causes a statement called the *loop body* to be executed repeatedly until the controlling expression compares equal to 0.

iteration statement executed repeatedly loop body

Commentary

This defines the term *loop body*. The term *loop* is commonly used as a noun by developers to refer to constructs associated with iteration statements (which are rarely referred to as *iteration statements* by developers). For instance, the terms *loop statement*, or simply a *loop* are commonly used by developers.

if statement 1744 operand compare against 0

Execution of the loop may also terminate because a **break**, **goto**, or **return** statement is executed. The discussion on the evaluation of the controlling expression in an **if** statement is applicable here.

Duff's Device

It is often necessary to access a block of storage (e.g., to copy it somewhere else, or to calculate a checksum of its contents). For anything other than the smallest of blocks the overhead of a loop can be significant.

```
1  void send(register unsigned char *to,
2            register unsigned char *from,
3            register int count)
4  {
5  do
6      *to++ = *from++;
7  while (--count > 0);
8  }
```

The above loop requires a comparison after ever item copied. Unrolling the loop would reduce the number of comparisons per items copied. However, because `count` is not known at translation time an optimizer is unlikely to perform loop unrolling. The loop can be unrolled by hand, making sure that code also handles the situation where the number of items being copied is not an exact multiple of the loop unroll factor. A technique proposed by Tom Duff[371] (usually referred to as *Duff's device*) is (the original example used `*to`, i.e., the bytes were copied to some memory mapped serial device):

```
1  void send(register unsigned char *to,
2            register unsigned char *from,
3            int count)
4  {
5  register int n = (count+7)/8;
6
7  switch (count % 8)
8     {
9     case 0: do{   *to++ = *from++;
10    case 7:       *to++ = *from++;
11    case 6:       *to++ = *from++;
12    case 5:       *to++ = *from++;
13    case 4:       *to++ = *from++;
14    case 3:       *to++ = *from++;
15    case 2:       *to++ = *from++;
16    case 1:       *to++ = *from++;
17                } while (--n > 0);
18    }
19 }
```

C++

The C++ Standard converts the controlling expression to type **bool** and expresses the termination condition in terms of true and false. The final effect is the same as in C.

Other Languages

In many other languages the model of a *for loop* involves a counter being incremented (or decremented) from a start value to an end value, while the model of a *while loop* (or whatever it is called) being something that iterates until some condition is met. There is considerable overlap between these two models (it is always possible to rewrite one form of loop in terms of the other). The differences between the two kinds of loop are purely conceptual ones, created by developer loop classification models. Loop classification is often based on deciding whether a loop has the attributes needed to be considered a *for loop* (e.g., the number of iterations being known before the first iteration starts), all other loops being classified as *while loop*s. Early versions of Fortran performed the loop termination test at the end of the loop. This meant that loops always iterated at least once, even if the test was false on the first iteration.

Coding Guidelines

Some coding guideline documents recommend that loop termination only occur when the condition expressed in the controlling expression becomes equal to zero. A number of benefits are claimed to accrue from adhering to this recommendation. These include, readers being able to quickly find out the conditions under which the loop terminates (by looking at the loops controlling expression; which might only be a benefit for one form of reading) and the desire not to jump across the control flow. It is always possible to transform source code into a form where loop termination is decided purely by the control expression. However, is there a worthwhile cost/benefit to requiring such usage? The following example illustrates a commonly seen need to terminate a loop early:

770 reading kinds of
1782 jump statement syntax

```
#define SPECIAL_VAL 999
#define NUM_ELEMS 10

extern int glob;
static int arr[NUM_ELEMS];

void f_1(void)
{
for (int loop = 0; loop < NUM_ELEMS; loop++)
   {
   /* ... */
   if (glob < NUM_ELEMS/2)
      {
      glob++;
      if (arr[loop] == SPECIAL_VAL)
         break;
      }
   else
      arr[loop] = glob;
   /* ... */
   }
}

void f_2(void)
{
for (int loop = 0; loop < NUM_ELEMS; loop++)
   {
   /* ... */
   if (glob < NUM_ELEMS/2)
      {
      glob++;
      if (arr[loop] == SPECIAL_VAL)
         loop = NUM_ELEMS;
      }
   else
      arr[loop] = glob;

   if (loop != NUM_ELEMS)
      { /* ... */ }
   }
}

void f_3(void)
{
_Bool terminate_early = 0;

for (int loop = 0; (loop < NUM_ELEMS) && !terminate_early; loop++)
   {
   /* ... */
   if (glob < NUM_ELEMS/2)
      {
```

```
52          glob++;
53          if (arr[loop] == SPECIAL_VAL)
54             terminate_early = 1;
55          }
56       else
57          arr[loop] = glob;
58
59       if (!terminate_early)
60          { /* ... */ }
61       }
62    }
```

Looking at the controlling expression in `f_1` and `f_2` it appears to be easy to deduce the condition under which the loop will terminate. However, in both cases the body of the loop contains a test that also effectively terminates the loop (in the case of `f_2` the body of the loop has increased in complexity by the introduction of an **`if`** statement). The function `f_3` handles the case where guidelines recommend against modifying the loop control variable in the loop body.

loop control variable 1774

Any guideline recommendation needs to be based on a comparison of the costs and benefits of the loop constructs in these functions (and other cases). Your author knows of no studies that provide the information needed to make such a comparison. For this reason this coding guideline subsection is silent on the issue of how loops might terminate. A loop where it is known, at translation time, that the number of iterations is zero, is a loop containing redundant code. The issue of redundant code is discussed elsewhere.

redundant code 190

The repetition occurs regardless of whether the loop body is entered from the iteration statement or by a jump.[DR268] 1767

Commentary

This is a requirement on the implementation.

This sentence was added by the response to DR #268.

Other Languages

Many languages (e.g., Pascal, Ada) treat loop bodies as indivisible entities and do not permit a jump into them (although it is usually possible to jump out of them).

Coding Guidelines

Some coding guideline documents recommend against jumping into the body of a loop. One argument is that a reader of the source may not notice that a loop could be entered in this way and makes a modification that fails to take this case into account (i.e., introduces a fault).

There are a variety of situations where jumping into the body of a loop may result in code that is less likely to contain faults and be less costly to maintain (see the example given for the **`goto`** statement).

goto EXAMPLE 1790

Jumping into the body of a loop is rare and no data is available on the kinds of faults in which it plays a significant contributing factor. For this reason a no guideline recommending is given.

---

block iteration statement

An iteration statement is a block whose scope is a strict subset of the scope of its enclosing block. 1768

Commentary

The rationale for this specification is the same as that given for the block implicitly created for a selection statement.

block selection statement 1741

---

block loop body

The loop body is also a block whose scope is a strict subset of the scope of the iteration statement. 1769

Commentary

The rationale for this specification is the same as that given for the block implicitly created for the substatements of a selection statement.

block selection substatement 1742

Example

In the following example the lifetime of the compound literal starts and terminates on every iteration of the loop.

```
1   struct S {
2             int mem_1;
3             int mem_2;
4             };
5
6   extern void g(struct S);
7
8   void f(void)
9   {
10  for (int i = 0; i < 10; i++)
11     g((struct S){.mem_1 = i, .mem_2 = 42});
12  }
```

1770 DR268) Code jumped over is not executed.

Commentary

This is a requirement on the implementation and is consistent with other situations where code is jumped over.

1762 EXAMPLE case fall through

This sentence was added by the response to DR #268.

1771 In particular, the controlling expression of a **for** or **while** statement is not evaluated before entering the loop body, nor is *clause-1* of a **for** statement.

Commentary

While any expressions in the loop header are not executed when the loop body is entered, the controlling expression evaluation that occurs at start of the next, and any subsequent, iterations of the loop is executed.

1763 iteration statement syntax
1766 iteration statement executed repeatedly

This sentence was added by the response to DR #268.

6.8.5.1 The while statement

1772 The evaluation of the controlling expression takes place before each execution of the loop body.

while statement

Commentary

The loop body of a **while** statement may be executed zero or more times.

Coding Guidelines

Why do developers choose to use a **while** statement rather than a **for** statement? Technically a loop can be written using either kind of statement. Both forms of iteration statement are likely to involve initializing, testing, and modifying one or more objects that systematically change over successive iterations. The **for** statement places these three components in a contiguous, visibly prominent, location. Other reasons for the choice (65.5% **for**, 34.5% **while**) include:

- *C culture.* The use of a particular kind of loop to perform a particular operation may be something that developers learn as part of the process of becoming a C programmer. Measurements of the two looping constructs (see Table 1763.1 and Table 1763.2) show that **for** statements often count up to some value and **while** statements iterate until an equality operator is true. The pattern of usage seen in the source being the sum of the operations (e.g., always using a **for** statement to loop over the elements of an array and a **while** statement to loop over a linked list) required to implement the application.

- *Individual habits.* While learning to program a developer may have chosen (perhaps a random selection, or purely a class exercise to practice the using a language construct) to use a particular construction to perform some operation. Reuse of the same construction to perform the same, or similar operations leads to it becoming established as part of their repertoire. The pattern of usage seen in source code being the sum of individual habits.

In both cases the choice of **for**/**while** involves a process of algorithmic problem classification. Which most closely matches the developers mental model of the operations being performed? At the time of this writing there is insufficient information to evaluate whether there is a cost/benefit case to the use of **while** statements, rather than **for** statements. These coding guidelines do not discuss this issue any further.

loop control variable 1774 controlling expression 1740 if statement

There is a commonly seen idiom that uses side effects in the evaluation of the controlling expression to modify the value of an object in the controlling expression (i.e., the loop control variable). The discussion on controlling expressions in an **if** statement showed that removing such side effects in the controlling expression of **while** statements would incur the cost of having to create and maintain two identical statements (one outside the loop and one inside). Your author is not able to estimate if this cost was less than the potential benefits of not having the side effects in the controlling expression. For this reason no guideline is specified here.

6.8.5.2 The do statement

do statement

The evaluation of the controlling expression takes place after each execution of the loop body. 1773

Commentary

The loop body of a **do** statement is always executed at least once.

Coding Guidelines

while statement 1772

The benefits associated with having side effects in the controlling expression of a **while** statement are not applicable to a **do** statement (because the loop is always executed at least once). Given that the use of a **do** statement is relatively rare and that developers are likely to be familiar with the side effect idioms that occur in controlling expressions, no guideline recommendation is given here.

Example

macro function-like 1933

One use of the **do** statement is to solve the dangling semicolon problem that can occur when a function-like macro replaces a function call. Bracketing a sequence of statement with braces creates a compound statement, which does not require a terminating semicolon. In most contexts a semicolon following a function-like macro invocation is a harmless null statement. However, as the following example shows, when it forms the first arm of an **if** statement that contains an **else** arm, the presence of a semicolon is a syntax violation. Enclosing a sequence of statements in the body of a **do** statement, whose controlling expression is false, avoids this problem.

```
#define STMT_SEQ(p)                  \
      do {                           \
         /* sequence of statements */ \
         }                           \
      while (0)

/* ... */

if (cond)
   STMT_SEQ(x);
else
   /* ... */
```

6.8.5.3 The for statement

1774 The statement

for statement

```
for ( clause-1 ; expression-2 ; expression-3 ) statement
```

behaves as follows:

Commentary

Rationale

In C89, for loops were defined in terms of a syntactic rewrite into **while** loops. This introduced problems for the definition of the **continue** statement; and it also introduced problems when the operands of cast and **sizeof** operators contain declarations as in:

```
enum {a, b};
{
    int i, j = b;
    for (i = a; i < j; i += sizeof(enum {b, a}))
        j += b;
}
```

not being equivalent to:

```
enum {a, b};
{
    int i, j = b;
    i = a;
    while (i < j) {
        j += b;                     // which b?
        i += sizeof(enum {b, a});  // declaration of b moves
    }
}
```

because a different `b` is used to increment `i` in each case. For this reason, the syntactic rewrite has been replaced by words that describe the behavior.

C90

Except for the behavior of a **continue** *statement in the loop body, the statement*

```
for ( expression-1 ; expression-2 ; expression-3 ) statement
```

and the sequence of statements

```
expression-1 ;
while (expression-2) {
statement ;
expression-3 ;
}
```

are equivalent.

C++

Like the C90 Standard, the C++ Standard specifies the semantics in terms of an equivalent **while** statement. However, the C++ Standard uses more exact wording, avoiding the possible ambiguities present in the C90 wording.

Other Languages

loop control variable 1774

In most other languages the ordering of expressions puts the controlling expression last. Or to be more exact, an upper or lower bound for the loop control variable appears last. Most other languages do not support having anything other than the loop control variable tested against a value that is known at translation time. Some languages (e.g., Ada, Algol 68, and Pascal) do not allow the loop control variable to be modified by the body of the loop.

Common Implementations

loop unrolling

Loop unrolling is the process of decreasing the number of iterations a loop makes by duplicating the statement in the loop body.[324] For instance:

```
1   for (loop = 0; loop < 10; loop++)
2      {
3      a[loop] = loop;
4      }
5   /*
6    * Can be unrolled to the following equivalent form:
7    */
8   for (loop = 0; loop < 10; loop+=2)
9      {
10     a[loop] = loop;
11     a[loop+1] = loop+1;
12     }
```

Loop unrolling reduces the number of jumps performed (which can be a significant saving when the loop body is short) and by increasing the number of statement in the loop body creates optimization opportunities (which, in the above example, could result in two loop bodies executing in less time than twice the time for a single iteration). When the iteration count is not exactly divisible by the loop body unrolling factor copies of the loop body may need to occur before the start, or after the end, or the loop statement.

At the minimum, loop unrolling requires knowing the number of loop iterations and the amount by which the loop control variable is incremented, at translation time. Implementations often place further restrictions on loops before that they unroll (requiring the loop body to consist of a single basic block is a common restriction).

Arbitrary amounts of loop unrolling (e.g., iterating 10 times over 100 copies of a loop body where the original is known to iterate 1000 times) does not necessarily guarantee improved performance. Duplicating the loop body increases code size, which decreases the probability that all of the loop body instructions will fit within the processor's instruction cache. Unless optimizers take into account the size of a processor's instruction cache when evaluating the cost effectiveness of loop unrolling they can end up reducing, rather than increasing, program performance.[484]

iteration statement syntax 1763

Jinturkar[670] analyzed the loops in a set of benchmarks to determine the complexity and size of loop bodies, and the nature of the loop bounds. The results were that in 50% of loops the iteration count could be deduced at translation time and that the generated machine code for the loop bodies of each loop that were unrolled was smaller than 256 bytes.

Coding Guidelines

Writers of coding guideline documents often regard the components of a **for** statement as having attributes that other loop statements don't have (e.g., they have an associated loop control variable). While it can be argued that many of these authors have simply grafted onto C concepts that only exist in other languages (or perhaps the encapsulation all of the loop control information in one visually delimited area of the source

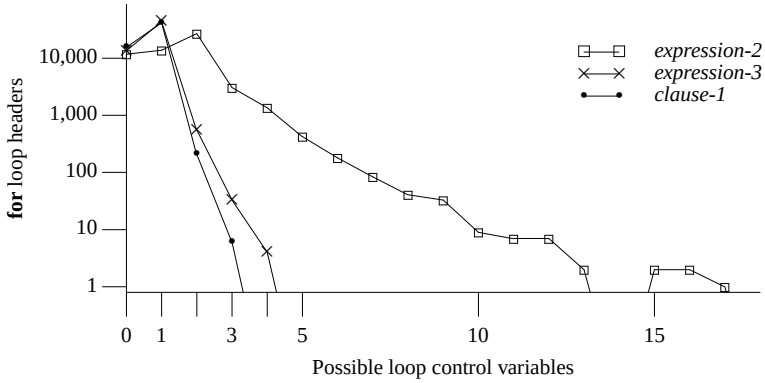

Figure 1774.1: Number of possible loop control variables appearing in *expression-2* (square-box) after filtering against the objects appearing in *expression-3* (cross) and after filtering against the objects appearing in *clause-1* (bullet). Based on the visible form of the `.c` files.

triggers a cognitive response that triggers implicit assumptions in readers), if a sufficient number of developers associate these attributes with **for** statements then they become part of the culture of C and need to be considered here. Other loop conceptualization issues are discussed elsewhere.

1772 while statement

This subsection discusses one attribute commonly associated with **for** statements that is not defined by the C Standard, the so-called *loop control variable* (or simply *loop variable*, or alternatively *loop counter*). A loop control variable is more than simply a concept that might occur during developer discussion, many coding guideline documents make recommendations about its use (e.g., a loop control variable should not be modified during execution of the body of the loop, or have floating-point type). Which of the potentially four different objects that might occur, for instance, in the most common form of loop header (see Table 1763.1) is the loop control variable?

loop control variable

0 MISRA

```
1   for (lcv_1=0; lcv_2 < lcv_3; lcv_4++)
```

The following algorithm frequently returns an answer that has been found to be acceptable to developers (it is based on the previous standard and has not been updated to reflect the potential importance of objects declared in *clause-1*). Note that the algorithm may return zero, or multiple answers; a union or structure member selection operator and its two operands is treated as a single object, but both an array and any objects in its subscript are treated as separate objects and therefore possible loop control variables:

1. list all objects appearing in *expression-2* (the controlling expression). If this contains a single object, it is the loop control variable (33.2% of cases in the `.c` files),
2. remove all objects that do not appear in *expression-3* (which is evaluated on every loop iteration). If a single object remains, that is the loop control variable (91.8% of cases in the `.c` files),
3. remove all objects that do not appear in *clause-1* (which is only evaluated once, prior to loop iteration). If a single object remains, that is the loop control variable (86.2% of cases in the `.c` files).

Unlike the example given above, in practice the same object often appears as an operand somewhere within all three components (see Figure 1774.1).

Because the controlling expression is evaluated on every iteration of the loop, the loop control variable can appear in contexts that are not supported in other languages (because most evaluate the three loop components only once, prior to the first iteration). For instance:

```
1   for (lcv_1=0, lcv_2=0; a1[lcv_1] < a2[lcv_2]; lcv_1++, lcv_2+=2)
```

Experience shows that developers often assume that, in a **for** statement, modification of any loop control variables only occurs within the loop header. This leads to them forming beliefs about properties of the loop, for instance, *it loops 10 times*. There tend to be fewer assumptions made about the use of **while** statements (which might not even be thought to have a loop control variable associated with them) and the following guideline is likely to cause developers to use this form of looping construct.

Cg 1774.1 A loop control variable shall not be modified during the execution of the body of a **for** statement.

Some coding guideline documents recommend that loop control variables not have floating-point type. It might be thought that such a recommendation only makes sense in languages where the loop termination condition involves an equality test (in C this case is covered by the guideline recommendation dealing with the type of the operands of the quality operators). However, the controlling expression in a C **for** statement can contain relational operators, which can also have a dependence on the accuracy of floating-point operations. For instance, it is likely that the author of the following fragment expects the loop to iterate 10 times. However, it is possible that 10 increments of `i` result in it having the value 9.9999, and loop termination not occurring until after the eleventh iteration.

equality operators not floating-point operands 1214.1

```
1   for (float i=0.0; i < 10.0; i++)
```

A possible developer response to a guideline recommendation that loop control variables not have floating point type is to use a **while** statement (which are not covered by the algorithm for deducing loop control variables). Some of the issues associated with the finite accuracy of operations on floating-point values can be addressed with guideline recommendations. However, the difficulty of creating wording for a recommendation dealing with the use of floating-point values to control the number of loop iterations is such that none is attempted here.

Table 1774.1: Occurrence of sequences of components omitted from a **for** statement header (as a percentage of all **for** statements). Based on the visible form of the `.c` files.

Components Omitted	%
clause-1	3.8
clause-1 expr-2	0.1
clause-1 expr-2 expr-3	2.5
clause-1 expr-3	0.1
expr-2	0.8
expr-2 expr-3	0.2
expr-3	1.6

controlling expression for statement

The expression *>expression-2* is the controlling expression that is evaluated before each execution of the loop body. 1775

Commentary

The loop body of a **for** statement may be executed zero or more times.

Other Languages

In many languages the termination condition of a **for** statement, specified in the header of the loop body, is fixed prior to the first iteration of the loop body (every time the loop statement is encountered). The commonly used termination condition being that the loop counter be equal to the value of a specified expression.

Coding Guidelines

The controlling expression in a **for** statement is sometimes written so that its evaluation also has the side effect of modifying the value of the loop control variable, removing the need for *expression-3*. A developer

may have any of a number of reasons for using such an expression, from use of an idiom to misplaced concern for efficiency (many of the issues associated with side effects within the controlling expression are the same as those that apply to **while** statements). 1772 while statement

---

1776 The expression *expression-3* is evaluated as a void expression after each execution of the loop body.

Commentary

The common usage is for the evaluation of this expression to modify the value of the loop control variable.

Other Languages

In many languages the value used to increment/decrement the loop counter of a **for** statement is fixed (every time the **for** statement is encountered) prior to the first iteration of the loop body.

1777 If *clause-1* is a declaration, the scope of any ~~variables~~ identifiers it declares is the remainder of the declaration and the entire loop, including the other two expressions;

Commentary

The phrase *entire loop* means *expression-2*, *expression-3*, and the loop body. 1766 loop body

The wording was changed by the response to DR #292.

C90

Support for this functionality is new in C99.

Other Languages

In some languages (e.g., Ada and Algol 68) the occurrence of an identifier as the loop control variable also acts as a definition of that identifier (its type is that of the controlling expressions).

Coding Guidelines

Some coding guideline documents warn of the dangers of accessing loop control variables outside of the loops they control. One of the reasons for this is that some languages do not define the value of this variable once the loop has terminated (which makes such accesses equivalent to those of an uninitialized variable). Loop control variables in C do not have this behavior and some form of related guideline recommendation is not required.

Declaring the loop control variable via *clause-1* has the benefit of localizing the visual context over which it is referenced. Possible costs include having to modify existing habits (e.g., looking for the declaration at the start of the function body) and possible lack of support for constructs new in C99 by ancillary tools. 1768 block iteration statement

Example

```
1  void three_different_objects_named_loc(void)
2  {
3  int loc = 20;
4
5  for (int loc = 0; loc < 10; loc++)
6     int loc = -8;
7  }
```

1778 it is reached in the order of execution before the first evaluation of the controlling expression.

Commentary

This requirement is necessary because it is intended that objects declared in *clause-1* appear in the controlling expression.

If *clause-1* is an expression, it is evaluated as a void expression before the first evaluation of the controlling expression.[134)] 1779

Commentary

This evaluation occurs once, every time the **for** statement head of the loop is encountered in the flow of control.

Both *clause-1* and *expression-3* can be omitted. 1780

Commentary

Saying in words what is specified in the syntax. A **for** statement loop header is essentially a means of visually highlighting the various components of a loop.

C++

The C++ Standard does not make this observation, that can be deduced from the syntax.

Other Languages

Being able to omit the specification for the initial value of a loop counter (i.e., *clause-1*) is unique to C (and C++). Most languages allow their equivalent of *expression-3* to be omitted and use a default value (usually either 1 or -1).

Coding Guidelines

Why would a developer choose to omit either of these constructs in a **for** statement, rather than using a **while** statement? This issue is discussed elsewhere.

iteration statement 1763
syntax
while statement 1772

An omitted *expression-2* is replaced by a nonzero constant. 1781

Commentary

Specifying that an omitted *expression-2* is replaced by a nonzero constant allows a more useful meaning to be given to those cases where *clause-1* or *expression-3* are present, than by replacing it by the constant 0. Omitting *expression-2* creates a loop that can never terminate via a condition in the loop header. Executing a **break**, **goto**, or **return** statement (or a call to the `longjmp` library function) can cause execution of the loop to terminate. The term *infinite loop* is often used to describe a **for** statement where the controlling expression has been omitted. In some freestanding environments the main body of a program consists of an infinite loop that is only terminated when electrical power to the processor is switched off.

Other Languages

Most languages require that the loop termination condition be explicitly specified. In Ada the loop header is optional (a missing header implies an infinite loop).

Common Implementations

The standard describes an effect that most implementations do not implement as stated. A comparison that is unconditionally true can be replaced by an unconditional jump.

Coding Guidelines

There is an idiom that omits *expression-2* when an infinite loop is intended (usually omitting the other two expressions as well). Does such an idiom have a more worthwhile cost/benefit than using a **while** statement, with a nonzero constant as the controlling expression? Existing source code contains both usages (see Table 1763.1, Table 1763.2) and given practice readers will learn to automatically recognize both forms. However, such automatic recognition takes time to learn and a **while** statement whose controlling expression is a nonzero constant probably requires less effort to comprehend (because it is not an implicit special case) for less experienced developers.

Example

```
#define TRUE 1

void f(void)
{
for (;;)
   { /* ... */ }

while (TRUE)
   { /* ... */ }
}
```

6.8.6 Jump statements

jump statement syntax

1782

jump-statement:
goto *identifier* **;**
continue ;
break ;
return $expression_{opt}$ **;**

Commentary

These are all jump statements in the sense they cause the flow of control to jump to another statement (in the case of the **goto** statement this could be itself).

Other Languages

Most imperative languages contain some form of **goto** statement, even those intended for applications involving safety-critical situations. Snobol 4 does not have an explicit jump statement. All statements may be followed by the name of a label, which is jumped to (it can be conditional on the success or failure of the statement) on completion of execution of the statement. The **come from** statement is described by Clark.[246]

A number of languages support some mechanism for early loop termination (e.g., Ada and Modula-2 support an **exit** statement). Some languages require the exit point to be labeled, others simply exit the loop containing the statement. Perl uses the keywords **next** and **last**, rather than **continue** and **break** respectively.

Common Implementations

On most modern processors instruction execution is broken down into stages that are executed in sequence (known as an *instruction pipeline*). Optimal performance requires that this pipeline be kept filled with instructions. Jump statements (or rather the machine code generated to implement them) disrupt the smooth flow of instructions into the pipeline. This disruption occurs because the instruction fetch unit assumes the next instruction executed will the one following the current instruction, the processor is not aware it has encountered a branch instruction until that instruction has been decoded, by which time it is one or more stages down the pipeline and the following instruction is already in the pipeline behind it. Until the processor executes the branch instruction it does not know which location to fetch the next instruction from, a pipeline *stall* has occurred. Branch instructions are relatively common, which means that pipeline stalls can have a significant performance impact. The main techniques used by processor vendors to reduce the impact of stalls are discussed in the following C sentences.

0 processor pipeline

One of the design principles of RISC was to expose some of the underlying processor details to the translator, in the hope that translators would make use of this information to improve the performance of the generated machine code. Some of the execution delays causes by branch instructions have been

exposed. For instance, many RISC processors have what is known as a *delay slot* immediately after a branch instruction. The instruction in this delay slot is always executed before the jump occurs (some processors allow delay slot instructions following a conditional branch to be annulled). This delay slot simplifies the processor by moving some of the responsibility for keeping the pipeline full to the translator writer (who at worst fills it with a no-op instruction). Most processors have a single delay slot, but the Texas Instruments TMS320C6000[1342] has five.

Fetching the instructions that will soon be executed requires knowing the address of those instructions. In the case of function calls the destination address is usually encoded as part of the instruction; however, the function return address is usually held on the stack (along with other housekeeping information). Maintaining a second stack, containing only function return addresses, has been proposed, along with speculative execution (and stack repair if the speculation does not occur along the control flow path finally chosen[1251]).

Calder, Grunwald, and Srivastava[191] studied the behavior of branches in library functions, looking for common patterns that occurred across all calls.

Coding Guidelines

The **`continue`** and **`break`** statements are a form of **`goto`** statement. Some developers consider them to be a *structured goto* and treat them differently than a **`goto`** statement. The controversy over the use of the **`goto`** statement has not abated since Dijkstra's, now legendary, letter to the editor was published in 1968.[357] Many reasons have been given for why source code should not contain **`goto`** statements; Dijkstra's was based on human cognition. Knuth argued that in some cases use of **`goto`** provided the best solution.[751]

Edsger W. Dijkstra

> *My second remark is that our intellectual powers are rather geared to master static relations and that our powers to visualize processes evolving in time are relatively poorly developed. For that reason we should do (as wise programmers aware of our limitations) our utmost to shorten the conceptual gap between the static program and the dynamic process, to make the correspondence between the program (spread out in text space) and the process (spread out in time) as trivial as possible.*

The heated debate on the use of the **`goto`** statement has generated remarkably little empirical research.[479] Are guideline recommendations against the use of **`goto`** simply a hang over from the days when developers had few structured programming constructs (e.g., compound statements) available in the language they used, or is there a worthwhile cost/benefit in recommending against their use?

It is possible to transform any C program containing jump statements to one that does not contain any jump statements. This may involve the introduction of additional **`while`** statements, **`if`** statements, and the definition of new objects having a boolean type. An algorithm for performing this transformation, while maintaining the topology of the original flow graph and the same order of efficiency, is given by Ashcoft and Manna.[61] Ammaraguellat[28] gives an algorithm that avoids code replication and normalizes all control-flow cycles into single-entry single-exit **`while`** loops. In practice automated tools tend to take a simpler approach to transformation.[397] The key consideration does not appear to be the jump statement itself, but the destination statement relative to the statement performing the jump. This issue is discussed elsewhere.

jump 1783 statement causes jump to

Usage

Numbers such as those given in Table 1782.1 and Table 1782.2 depend on the optimizations performed by an implementation. For instance, unrolling a frequently executed loop will reduce the percentage of branch instructions.

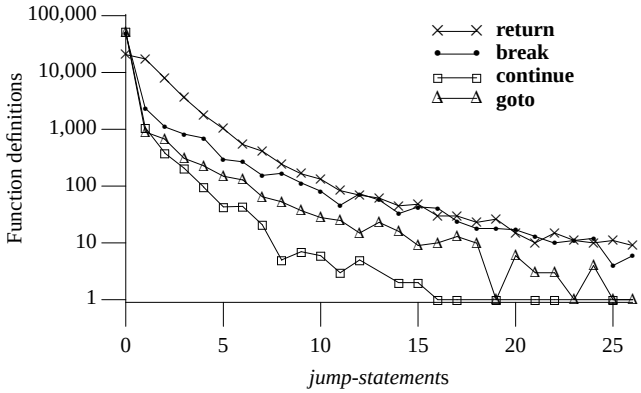

Figure 1782.1: Number of function definitions containing a given number of *jump-statement*s. Based on the translated form of this book's benchmark programs.

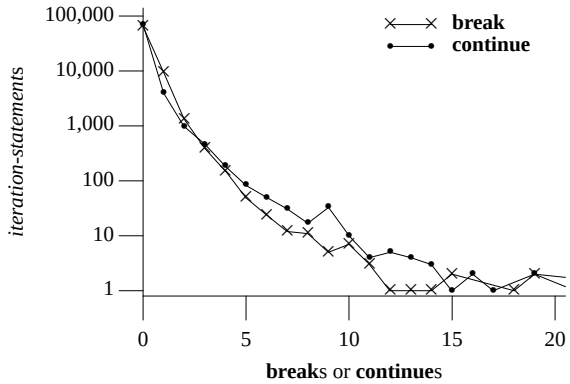

Figure 1782.2: Number of *iteration-statement* containing the given number of **break** and **continue** Based on the visible form of the `.c` files.

Table 1782.1: Dynamic occurrence of different kinds of instructions that can change the flow of control. *%Instructions Altering Control Flow* is expressed as a percentage of all executed instructions. All but the last row are expressed as percentages of these, control flow altering, instructions only. The kinds of instructions that change control flow are: conditional branches *CB*, unconditional branches *UB*, indirect procedure calls *IC*, procedure calls *PC*, procedure returns *Ret*, and other breaks *Oth* (e.g., signals and **switch** statements). *Instructions between branches* is the mean number of instructions between conditional branches. Based on Calder, Grunwald, and Zorn.[192]

Program	%Instructions Altering Control Flow	%CB	%UB	%IC	%PC	%Ret	%Oth	%Conditional Branch Taken	Instructions Between Branches

Semantics

jump statement causes jump to

A jump statement causes an unconditional jump to another place. 1783

Commentary

For the **goto**, **continue**, and **break** statements the other place is within the function body that contains the statement.

Other Languages

Some languages allow labels to be treated as types. In such languages jump statements can jump between functions (there is usually a requirement that the function jumped to must have an active invocation in the current call chain at the time the jump statement is executed). In Algol 68 a label is in effect a function that jumps to that label. It is possible to call that function or take its address. In C terms:

```
somewhere:
    /* ... */
    if (problem)
       somewhere();    /* Same as "go to somewhere". */
    /* ... */
    void (*fp)(void) = &somewhere;
```

Common Implementations

The **goto**, **continue** and **break** statements usually map to a single machine instruction, an unconditional jump. Jumping out of a compound statement nested within another compound statement often creates a series of jumps. For instance, in the following example:

```
if (x)
   {
   for (;;)
      {
      some_code;
      if (y)
         break; /* Jump out of loop. */
      }
/* Place A */
   }
```

```
11  else
12     some_more_code;
13  /* Place B */
```

the branch instruction out of the loop, generated by the **break** statement, is likely to branch to an instruction (at place A) that branches over the **else** arm of the **if** statement (to place B). One of the optimization performed by many translators is to follow a *jump chain* to find the final destination. The destination of the branch instruction at the start of the chain being modified to refer to this place.

Many processors have span-dependent branch instructions. That is, a short-form (measured in number of bytes) that can only branch relatively small distances, while a long-form can branch over longer distances. When storage usage needs to be minimized it may be possible to use a jump chain to branch to a place using a short-form instruction, rather than a direct jump to that place using a long-form instruction (at the cost of reduced execution performance).[846]

Coding Guidelines

The term *spaghetti code* is commonly used to describe code containing a number of jump statements whose various destinations cause the control flow to cross the other control flows (a graphical representation of the control flow, using lines to represent flow, resembled cooked spaghetti, i.e., it is intertwined).

Jumps can be split into those cases where the destination is the most important consideration and those where the jump/destination pair need to be considered— as follows:

- *Jumping to the start/end of a function/block*— the destination being in the same or outer block relative to the jump . This has a straight-forward interpretation as restarting/finishing the execution of a function/block. The statement jumped to may not be the last (some termination code may need to be executed, or a guideline recommendation that functions have a single point of exit may cause the label to be on a **return** statement).
- *Jumping into a nested block.* This kind of jump/destination pair is the one most often recommended against.
- *Jumping out of a nested block.* This kind of jump/destination pair may be driven by the high cost of using an alternative construct. For instance, adding additional flags to cause a loop to terminate may not introduce excessive complexity when a single nesting level is involved.
- *Jumping within the same block.* This is the most common kind of **goto** statement found in C source (see right plot of Figure 1783.2).

1790 goto EXAMPLE

1766 iteration statement executed repeatedly

Jump statements written by the developer can create a flow of control that is that requires a lot of effort to comprehend. Some guideline documents recommend against the use of any jump statement (including a **return**, unless it is the last statement within a function). Comprehending the flow of control is an important part of comprehending a function. The use of jump statements can increase the cost of comprehension (by increasing the complexity of the flow of control) and can increase the probability that the comprehension process reaches the wrong conclusion (unlike other constructs that change the flow of control, there are not usually any addition visual clues, e.g., indentation, in the source signaling the presence of a jump statement). However, there is no evidence to suggest that the cost of the alternatives is any lower and consequently no guideline recommendation is made here.

Any statements that appear after a *jump-statement*, in the same block, are dead code.

190 dead code

Usage

A study by on Gellerich, Kosiol, and Ploedereder[479] analyzed **goto** usage in Ada and C. In the translated form of this book's benchmark programs 20.6% of **goto** statements jumped to a label that occurred textually before them in the source code.

1784 134) Thus, *clause-1* specifies initialization for the loop, possibly declaring one or more variables for use in the loop;

footnote 134

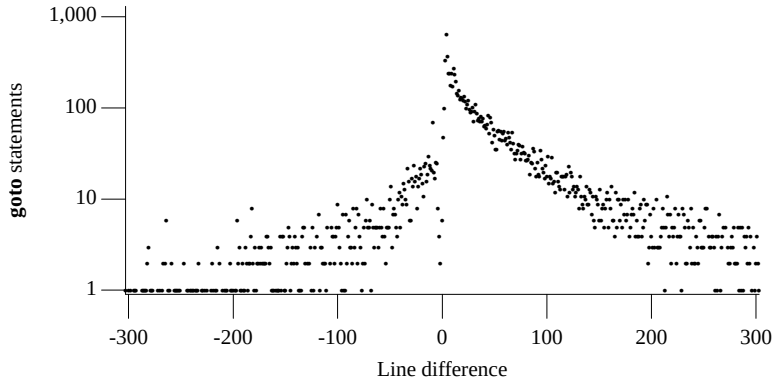

Figure 1783.1: Number of `goto` statements having a given number of visible source lines between a `goto` statement and its destination label (negative values denote backward jumps). Based on the translated form of this book's benchmark programs.

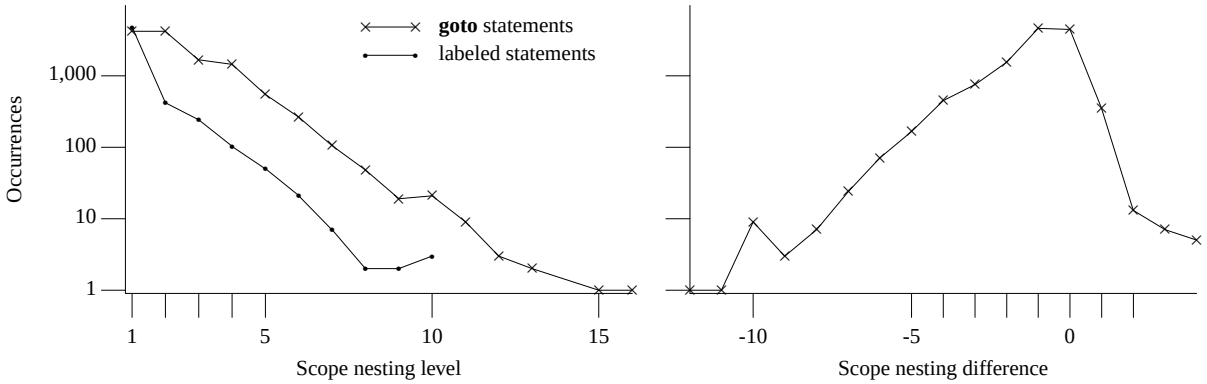

Figure 1783.2: Number of `goto` statements and labels having a given scope nesting level (nesting level 1 is the outermost block of a function definition), and on the right the difference in scope levels between a `goto` statement and its corresponding labeled statement (negative values denote a jump to a less nested scope). Based on the translated form of this book's benchmark programs.

Commentary

Technically the evaluation *clause-1* need have no connection with the contents of the body of the loop. This wording expresses the view of C committee about how they saw this construct being used by developers.

C90

Support for declaring variables in this context is new in C99.

C++

The C++ Standard does not make this observation.

---

the controlling expression, *expression-2*, specifies an evaluation made before each iteration, such that execution of the loop continues until the expression compares equal to 0; 1785

Commentary

In C90 this wording appeared in a footnote, where it was an observation about the equivalence between a **for** statement and a **while** statement. In C99 this wording plays the role of a specification.

controlling expression 1775 for statement

Coding Guidelines

The discussion on the controlling expression in an **if** statement is applicable here.

---

and *expression-3* specifies an operation (such as incrementing) that is performed after each iteration. 1786

Commentary

The *incrementing* operation referred to here is the concept of a loop control variable having its value increased (often by one). Decrementing (i.e., decreasing the value of the loop control variable) is a less commonly specified operation (as is walking a linked list). There is often a causal connection between the operand that is incremented and one of the operand appearing in *expression-2*.

6.8.6.1 The goto statement

Constraints

1787 The identifier in a **goto** statement shall name a label located somewhere in the enclosing function.

goto statement

Commentary

The situation where a label having a corresponding name does not occur within the enclosing function is likely to be some kind of fault. Having translators issue a diagnostic is probably the most useful behavior for the standard to specify.

Other Languages

Some languages that support nested function definitions (e.g., Pascal) only require that the label name be visible (i.e., it is possible to jump to a label in a different function). Other languages (e.g., Algol 68) give labels block scope, which restricts its visibility. Perl has a form of **goto** that causes the function named by the label to be called. However, when that function returns control is returned to the function that called the function that performed the **goto** (i.e., the behavior is as-if control returns to the **goto** which then immediately performs a return).

1788 A **goto** statement shall not jump from outside the scope of an identifier having a variably modified type to inside the scope of that identifier.

goto past variably modified type

Commentary

Storage allocation for objects having a variably modified type differs from storage allocation for objects having other types in that it requires internal implementation housekeeping code to be executed, when its definition is encountered during program execution, for it to occur (storage for objects having other types can be reserved at translation time). Similarly, storage deallocation requires housekeeping code to be executed when the lifetime of an object having a variably modified type ends (implementation techniques that have no dependency between execution of an objects definition and the termination of its lifetime discussed elsewhere); storage deallocation for objects having other types does not require any execution time actions.

464 VLA lifetime starts/ends
1354 storage layout

464 VLA lifetime starts/ends
1749 switch past variably modified type

This constraint, along with an equivalent one for the **switch** statement, provides a guarantee to implementations that if the storage deallocation code is executed, then the storage allocation code will have been previous executed (i.e., there is no way to bypass it in a conforming program). Jumping from outside of the scope of an identifier denoting such an object to inside the scope of that identifier bypasses execution of its definition. Bypassing the definition might be thought to be harmless if the object is never referenced. However, storage for the object has to be deallocated when its lifetime terminates, which is a (implicit) reference to the object.

This constraint does not require the identifier to be visible at the jumped to label, only that the label be within the scope of the identifier. Also, there is no constraint prohibiting the block containing the **goto** statement from containing an object defined to have a variably modified type and the destination of the jump to be outside of that block.

C90

Support for variably modified types is new in C99.

C++

Support for variably modified types is new in C99 and they are not specified in the C++ Standard. However, the C++ Standard contains the additional requirement that (the wording in a subsequent example suggests that

being visible rather than *in scope* more accurately reflects the intent):

6.7p3 *A program that jumps[77] from a point where a local variable with automatic storage duration is not in scope to a point where it is in scope is ill-formed unless the variable has POD type (3.9) and is declared without an* `initializer` *(8.5).*

A C function that performs a jump into a block that declares an object with an initializer will cause a C++ translator to issue a diagnostic.

```
1  void f(void)
2  {
3  goto lab;    /* strictly conforming */
4               // ill-formed
5  int loc = 1;
6
7  lab: ;
8  }
```

Semantics

goto causes unconditional jump

A **goto** statement causes an unconditional jump to the statement prefixed by the named label in the enclosing function. 1789

Commentary

dead code 190

Unless prefixed by a label, statements appearing after a **goto** statement, in the same block, are dead code.

Other Languages

Some languages (e.g., Pascal) support jumping to statements contained within other functions.

Common Implementations

There are a number of practical algorithms for analyzing program control flow that depend on the graph of the control flow being reducible[17,558] (i.e., not irreducible; an irreducible graph might be thought of one that contains a cycle with multiple entry points). To create an irreducible flow graph in C requires the use of the **goto** statement, for instance:

```
1        if (a > b)
2           goto L_1;
3  L_2: a++;
4  L_1: if (a < 3)
5           goto L_2;
```

Although algorithms are available for transforming an irreducible flow graph into a reducible one,[1388] many optimizers and static analyzers don't perform such transformations (because of the potentially significant increase in code size created by the node splitting algorithms,[205] and because it is believed that function definitions rarely have a control flow that is irreducible[14]). For this reason the quality of the machine code generated for the few functions that do contain an irreducible control flow graph can be much lower than that for other functions (because irreducibility can prevent some of the information needed for optimization being deduced).

goto EXAMPLE

EXAMPLE 1 It is sometimes convenient to jump into the middle of a complicated set of statements. The following outline presents one possible approach to a problem based on these three assumptions: 1790

1. The general initialization code accesses objects only visible to the current function.
2. The general initialization code is too large to warrant duplication.

3. The code to determine the next operation is at the head of the loop. (To allow it to be reached by **continue** statements, for example.)

```
/* ... */
goto first_time;
for (;;) {
        // determine next operation
        /* ... */
        if (need to reinitialize) {
                // reinitialize-only code
                /* ... */
        first_time:
                // general initialization code
                /* ... */
                continue;
        }
        // handle other operations
        /* ... */
}
```

Commentary

While this might seem like a contrived example, the same could probably be said for all examples of the use of the **goto** statement.

1791 EXAMPLE 2

EXAMPLE goto variable length

A **goto** statement is not allowed to jump past any declarations of objects with variably modified types. A jump within the scope, however, is permitted.

```
goto lab3;                      // invalid: going INTO scope of VLA.
{
        double a[n];
        a[j] = 4.4;
lab3:
        a[j] = 3.3;
        goto lab4;              // valid: going WITHIN scope of VLA.
        a[j] = 5.5;
lab4:
        a[j] = 6.6;
}
goto lab4;                      // invalid: going INTO scope of VLA.
```

Commentary

It is a constraint violation for a **goto** statement to jump past any declarations of objects with variably modified types.

1788 goto past variably modified type

6.8.6.2 The continue statement

Constraints

1792 A **continue** statement shall appear only in or as a loop body.

continue shall only appear

Commentary

The behavior of the **continue** statement is only defined in this context.

Coding Guidelines

Some coding guideline documents recommend against the use of the **continue** statement. The rationale appears to be based on an association being made with the **goto** statement.

The **continue** statement can be thought about either in implementation terms (i.e., jump to just before the end of the iteration statement that contains it) or conceptual terms (i.e., execute the next iteration of the loop).

Neither of these are likely to require significant effort to comprehend. While it may not require a significant amount of effort to comprehend, readers still have to notice its existence in the source code. The **continue** statement has the same reader visibility issues as all jump statements.

jump 1783 statement causes jump to

Semantics

A **continue** statement causes a jump to the loop-continuation portion of the smallest enclosing iteration statement; 1793

Commentary

The **continue** statement performs the dual role of **goto** statement and virtual label creator.

Rationale The C89 Committee rejected proposed enhancements to **continue** and **break** which would allow specification of an iteration statement other than the immediately enclosing one on grounds of insufficient prior art.

---

that is, to the end of the loop body. 1794

Commentary

The following C statement clarifies what is meant by "end of the loop body".

More precisely, in each of the statements 1795

```
while (/* ... */) {    do {                    for (/* ... */) {
   /* ... */                 /* ... */              /* ... */
   continue;                 continue;              continue;
   /* ... */                 /* ... */              /* ... */
contin: ;                contin: ;               contin: ;
}                       } while (/* ... */);     }
```

unless the **continue** statement shown is in an enclosed iteration statement (in which case it is interpreted within that statement), it is equivalent to **goto contin;**.[135)]

Commentary

These equivalent mappings describe an effect, not an implementation technique. The **for** statement example could be rewritten as:

```
1  {
2  clause_1;
3  while (expression_2)
4     {
5       {
6       /* ... */
7       continue;
8       /* ... */
9       contin: ;
10      }
11    expression_3;
12    }
13 }
```

C++

The C++ Standard uses the example (6.6.2p1):

6.6.2p1

```
while (foo) {          do {           for (;;) {
  {                     {              {
   // ...                // ...         // ...
  }                     }              }
contin: ;              contin: ;      contin: ;
}                      } while (foo);  }
```

The additional brace-pair are needed to ensure that any necessary destructors (a construct not supported by C) are invoked.

Coding Guidelines

Many developers have a mental model in which the **continue** statement jumps to the top of the loop. This model makes sense in that there is usually no information at the end of the loop body that developers need to consider (use of the **do** statement is relatively rare).

6.8.6.3 The break statement

Constraints

1796 A **break** statement shall appear only in or as a switch body or loop body.

Commentary

The behavior of the **break** statement is only defined in these contexts.

Other Languages

In most languages the arms of a **switch** body are syntactic units, each having an implicit **break** statement after the last statement. There is no requirement for a construct having the behavior of the C **break** statement, in a **switch** body context.

1739 selection statement syntax

Coding Guidelines

The coding guideline discussion for the **continue** statement is also applicable to the **break** statement. In the context of a **switch** statement developers are invariably going to need to use to **break** statements. Given that many of the reader comprehension issues apply to all uses of jump statements, any argument against the use of **break** statements could also be used to argue that **switch** statements should not be used.

1792 continue shall only appear

Semantics

1797 A **break** statement terminates execution of the smallest enclosing **switch** or iteration statement.

Commentary

Using the analogy given earlier for the **continue** statement:

```
1  {                       {                       {
2  while (/* ... */) {     do {                    for (/* ... */) {
3    /* ... */               /* ... */               /* ... */
4    break;                  break;                  break;
5    /* ... */               /* ... */               /* ... */
6    }                       } while (/* ... */);    }
7  brea: ;                 brea: ;                 brea: ;
8  }                       }                       }
```

The outer pairs of braces not appearing in the source code, they have been added here to show an affect.

Other Languages

Some languages allow blocks to be labeled. This label name can then appear in a statement (sometimes using the keyword **exit**), indicating that execution of that block is to terminate.

In most other languages **case** and **default** labels are part of the syntax of the **switch** statement. When the statement associated with these labels completes execution flow of control is defined to continue after the **switch** statement (there is an implicit break statement). These languages do not usually support a special statement whose purpose is to terminate execution of a **switch** statement (a **goto** statement could be used to do this). In BCPL the **ENDCASE** statement is equivalent to the C **break** statement within a **switch** statement (the BCPL **break** statement terminates execution of loops only).

---

footnote 135

135) Following the **contin:** label is a null statement. 1798

Commentary

That is, there are no statements from the loop body that were written by the developer.

6.8.6.4 The return statement

Constraints

---

return void type

A **return** statement with an expression shall not appear in a function whose return type is **void**. 1799

Commentary

base document 1

The base document did not define any semantics for this case (and simplifying automatic C source code generators was not considered to be sufficiently important for the committee to define any).

C++

6.6.3p3 *A return statement with an expression of type "cv **void**" can be used only in functions with a return type of cv void; the expression is evaluated just before the function returns to its caller.*

Source developed using a C++ translator may contain **return** statements with an expression returning a void type, which will cause a constraint violation if processed by a C translator.

```
1  void f(void)
2  {
3  return (void)4; /* constraint violation */
4                  // does not change the conformance status of a program
5  }
```

Other Languages

Many other languages support constructs called *procedure*s or *subroutine*s to take the role performed by function returning type **void**. The **return** statements appearing within these constructs are not allowed to include an expression.

---

return without expression

A **return** statement without an expression shall only appear in a function whose return type is **void**. 1800

Commentary

base document 1

The base document did not provide a mechanism enabling function declarations to explicitly specify that they did not return a value. It was common practice to omit the return type in the function definition to indicate that the function did not return a value. Unfortunately it was also common practice for developers to omit a return type and rely on the translator supplying an implicit **int** type. The type **void** was introduced into C by the C90 Standard.

type specifiers 1382 possible sets of

This constraint is new in C99 and ties in with the removal of support for *implicit int* in declarations.

function termination 1844 reaching }

The behavior that occurs after executing the last statement in a function definition, when it is not a **return** statement, is discussed elsewhere.

C90

This constraint is new in C99.

```
1  int f(void)
2  {
3  return; /* Not a constraint violation in C90. */
4  }
```

Other Languages

Many languages do not permit the expression in a **return** statement to be omitted when the containing function is defined to return a value.

Common Implementations

Some C90 implementations provided an option to switch on the diagnosing of additional constructs. The requirement specified in this constraint was often one of these additional constructs.

Coding Guidelines

This constraint is new in C99 and the majority of existing, C90, implementations do not issue a diagnostic for a violation of it. Any coding guideline documents that continue to be based on the C90 Standard (e.g., MISRA) might like to consider including a guideline recommendation along the lines of this constraint. The practice of not specifying an expression when it is known that the caller does not make use of the returned value also occurs in existing code, this issue is discussed elsewhere.

0 MISRA

1844 function termination reaching }

Usage

The translated form of this book's benchmark programs contained 19 instances of a **return** statement without an expression appearing in a function whose return type was **void**.

Semantics

1801 A **return** statement terminates execution of the current function and returns control to its caller.

Commentary

The **return** statement is one of the two constructs that can be used to terminate execution of the current function (use of `longjmp` is relatively rare).

Other Languages

Some languages (e.g., Pascal) support nested functions and what are known as *non-local goto* statements. Within a body of a nested function it is possible to perform non-local goto to a label visible in the body of an outer function. Fortran supports what is known as an *alternative return*. This kind of return (it is only supported for subroutines, not functions) causes control to resume at some location other than the statement following the one that performed the call. The alternative locations at which execution resume are passed as arguments to the call.

Common Implementations

Many processors include a return instruction that is the inverse of the one used to perform a call. A return instruction has to reinstate the stack (the most common form used to implement function call and return) to the state it was in prior to the call. This is often simply a matter of resetting the stack pointer to its value prior to the call. The return address may be loaded into a register (and an indirect jump performed) or popped from the stack (many processors contain an instruction that pops an address off the stack and jumps to it).

Depending on the calling conventions used either the caller or callee will restore any registers whose contents were saved prior to the call. Implementations where the callee restores the registers are likely to translate a **return** statement into a branch to the end of the function,[325] reducing duplication of the common housekeeping code.

1004 register function call housekeeping

It is unlikely that storage allocated to objects having variably modified types will be treated any differently than storage allocated to objects having other types (because, like them, it is allocated on the stack).

A function may have any number of **return** statements. 1802

Commentary

When the C language was first specified it was not uncommon for languages definitions to specify that a **return** statement ended the body of a function/procedure/subroutine.

C++

The C++ Standard does not explicitly specify this permission.

Other Languages

Some languages (e.g., Pascal) have no **return** statement. A function (or procedure/subroutine) returns when the flow of control reaches the end of its body.

Coding Guidelines

Some coding guideline documents specify that function definitions should contain a single **return** statement. Adhering to such a recommendation may involve using either a **goto** statement or additional flags (that prevent statements following the return decision point being executed). The cost of using these alternative constructs does not appear to be less than that associated with using multiple **return** statements.

iteration statement 1766 executed repeatedly

If a **return** statement with an expression is executed, the value of the expression is returned to the caller as the value of the function call expression. 1803

Commentary

C specifies that functions return values, not references. Implementations need to act as if temporary storage was used to hold the value being returned by a function. In an assignment statement this temporary object and the object being assigned to do not overlap.

footnote 1806 136

C++

The C++ Standard supports the use of expressions that do not return a value to the caller.

return void type 1799

Other Languages

In some languages (e.g., Fortran and Pascal) the last value assigned to an identifier, whose spelling is the same as that of the called function, is the result of a function call. Pascal does not support a **return** statement and execution of a function does not terminate until control reaches the end of that function. In Algol 68 the value returned by a function is the value of the last expression in its body (rather like the behavior of the `gcc` compound expression).

compound expression 1313

Common Implementations

Values having scalar type are usually returned in a register. Those having a structure type are usually returned in an area of storage allocated by the caller (often passed as a hidden parameter to the called function).

---

return implicit cast

If the expression has a type different from the return type of the function in which it appears, the value is converted as if by assignment to an object having the return type of the function.[136)] 1804

Commentary

This situation can only occur if the expression has a scalar type. As the response to DR #094 pointed out, this *as if* assignment implies that the constraints given for the assignment operator also apply here.

assignment operator modifiable lvalue 1289

C++

In the case of functions having a return type of *cv* **void** (6.6.3p3) the expression is not implicitly converted to that type. An explicit conversion is required.

Coding Guidelines

The guideline recommendations applicable here are the same as those that apply to any implicit conversions.

operand convert automatically 653

1805 EXAMPLE In:

```
struct s { double i; } f(void);
union {
        struct {
                int f1;
                struct s f2;
        } u1;
        struct {
                struct s f3;
                int f4;
        } u2;
} g;

struct s f(void)
{
        return g.u1.f2;
}

/* ... */
g.u2.f3 = f();
```

there is no undefined behavior, although there would be if the assignment were done directly (without using a function call to fetch the value).

Commentary

Neither is there any undefined behavior if the function `f` is defined as an inline function. 1526 inline function

1806 136) The **return** statement is not an assignment. footnote 136

Commentary

The difference between the **return** statement and the assignment operator is that in the former case the value is required to act as if it were held in temporary storage before it is assigned (rather like the difference between the `memcpy` and `memmove` library functions). In an assignment statement it is intended that implementations be able to perform the operation without the need of temporary storage. Possible differences in behavior can only occur when operating storage for the two operands overlaps.

C90

This footnote did not appear in the C90 Standard. It was added by the response to DR #001.

C++

This distinction also occurs in C++, but as a special case of a much larger issue involving the creation of temporary objects (for constructs not available in C).

A return statement can involve the construction and copy of a temporary object (12.2). 6.6.3p2

Temporaries of class type are created in various contexts: binding an rvalue to a reference (8.5.3), returning an rvalue (6.6.3), . . . 12.2p1

Common Implementations

Translators that inline function calls, returning a structure or union type, have to be careful about how they handle **return** statements. Mapping them to an assignment may not produce the same affect as a function call. 1529 inline suggests fast calls

The overlap restriction of subclause 6.5.16.1 does not apply to the case of function return. 1807

Commentary

assignment 1304 value overlaps object

This is effectively a requirement on implementations to ensure that the behavior is well defined (not undefined as specified elsewhere).

The representation of floating-point values may have wider range or precision and is determined by FLT_EVAL_METHOD. 1808

Commentary

floating 353 operands evaluation format

This sentence calls out behavior that is specified elsewhere as applying to the expression in a **return** statement.

This sentence was added by the response to DR #290.

A cast may be used to remove this extra range and precision. 1809

Commentary

return 1804 implicit cast

An implicit conversion is only performed on the value in a **return** statement if the type of this value is different from that of the return type.

This sentence was added by the response to DR #290.

6.9 External definitions

translation unit syntax
external declaration syntax

1810

```
translation-unit:
                external-declaration
                translation-unit external-declaration
external-declaration:
                function-definition
                declaration
```

Commentary

syntactically 138 analyzed preprocessor 1854 directives syntax
translation unit 110 known as

A *translation-unit* is the terminal production of C syntax. By the time a translator needs to perform syntax analysis the preprocessor directives, such as **#include** and **#define**, have been deleted (C syntax essentially has two terminal productions, the other being *preprocessing-file*). The term *translation unit* applies to the result of preprocessing a source file. This syntax requires that a translation unit contain at least one declaration (i.e., a source file that only contains preprocessing directives is not conforming). One of the reasons for this requirement is that some translators require the object file they create to contain at least one symbol.

The mechanism by which identifiers declared in separate translation units are made to refer to each other is linkage.

linkage 420

C++

The C++ syntax includes function definitions as part of declarations (3.5p1):

3.5p1 *translation-unit:* *declaration-seq*$_{opt}$

While the C++ Standard differs from C in supporting an empty translation unit, this is not considered a significant difference.

Other Languages

Some languages (e.g., Cobol and the first Pascal Standard) do not support any external definitions because they require all of a programs source to be translated at the same time. While other languages (e.g., Ada)

provide sophisticated separate compilation mechanisms. Some languages impose a structure, or ordering, on the components in a translation unit. For instance, Pascal requires constants to be declared first, followed by type declarations, then variable declarations and then function/procedure declarations.

Coding Guidelines

Although the interface issues are generally considered to be a significant source of faults in software there have been few empirical studies of these kinds of fault. Although a few studies have looked at source code level (e.g., incorrect number of parameters),[1344] most have tended to investigate higher level algorithmic or design issues.[1077]

Prototypes

prototypes cost/benefit

Use of function prototypes are strong recommended, if not mandated, by nearly every coding guideline document. Surprisingly there is little empirical evidence to support the claimed benefits over not using a prototype (because nobody has done the experiments). The one study that has been performed,[1121] using experienced developers, showed that use of prototypes did increase productivity. The experiment was not typical of industry practice in that subjects were provided with a paper listing of the names of all types, constants, and functions that might be required. If a program is being written from scratch the cost of using prototypes is minimal and is probably recouped the first time a translator diagnoses a mismatch between the number of parameters in a function definitions and the number arguments given in a call to it. Use of prototypes are the only economically worthwhile option.

Cg 1810.1

An *external-declaration* that declares a function shall always contain a parameter type list (i.e., a function prototype).

However, the cost/benefit decision is not so clear-cut when modifying existing code that contains old-style definitions. When making a small modification to existing code, for instance adding a function call, the impact of changing the called function (to use a prototype in its definition) may extend throughout a programs source tree. Other source files, that are not directly touched by the original modification, may contain calls to the function whose definition has been changed (to use a prototype).

Should function definitions in existing code, that don't use prototypes, be changed to use prototypes on an individual basis, as small modifications are made to the source? Or should such changes to function definitions only be performed as part of a more global reengineering of the source code? The answer to these questions will depend on what phase of its life cycle a program is in, the current commercial environment, and technical factors such as the product development environment and the product testing procedures used.

Ordering of declarations

Within a source file external declarations usually occur in some kind of recognizable order. For instance, function definitions usually appear after all of the other kinds of declarations and definitions. There is a benefit in using a recognizable order for declarations and definitions, it is information that readers can use when searching for the declaration of a particular identifier. There are a number of factors that might be considered when ordering identifier declarations, including:

- Ordering by C language attributes associated with the declared identifier. For instance, one ordering might be: some preprocessor directives (see elsewhere for a discussion on the ordering of preprocessor directives), followed by typedef names, definitions of objects with external linkage, then objects with internal linkage, and so on.

1854 preprocessor directives syntax

- Ordering by algorithmic or implementation attributes associated with the declared identifier. For instance, the macro names, typedef names, and objects color, in a translation unit that handles printing, might all be declared together in one section of the source file.

Both ordering have their own costs and benefits. For instance, ordering by C language attribute allows identifiers having that attribute to be quickly located within a source file. However, reading the declaration

of an identifier may create the need to obtain information about identifiers associated with it (e.g., type declarations). An ordering that places declarations of identifiers sharing some form of algorithmic or implementation attributes together could reduce effort for searches based on these attributes.

Selecting an optimal declaration ordering requires information on the search patterns of future readers of the source. Given that this information is unlikely to be available, the most that the authors of declarations can do is ensure they use an ordering that future readers will recognize and be able to use when searching for identifier declarations.

declarations in which source file

Which declarations in which source file?

Technically any external declaration of an object or function could be defined in any of the sources files used to build a program (provided the necessary type definitions were visible). However, experience shows that when writing a new declaration, developers often attempt to put it in a source file containing other external declarations that are considered to be related to it. The set of external object and function contained in a translation unit are often considered to be members of a category. For instance, the contents of the library headers defined by the C Standard (e.g., string handling, time information, character handling, etc.).

categorization developers organized knowledge

This developer behavior of organizing object and function definitions into categories is a special case of general human categorization behavior. People use information about category membership in a number of ways. For instance, as an aid to recall, or to deduce properties or behavior of a category member based on their knowledge of other category members.

If the classification process is driven by individual choice, then it is necessary to ask to what extent the classification chosen by one developer is of benefit to another developer. At the time of this writing there have been no studies of developer classification behavior that might be used to suggest an answer to this question (although the semantic processed involved in creating identifier spellings may be related).

A number of mathematical methods for *software clustering* (as the field has become known) have been proposed. These methods are generally legacy systems oriented in that they take the source of an existing program and attempt to find the subsystems from which it is composed.[1462] They vary in the algorithms used and the measure of source code similarity used. Mitchell and Mancoridis[944] empirically compare various algorithms and similarity measures. Fasulo[410] provides an analysis of recent mathematical work on general clustering algorithms (i.e., not software specific).

application evolution

A common characteristic of programs that have an active community of users is that they continue to grow and evolve. For instance, an analysis, by Godfrey and Tu[499] of 96 releases of the source of the Linux kernel found that the number of uncommented lines of code closely fitted the equation $0.21 \times X^2 + 252 \times X + 90055$, where X is the number of days since release 1.0. At the other end of the scale are programs that are rarely used and whose source is relatively unchanging. The source files are changed tend to be those dealing with areas that are important to business.[720]

When adding new functionality to existing code developers are faced with making a cost/benefit analysis. Should they perform any restructuring that they feel is necessary (e.g., breaking up the contents of large source file into smaller source files, each representing some facet of the category represented by the original source), an investment cost that may not be repaid by a future benefit, or should they ignore future costs and minimize current costs (i.e., no restructuring)?

These issues are very complex and at the time of this writing it does not appear to be possible to give any simple guideline recommendation on which source file object and function declarations should appear in.

coupling

The coupling between two source files (i.e., the extent to which their objects and functions each other) has been found to affect the number of faults in a program.[97, 1212] The commercial benefits, to hardware vendors, of minimizing the coupling between separate units is well documented.[87] However, the benefits may not unconditionally apply to software[162] and minimizing coupling may even increase costs in some cases.[90] Until the costs and benefits associated with coupling are better understood it is not possible to know if any guideline recommendation would be worthwhile.

By default, in C, external declarations of identifiers for objects and functions are visible outside of the translation unit that declares them (i.e., they have external linkage). Explicitly declaring identifiers to have

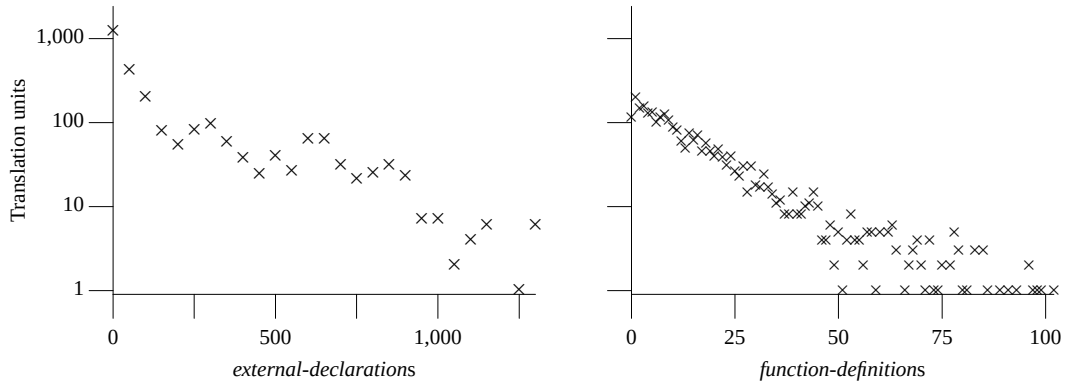

Figure 1810.1: Number of translation units containing a given number of *external-declaration*s and *function-definition*s declarations (rounded to the nearest fifty and excluding identifiers declared in any system headers that are **#include**d). Based on the translated form of this book's benchmark programs.

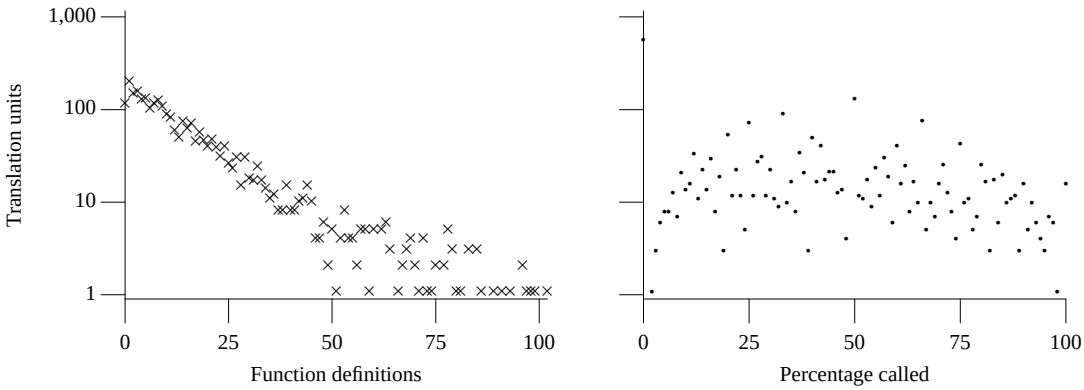

Figure 1810.2: Number of translation units containing a given number of function definitions and percentage of functions that are called within the translation unit that defines them. Based on the translated form of this book's benchmark programs.

internal linkage has the benefit of reducing the probability of name clashes with identifiers declared in other translation units. However, while the developer cost of typing the keyword **static** is negligible, the cost of working out which identifiers can be so declared may be nontrivial. Since the cost of a guideline recommending the use of internal linkage, where possible, may often be greater than the benefit, no such recommendation is made here.

Usage

On a large development project it is possible that more than one person will write some set of functions performing similar operations. This duplication of functionality occurs at a higher-level than copying and reusing sequences of statements (discussed elsewhere), it is a concept that is being duplicated. Marcus and Maletic[895] used latent semantic analysis to identify related source files (what they called *concept clones*). Source code identifiers and words in comments were used as input to the indexing process. An analysis of the Mozilla source code highlighted two different implementations of linked list functions and four files that contained their own implementations.

1821 duplicate code
792 latent semantic analysis

Constraints

1811 The storage-class specifiers **auto** and **register** shall not appear in the declaration specifiers in an external declaration.

external declaration not auto/register

Commentary

While it would have been possible to allow the storage-class specifier **register** to appear on some external declarations (e.g., those having internal linkage) the Committee did not.

C++

The C++ Standard specifies where these storage-class specifiers can be applied, not where they cannot:

7.1.1p2 *The **auto** or **register** specifiers can be applied only to names of objects declared in a block (6.3) or to function parameters (8.4).*

A C++ translator is not required to issue a diagnostic if the storage-class specifiers **auto** and **register** appear in other scopes.

Common Implementations

Some implementations[1437] take the complete program into account, during register allocation, rather than just one individual function definitions at a time. However, this is one case where developers may still be able to use their knowledge of program behavior to make better use of register resources (high-quality automatic register allocation is very dependent on the use of program execution traces). `gcc` supports the **register** storage class appearing in the declaration of objects at file scope. However, the register to be used needs to be explicitly specified, for instance in:

```
1  register int *ipc asm("a5");
```

the register `a5` is dedicated to holding the value of the object `ipc`.

---

definition one external

There shall be no more than one external definition for each identifier declared with internal linkage in a translation unit. 1812

Commentary

external definition 1817, tentative definition 1849, extern 426, identifier linkage same as prior declaration

This C sentence is referring to an *external definition*, as defined below. It is possible for there to be no explicit external definition, in which case a tentative one is implicitly created. It is possible for the same *external definition* to be declared more than once in the same translation unit.

Other Languages

linkage 420

Most languages only allow one definition of any kind of identifier. Fortran allows more than one and linkers are expected to pick a unique instance.

---

internal linkage exactly one external definition

Moreover, if an identifier declared with internal linkage is used in an expression (other than as a part of the operand of a **sizeof** operator whose result is an integer constant), there shall be exactly one external definition for the identifier in the translation unit. 1813

Commentary

external definition 1817

This C sentence is referring to an external definition, as defined below, not an identifier declared with external linkage. An identifier may be declared with internal linkage and a function type. A definition for this function is only required (apart from the specified special case) if the identifier is used in an expression. If the result of the **sizeof** operator is an integer constant its evaluation can be performed during translation and there is no need for a definition to exist.

C++

The C++ Standard does not specify any particular linkage:

3.2p3 *Every program shall contain exactly one definition of every non-inline function or object that is used in that program; no diagnostic required.*

The definition of the term used (3.2p2) also excludes operands of the **sizeof** operator.

Other Languages

Some languages (e.g., Ada and Pascal) require a definition if there is a declaration of an identifier.

Coding Guidelines

Function declarations, with internal linkage, that are not referenced within a translation unit are redundant. The issue of redundant code is discussed elsewhere.

190 redundant code

Semantics

1814 As discussed in 5.1.1.1, the unit of program text after preprocessing is a translation unit, which consists of a sequence of external declarations.

Commentary

Clause 5.1.1.1 defines the term *translation unit* as such. The use of the term *external declarations* here refers to the syntactic definition. These external declarations include declarations of identifiers that have internal linkage.

110 translation unit known as
1810 external declaration syntax

C++

The C++ Standard does not make this observation.

1815 These are described as "external" because they appear outside any function (and hence have file scope).

Commentary

A term that is commonly used to refer to such declarations, by developers working in a variety of computer languages, is *global*.

C++

The C++ Standard does not refer to them as "external" in the syntax.

Coding Guidelines

Many developers intermix the terms *external* and *global*. There is no obvious benefit to be had in changing this practice (if this were at all possible).

1816 As discussed in 6.7, a declaration that also causes storage to be reserved for an object or a function named by the identifier is a definition.

Commentary

The discussion of this C behavior occurs elsewhere.

1353 definition identifier

1817 An *external definition* is an external declaration that is also a definition of a function (other than an inline definition) or an object. external definition

Commentary

This defines the term *external definition*. The definition of an inline definition specifies that it does not provide an external definition.

1541 inline definition not an external definition

C90

Support for inline definitions new in C99.

C++

The C++ Standard does not define the term *external definition*, or one equivalent to it.

Coding Guidelines

While many developers intermix the terms *external definition* and *external declaration*, the distinction between them is significant. Coding guideline documents need to ensure that they use correct terminology.

external linkage exactly one external definition

If an identifier declared with external linkage is used in an expression (other than as part of the operand of a **sizeof** operator whose result is an integer constant), somewhere in the entire program there shall be exactly one external definition for the identifier; 1818

Commentary

internal linkage 1813 exactly one external definition

This requirement is the external linkage equivalent of the requirement given for identifiers having internal linkage. However, violation of this requirement causes undefined defined behavior, it is not a constraint violation. The reason for this difference in behavior is that the C committee wanted implementations to be able to use third-party (e.g., the host OS vendor) linkers provided as part of the translation host environment. Some of these linkers support more relaxed, Fortran style, linkage conventions, and it is not possible to guarantee that a diagnostic will be issued for a violation of this requirement.

linkers 140

linkage 420

C90

Support for the **sizeof** operator having a result that is not a constant expression is new in C99.

C++

internal linkage 1813 exactly one external definition

The specification given in the C++ is discussed elsewhere.

Other Languages

Some languages (e.g., Ada) have sophisticated separate compilation mechanisms that require specialist linker support, while the designers of other languages have been willing to live within the limitations of linkers that their implementations are likely to make use of.

Common Implementations

Many linkers do not issue a diagnostic if more than one definition of the same identifier is contained within their input files. However, most linkers do issue a diagnostic if the program image they are asked to create includes a reference to an identifier for which there is no available definition.

Many linkers create identifiers for their own internal use. For instance some Unix linkers create the identifiers `etext`, `edata`, and `end`, to designate special addresses within a programs address space. These identifiers are used purely as symbols that represent an address, they occupy no storage. Some programs make use of the information provided by these addresses. Declarations, such as the following, can be used to provide an identifier that can be referenced in expressions (there is no definition of the object provided in the source of the program, it is provided by the linker).

```
1  extern const void end;
```

A fuller discussion of using such a declaration can be found in DR #012.

Coding Guidelines

identifier 422.1 declared in one file

Following the guideline recommendation dealing with the textual placement of all identifiers, having external linkage, in a single header prevents the creation of multiple declarations that may be incompatible with each other. However, every object or function referenced, in a program, requires a unique definition. One translation unit needs to contain an identifier's definition, while all the others only contain its declaration. There are a number of techniques for ensuring that declarations and their corresponding definition match. Two commonly seen techniques are:

1. using a macro, often called `EXTERN`, or `EXTERNAL`. For instance, consider a developer written header containing the following declaration:

   ```
   1  EXTERN int glob;
   ```

   In every translation unit, except one, that includes this header, the identifier `EXTERN` is defined as an object-like macro that expands to the keyword **extern**. In one translation unit the macro name expands to nothing, causing that declaration to become a definition. Variations on this technique are used to handle explicit initialization (in fact if an explicit initializer is given the absence or presence of the **extern** storage-class specifier is irrelevant, a definition is always created),

macro 1931 object-like

object 1354 reserve storage

2. placing a definition of the identifier, that is textually separate from the declaration in the header file, in one of the translation units. Use of this technique does violate the guideline recommendation specifying a single textual occurrence of a declaration (a definition is also a declaration). Recreating the problem of ensuring that both declarations are the same. 1353 definition identifier

In the case of functions, their declarations and definitions have to be textually separate. The complexities of using preprocessor directives to enable one textual occurrence to be used both as the declaration and the definition has a much higher cost than benefit. A method of ensuring that the two textual occurrences are the same is needed. One solution, that can be applied to both object and function declarations, is to make use of a property of the C language. It is possible to have multiple declarations of the same identifier, in the same scope, with external linkage, provided their declarations are compatible (a slightly less restrictive requirement than being the same). Translators are required to issue a diagnostic if the types are not compatible, so automated checking is performed.

Cg 1818.1

A source file that contains a textual definition of an object or function, having external linkage, shall **`#include`** the header file that contains its textual declaration.

1819 otherwise, there shall be no more than one.[137)]

Commentary

An identifier declared in a program may also be defined, even if it is not referenced in the program. However, whether such an identifier is referenced or not, the requirement on there being at most one definition is the same.

C++

The C++ Standard does not permit more than one definition in any translation unit (3.2p1). However, if a non-inline function or an object is not used in a program it does not prohibit more than one definition in the set of translation units making up that program.

Source developed using a C++ translator may contain multiple definitions of objects that are not referred.

Common Implementations

Some translators optimize away (by not writing any information about them to the object file) objects with internal linkage that are not referenced within the translation unit that contains their definition. Many linkers attempt to only include the definitions of objects and functions, in a program image, that are referenced from within that program.

Coding Guidelines

An identifier that is defined and not referenced is redundant code. This issue is discussed elsewhere. 190 redundant code

---

1820 137) Thus, if an identifier declared with external linkage is not used in an expression, there need be no external definition for it. footnote 137

Commentary

This permission is needed to support the C model of separate translation. A header file containing many declarations may be included in the source files used to build a program. However, because a definition for an identifier declared in a header is only required if the identifier is referenced, developers do not have to be concerned about what is declared in the headers they include.

C++

The C++ Standard does not make this observation.

Other Languages

Whether or not it is possible to declare an identifier without also providing a definition depends on the separate translation model used by a language.

6.9.1 Function definitions

function definition syntax

```
function-definition:
          declaration-specifiers declarator declaration-list_opt compound-statement
declaration-list:
          declaration
          declaration-list declaration
```

Commentary

Syntactically it is not possible to tell the difference between a function definition and a function declaration until the first token after the declaration list is seen (which could be either a semicolon, an opening brace, or an identifier).

C++

The C++ Standard does not support the appearance of *declarator-list*$_{opt}$. Function declarations must always use prototypes. It also specifies additional syntax for *function-definition*. This syntax involves constructs that are not available in C.

Other Languages

Many other languages use a keyword to indicate that a body of code is being defined. The keywords used include **procedure**, **function**, and **subroutine**. Fortran supports the creation of statement functions within a subroutine. They essentially specify a form of parameterized expression, that can also access the objects visible at the point they are defined. They are invoked using the function call notation.

Common Implementations

An extension supported by `gcc` allows developers to specify attributes that a function definition possesses. For instance, some functions do not modify any objects that are not defined within their body. Making such information available to an optimizer means it does not have to make worst-case assumptions about the affects of a function call. The following declaration specifies that the function `square` has this attribute:

```
1  int square(int) __attribute__((const));
```

The IAR PICmicro compiler[612] supports the **`__monitor`** specifier, which causes machine code to be generated that ensures the specified function is executed as an atomic entity (i.e., interrupts are disabled during its execution).

value profiling 940

Recent research has shown that the value of some function parameters is the same over a large percentage of calls (for instance, based on using the SPEC95 dataset as input to `gcc`, in 70% of cases the value of the third parameter of calls to the function `simplify_binary_operation` was 34[986]). A cost/benefit analysis can be used to decide whether it is worthwhile creating a specialized version, optimized for a known value of one of the parameters, of a function. The cost of such specialization is the addition, by the translator, of a check against the common value to decide whether to jump to the specialized or unspecialized version. The benefit occurs when the specialized version executes much more quickly (flow analysis making use of the known parameter value to improve the quality of machine code generated for the specialized version). To be worthwhile the overall increase in performance in the specialized version has to be greater than the decrease in performance caused by the test against the frequently occurring value on function entry.

Coding Guidelines

A program usually contains more than one function. Splitting a program up into what are sometimes called *modules* (i.e., C functions) has a long history. A variety of reasons for creating and using functions have been proposed, including the following:

- Use of appropriately sized functions (not to big and not to small, sometimes known as the *Goldilocks principle*) is believed to have various benefits (although studies validating these claims appear to be non-existent[445]). Park[1054] discusses how statements might be counted, and Fenton[417] discusses using size metrics to predict the likely number of defects contained in software. While it is possible to plot measurements of various quantities against each other (e.g., a plot of defect density against function size produces a U-shaped curve, showing that very small functions and very large functions contain more defects per line of code than medium sized functions[550]), the measurements are usually averaged over all functions in a program and causal links between the two quantities are rarely established. One problem with measurements based on the size of individual functions is that it is possible artificially change the results obtained, by splitting one function into many, or merging several into one function. For instance, reducing the number of control flow paths[1447] through a function is often seen as beneficial, because it reduces the amount of path testing that needs to be performed. A reduction in the number of paths in any function definition can be achieved by breaking it up into smaller functions. However, the reduction achieved is an artifact of the measuring process, which is based on individual definitions. The number of paths through the program has not been reduced.

- It is part of the culture of writing source code (it's what students are told they must do when learning to program, and developers who don't split their code into appropriately sized functions are often chastised for this behavior). Various program designed methodologies have specified rules for how a program should be decomposed. For instance, the structured design movement (the original Stevens, Myers, and Constantine paper was recently republished[1296]) used the idea of coupling and cohesion between statements as a means of deciding which of them belonged in a module. There have been proposals to define the concepts of coupling[1027] and cohesion[993] in more mathematical terms. However, while this formalism enables calculations to be made by automatic tools, studies of applicability of these definitions to human readers are lacking (see Halliday and Hasan[536] for a discussion of cohesion in English text). Concept analysis is a technique for identifying groupings of objects, in existing source code, that share common attributes. It has been used identify possible C++ classes in C source code.[1235]

  coupling and cohesion

  concept analysis

- It enables the available work to be distributed to be distributed across more than one person.

- Reducing the amount of duplicate, or very similar, code in a program. This can reduce maintenance costs by minimizing the amount of existing code that needs to be modified when changes to the behavior of a program are made (measurements of duplicate code remaining in existing programs are discussed elsewhere).

  1821 duplicate code

- Splitting a program into independent modules makes it easier to change parts of it in the future. The flexibility offered by the ability to upgrade parts of a hardware system, as technology improved, rather than having to buy a new system has been shown to offer significant economic advantages for both vendors and users.[87] Breaking a system up into modules is not enough, it is also necessary to hide information; to be exact, information that is likely to change has to be hidden within individual modules.[1059] Predicting in advance which parts of a program are likely to be changed is a difficult problem. One proposed solution is based on the economic theory of options,[1312] valuing software structures on the basis of the cost of changing them in the future.

- Reuse of software once written (e.g., libraries of functions). This issue is not considered in these coding guidelines.

A large part of comprehending a program involves comprehending the side effects generated from executing the statements contained in particular function definitions.[1821.1] A developer's ability to predict the behavior of a program is based on their knowledge of the behavior of individual function definitions (e.g., how they modify data structures and which other functions they might call). A question often asked, by developers, about a function is "what does it do?". In many ways a function definition represents an episode of a program, which when executed in sequence with other functions tell the story that is program execution.

statement 1707 syntax

The coding guideline discussion on statements drew a parallel with studies of human sentence processing, in an effort make use of some of the findings of those studies. The discussion in of function definitions, in this coding guideline subsection, extends the use of this parallel to studies of story comprehension. It is assumed that existing human story telling and comprehension skills are something developers apply to the reading and writing of code.

A function definition is the largest unit of contiguous source code that readers might generally expect to read from start to finish.[1821.2] Reading the story of a programs execution invariably requires readers to look at a variety of different functions which are not usually visually close to the text of the definition current being read. This behavior differs from that required to read the written form of prose stories, where the intended narrative flows sequentially through visually adjacent text (although readers might only read a few chapters at a time).

memory 0 episodic
memory 0 semantic

Developer memory for a function definition may depend on when they last read it. For instance, a definition that has just been read might be stored in episodic memory, while one that was read some a few days ago might be stored in semantic memory. Whether or not these differences in human memory storage mechanism, for source code information, affects developer performance is not known.

Adults have an extensive knowledge of routine activities (e.g., eating in a restaurant or going shopping) and spend a significant amount of their time performing these activities (they are very practiced at performing some of them). The *script theory* of Schank and Abelson[1218] proposes that part of a person's knowledge is organized around a large number of sterotypical situations involving activities that are often performed.

Studies of the structure of narrative stories have a long history, while the study of the structure of source code is still in its infancy. The following illustrates some of the studies that have investigated regularity and repeated elements in prose stories and source code:

- A study by Mandler and Johnson[894] analyzed the structure of simple stories and created a grammar to describe it. In the following grammar STATE may be external (e.g., a current conditional of the world) or internal (e.g., an emotional state of mind). An EVENT is any occurrence or happening and may also be external or internal. The terminals AND, THEN, and CAUSE represent various relationships that may connect states and events.

```
STORY      -> SETTING AND EVENT_STRUCTURE
SETTING    -> STATE* (AND EVENT*) | EVENT*
STATE*     -> STATE ((AND STATE)^N)
EVENT*     -> EVENT (((AND | THEN | CAUSE) EVENT)^N)((AND STATE)^N)
EVENT_STRUCTURE -> EPISODE ((THEN EPISODE)^N)
EPISODE    -> BEGINNING CAUSE DEVELOPMENT CAUSE ENDING
BEGINNING -> EVENT* | EPISODE
DEVELOPMENT       -> SIMPLE_REACTION CAUSE ACTION | COMPLEX_REACTION CAUSE GOAL_PATH
SIMPLE_REACTION  -> INTERNAL_EVENT ((CAUSE INTERNAL_EVENT)^N)
ACTION     -> EVENT
COMPLEX_REACTION -> SIMPLE_REACTION CAUSE GOAL
GOAL       -> INTERNAL_STATE
GOAL_PATH -> ATTEMPT CAUSE OUTCOME | GOAL_PATH (CAUSE GOAL_PATH)^N
ATTEMPT    -> EVENT*
```

[1821.1] Many source code metrics are based purely on counting some attribute of the contents of function definitions.
[1821.2] In object-oriented languages the largest such unit might sometimes be a class.

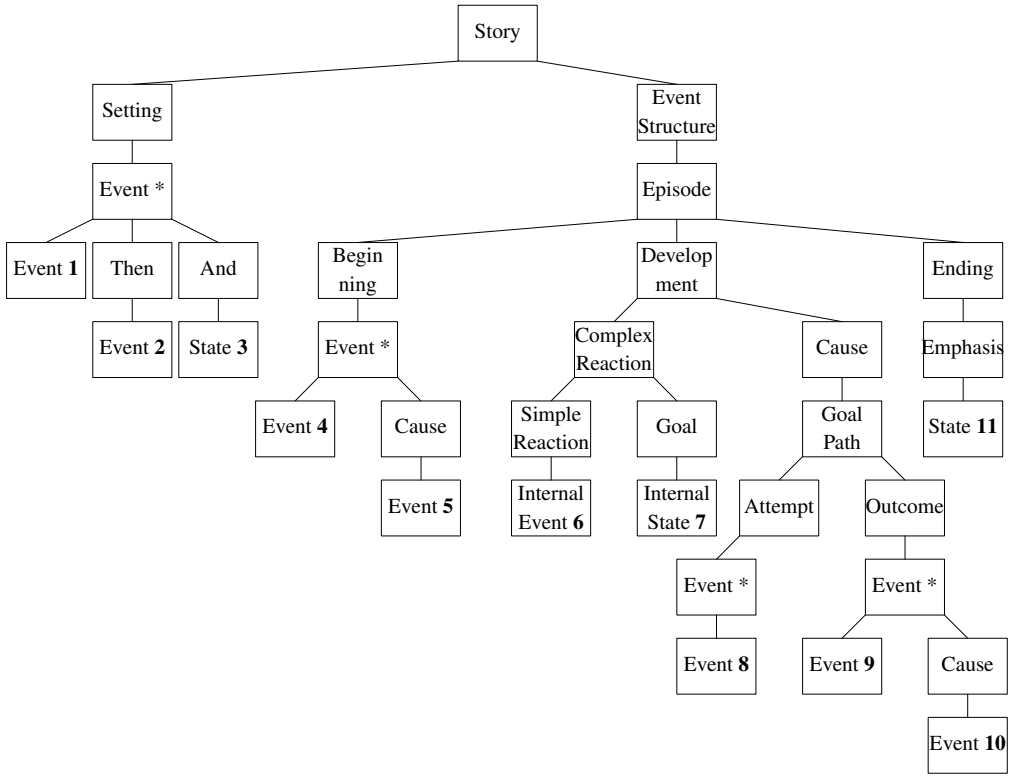

Figure 1821.1: Parse, using the Story grammar, of the tale of a dog and piece of meat. Adapted from Mandler and Johnson.[894]

```
OUTCOME   -> EVENT* | EPISODE
ENDING    -> EVENT* (AND EMPHASIS) | EMPHASIS | EPISODE
EMPHASIS  -> STATE
```

The following is an example of a story following this grammar:[894]

```
1  It happened that a dog had got a piece of meat
2  and was carrying it home in his mouth.
3  Now on his way home he had to cross a plank lying across a stream.
4  As he crossed he looked down
5  and saw his own shadow reflected in the water beneath.
6  Thinking it was another dog and another piece of meat,
7  he made up his mind to have that also.
8  So he made a snap at the shadow,
9  but as he opened his mouth the piece of meat fell out,
10 dropped into the water,
11 and was never seen again.
```

- Most attempts to find semantic narrative in software have been based on what are called *programming plans*. Global plans being built in a bottom-up fashion from a database of known local plans. A local plan is based on the control and data flow constructs of a group of statements (e.g., a loop over the elements of an array that performs some action when one of the elements matches a fixed value may match a linear search plan) (Hartman[546] discusses the recognition of local plans based on concepts from a number of domains, including the application domain, mathematics, and known programming techniques; Wills[1470] describes building a database of clichés and searching for them in a graphical

representation of the program). The problem of recognizing a particular program plan in source code is NP-hard[1483] ($O(S^A)$, where S is the size of the program, measured in units matched by subplans, and A is the number of subplans within the plan). Various matching heuristics have been proposed, including constraint based methods Woods.[1482] Once detected plans (clichés, concepts, schemas, templates, or some other term) have been used to locate and correct common novice programmer mistakes,[676] recognize algorithms that can be transformed into a more efficient form (e.g., matrix multiply).[352]

When presented with a sequence of actions peoples attempt to match them against patterns of action they are familiar with. A brief description, providing an overview, can have a significant impact on comprehension and recall performance (this issue is discussed elsewhere).

identifier 792
cue for recall

A persons experience with the form and structure of these repeated elements seems to be used to organize the longer-term memories they form about them. The following studies illustrate the affect that peoples knowledge of the world can have on their memory for what they have read, particular with the passage of time, and their performance in interpreting sequences of related facts they are presented with:

- A study by Bower, Black, and Turner[146] gave subjects a number of short stories describing various activities (i.e., scripts), such as visiting the dentist, attending a class lecture, going to a birthday party, etc., to read. Each story contained about 20 actions, such as looking at a dental poster, having teeth x-rayed, etc. There was then a 20 minute interval, after which they were asked to recall actions contained in the stories. The results showed that subjects around a quarter of recalled actions might be part of the script, but that were not included in the written story. Approximately seven percent of recalled actions were not in the story and would not be thought to belong to the script. A second experiment involved subjects reading a list of actions which, in the real world, would either be expected to occur in a known order or be not expected to have any order (e.g., the order of the floats in a parade). The results showed that, within ordered scripts, actions that occurred at their expected location were recalled 50% of the time while actions occurring at unexpected locations were recalled 18% of the time at that location. The recall rate for unordered scripts (i.e., the controls) was 30%.
- A study by Graesser, Woll, Kowalski, and Smith[511] read subjects stories representing scripted activities (e.g., eating at a restaurant). The stories contained actions that varied in the degree to which they were typical of the script (e.g., Jack sat down at the table, Jack confirmed his reservation, and Jack put a pen in his pocket).

Table 1821.1: Probability of subjects recalling or recognizing typical or atypical actions present in stories read to them, at two time intervals (30 minutes and 1 week) after hearing them. Based on Graesser, Woll, Kowalski, and Smith.[511]

Memory Test	Typical (30 mins)	Atypical (30 mins)	Typical (1 week)	Atypical (1 week)
Recall (correct)	0.34	0.32	0.21	0.04
Recall (incorrect)	0.17	0.00	0.15	0.00
Recognition (correct)	0.79	0.79	0.80	0.60
Recognition (incorrect)	0.59	0.11	0.69	0.26

The results showed (see Table 1821.1) that recall was not affected by typicality over short periods of time, but that after one week recall of atypical actions dropped significantly. Recognition (i.e., subjects were asked if a particular action occurred in the story) performance for typical vs. atypical actions was less affected by the passage of time.

- A study by Dooling and Christiaansen[366] asked subjects to read a short biography containing 10 sentences. The only difference between the biographies read by subjects was that in some cases the name of the character was fictitious (i.e., a made up name), while in other cases it was the name of an applicable famous person. For instance, one biography described a ruthless dictator and used

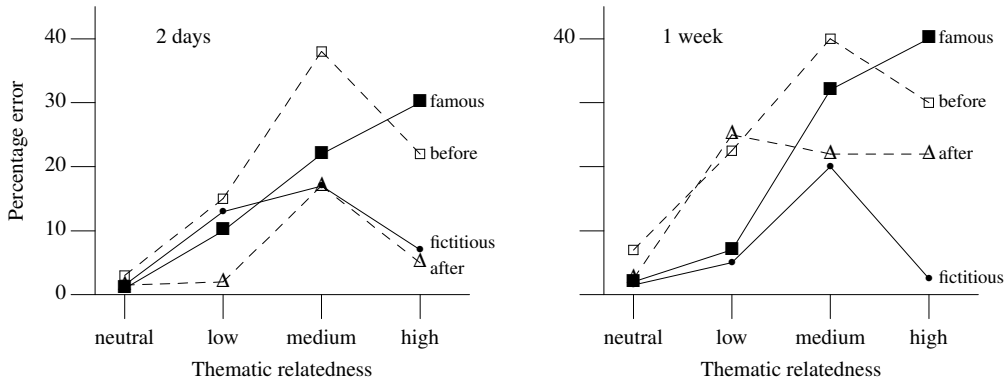

Figure 1821.2: Percentage of false-positive recognition errors for biographies having varying degrees of thematic relatedness to the famous person, in *before*, *after*, *famous*, and *fictitious* groups. Based on Dooling and Christiaansen.[366]

either the name Gerald Martin or Adolph Hitler. After a period of two days, and then after one week, subjects were given a list of 14 sentences (seven sentences that were included in the biography they had previously read and seven that were not included) and asked to specify which sentences they had previously read. To measure the impact of subjects' knowledge about the famous person, on recognition performance, some subjects were given additional information. In both cases the additional information was given to the subjects who had read the biography containing the made up name (e.g., Gerald Martin). The *before* subjects were told just before reading the biography that it was actually a description of a famous person and given that persons name (e.g., Adolph Hitler). The *after* subjects were told just before performing the recognition test (they were given one minute to think about what they had been told) that the biography was actually a description of a famous person and given that persons name.

The results (see Figure 1821.2) are consistent with the idea that remembering is constructive. After a week subjects memory for specific information in the passage is lost. Under these conditions recognition of sentences is guided by subjects general knowledge. Variations in the time between reading the biography and identity of a famous character being revealed affected the extent to which subjects integrated this information.

- A study by Kintsch, Mandel, and Kozminsky[737] measured the time taken to read and summarize 1,400 word stories. In the text seen by some students the order of the paragraphs (not the sentences) forming the story were randomized. The results showed that while it was not possible to distinguish between the summaries produced by subjects reading ordered vs. randomised stories, reading time for random paragraph ordering was significantly longer (9.05 minutes vs. 7.34).

Developers do not read the source code of a function definition every time they encounter a reference to it. If it has been read before they may be able to recall sufficient information about it to satisfy their immediate needs (how people trade-off the costs of recalling knowledge in their heads against obtaining knowledge from the real world is discussed elsewhere). The results of studies of story recall performance suggest that recall of events is more accurate when the events that occur correspond to reader expectations (which might be based on their knowledge of program plans, or application domain knowledge) about what events should occur.

0 cost/accuracy trade-off

Developers use their knowledge of what functions do in several ways, including:

- to deduce the expected affects of performing a call to that function,
- to work out which functions need to be updated when modifying the behavior of a program, and
- to work out which functions may be affected by changes to the definition of other functions,

In all cases forgetting about an action performed by the function definition or assuming that it performs some action, when it does not it, can result in unexpected behavior during program execution.

The expectations that a reader might have about the actions performed by particular function definitions may require knowledge of the application domain, algorithms, C idioms, and development group conventions. The analysis of what actions do, or don't, meet these expectations can only be carried out (for the time being) by developers familiar with these domains. Also it might not be possible to simultaneously satisfy expectations from all of these domains, it is likely that trade-offs will need to be made.

An example of an action carried out within a function definition that would be surprising, or unexpected, might be the disabling of interrupts within a function that performs block copies of storage (perhaps special registers used by the operating system are being used to speed up the copy operation, which are restored once the copy has completed).

The parameters in a function definition are likely to be read more often that the parameters in any declaration of it. For this reason it is likely to be worth investing more in laying out the visible form of parameter declarations. The issue of declaration layout is discussed elsewhere.

declaration 1348
visual layout

mixing declarations and statements

Order of declarations and statement

Developers often have some flexibility in how they order declarations and statements within a function. For instance, one or more of the following patterns of usage are often seen in source:

- The declarations for all of the locally defined objects occur at the start of the function (it is rare to see a compound block opened and closed around a short sequence of statements purely to declare an object whose required lifetime and scope is limited to those statements) (see Figure 408.1).
- Grouping statements by the action they perform. For instance, initializing all objects at the start of a function, or performing all output at the end of a function.
- Grouping statements that access the same objects together. For instance, initializing objects close to where they are first accessed, or performing output as soon as the necessary values are known.

There are a number of reasons why grouping statements by the objects they access might offer greater benefits than other grouping algorithms, including:

- Minimizing the number of separate sequences of source that need to be cut-and-pasted when copying or reorganizing code.
- Minimizing the amount of source that intervenes between two statements containing information that needs to be integrated (into a model of function behavior) increases the probability that readers will make the correct inferences.

statements 1707
integrating information between

Recommending that related sequences of statements and/or declarations be grouped together begs the question of how to measure *related*. Given the current lack of an algorithmic measure the only alternative is to fall back on developer preferences (e.g., code reviews).

Rev 1821.1 Where possible, statements that are related to each other shall be visible close to each other in the source code.

Some coding guideline documents recommend a maximum number of lines, or statements, in a function definition. However, arbitrarily splitting a function into smaller functions purely to meet some recommended limit (experience suggests that some developers do arbitrarily split function that are considered to be too large; adherence to guideline recommendations cannot force developers to think deeply about what they are doing).

Knowing when to split a large function into smaller functions depends on developer ability to spot separate concepts. It is a matter of experience.

One practical consideration is the finite number of source lines that can be viewed on a display device at any time. Being able to view the complete source of a function removes the need for any external effort apart from eye movements (developers trading off the costs of physical and mental effort, needed to obtain information, is discussed elsewhere). It may, or may not, be possible to comprehend a function by reading its visible source without referring back to previously read material that are no longer visible on the display.

0 cost/accuracy trade-off

Functions definitions do not always increase in size. For instance, duplicate sequences of code, appearing in different parts of the same or different functions, may suggest the creation of a function containing a single instance of that code (this process reduces the size of existing functions).

Duplicate source code

duplicate code

The same code may occur in several places of the same program (the source does not have to be character for character identical to be considered *the same*, commenting or layout may differ, some identifiers may have different spellings, or one or more lines may have been added or deleted). The terms *duplicate code* or *clones* is often used to describe instances of similar code.

The following are some of the reasons why duplicate code may exist in a program:

- The functionality required is very similar to that implemented by some existing source. The developer copies this existing source to use as a template for the new functionality, which may only involve a few changes to the original.
- Enhancing performance. For instance, replacing a function call, within a loop, by a copy of the body of the function.
- C's lack of support for generic types. For instance, a function defined to perform some operation on objects of type `X` and a duplicate definition that performs the same operation on objects having type `Y`. One solution here is to use call backs (e.g., the `qsort` library function has no need of any knowledge of the type of the objects being compared because it calls a developer supplied function to perform comparisons).
- Oversight. On large development efforts it is not unknown for two developers to implement functions having the same functionality.
- Coincidence. In any large program there are likely to be sequences of statements that are very similar, even though their purpose is completely different.

Duplication of source code not only increases the size of programs, it also increases the possibility of faults being created by modifications to existing code.[667] For instance, when one sequence of statements is modified, but a duplicate sequence in another part of the program is left unmodified (the unmodified statements may not have needed modification; however, experience suggests that there is a very real likelihood that they did).

Merging duplicate sequences of statements into a single textual occurrence ensures that any changes that need to be made only need to be made in one place. Whether this one place is a function (inline or not) or a macro is a developer decision.

0 agenda effects decision making

It is to be expected that programs will contain individual lines that are identical. Similarity only becomes noteworthy when significant amounts of code have a high degree of similarity. Judgments of what constitutes significant can vary. Detecting duplicate code can be a computationally expensive process and a number of different algorithms have been proposed, including:

- Baker[85] built a C based tool `dup` that looked for either exact matches (ignoring white space) or parameterized matches (called *p-matches*, where the spelling of identifiers and constant literals could be different). Running `dup` on 714,479 lines of the X Window System it found 2,487 matches (representing 976 groups, each instances of code that had been copied and edited) of at least 30 lines (representing 19% of the code).

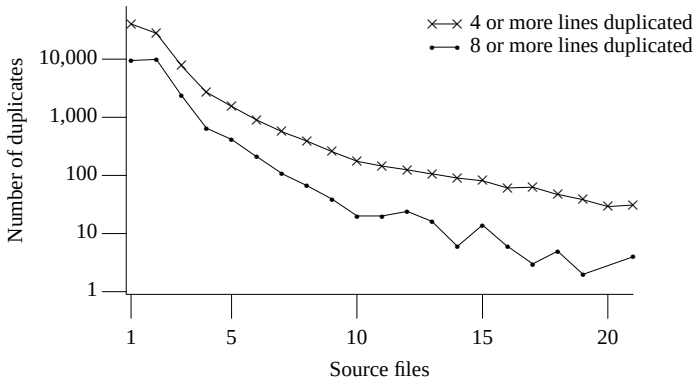

Figure 1821.3: Number of instances of duplicate physical lines, where a given duplicate line sequence is contained within a single source file or more than one source file (ignoring comments and blank lines) for sequences having at least 4 and 8 lines. Data created by processing the `.c` files (for each of the book's program's complete source tree) using `Simian`.[1151]

Table 1821.2: Number of clones (the same sequence of 30 or more tokens, with all identifiers treated as equivalent) detected by CCFinder between three different operating systems (Linux, FreeBSD, and NetBSD). Adapted from Kamiya, Kusumoto, and Inoue.[711]

O/S pairs	Number of Clone Pairs	% of Lines Included in a Clone	% of Files Containing a Clone
FreeBSD/Linux	1,091	FreeBSD (0.8) Linux (0.9)	FreeBSD (3.1) Linux (4.6)
FreeBSD/NetBSD	25,621	FreeBSD (18.6) NetBSD (15.2)	FreeBSD (40.1) NetBSD (36.1)
Linux/NetBSD	1,000	Linux (0.6) NetBSD (0.6)	Linux (3.3) NetBSD (2.1)

- Code that has been cut-and-pasted may subsequently have small changes made to it. A number of researchers have attempted to detect plagiarism,[1120, 1417] where an attempt has been made to hide the origins of the code (e.g., in student assignments).
- It is often possible for different sequences of the same set of statements to have the same effect. However, the dependencies between statements will not be affected by any differences in ordering and comparisons based on a dependence graph will be able to find duplicates.[773]
- Other studies have used similarity measures based on the abstract syntax tree,[102] software metrics,[907] and the visible source (after white space and comments had been removed).[370]

Analysis of programs, that have been developed over a period of time, shows that they contain a surprisingly large amount of duplicate code, and that the percentage of clone functions stays approximately the same over multiple releases of a product (6–8% clones over 6 product releases as the number of function grew from 170,00 to 206,000[791]).

Not all applications are made up of a single program. For large applications it can be worthwhile to have a number of smaller programs, each performing a specific function. Once the decision is made to have separate programs there is the real possibility that source code will be cut-and-pasted between different programs, rather than a common set of library functions created.

A study by Tonella, Antoniol, Fiutem, and Calzolari[1355] describes an application containing 4.7 M lines of code making up 402 programs (there were that many functions called main) linking against 815 compiled translation units (libraries). A metric taxonomy[907] was used to detect function clones. Out of 7,277 functions; 1,016 had the same name and metric values, 609 had different names but the same metric

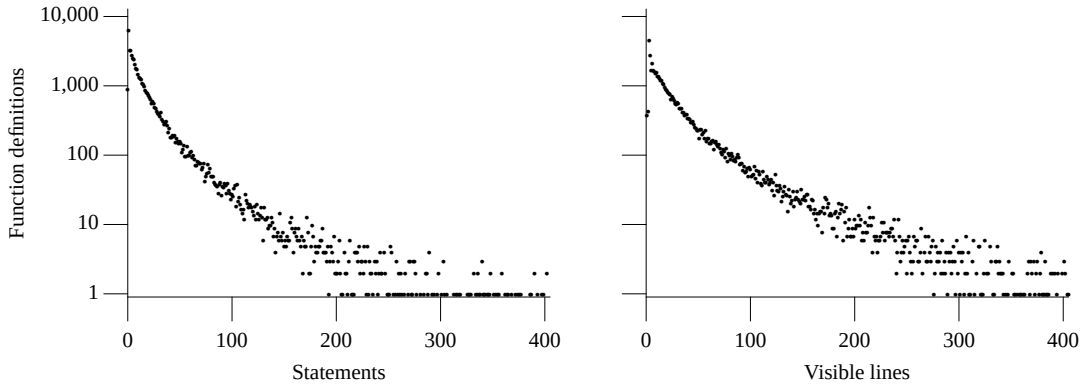

Figure 1821.4: Number of function definitions containing a given number of statements and visible source lines. Based on the translated form of this book's benchmark programs.

values, and 621 functions differed by a single metric. No results were given for how many functions were actually removed from the complete application suite. They were under considerable time pressure which meant it was not possible to consider all function clones.

Use of functions invariably causes developers to consider efficiency issues. The efficiency issues associated with the call/return overhead are discussed elsewhere as are the issue of passing parameters versus using global objects.

1004 register function call housekeeping
288 limit parameters in definition

Usage

A study of over 3,000 C functions by Harrold, Jones, and Rothermel[545] found that the size of a functions control dependency graph was linear in the number of statements (the theoretical worst-case is quadratic in the number of statements).

A study by Neamtiu, Foster, and Hicks[998] of the release history of a number of large C programs, over 3-4 years (and a total of 43 updated releases), found that in 81% of releases one or more existing function definitions had their argument signature changed, while one or more function definitions had their return type changed in 42% of releases and one or more function definitions had their name changed in 49% of releases.[997]

Table 1821.3: Static count of number of functions and uncalled functions in SPECint95. Adapted from Cheng.[222]

Benchmark	Lines of Code	Number of Functions	Uncalled Functions	Benchmark	Lines of Code	Number of Functions	Uncalled Functions
008.espresso	14,838	361	46	126.gcc	205,583	2,019	187
023.eqntott	12,053	62	2	130.li	7,597	357	1
072.sc	8,639	179	8	132.ijpeg	29,290	477	16
085.cc1	90,857	1,452	51	134.perl	26,874	276	13
124.m88ksim	19,092	252	13	147.vortex	67,205	923	295

How many instructions are executed, on average, in a function definition? It will depend on the characteristics of the translator and host processor (see Table 1821.4).

0 translation technology

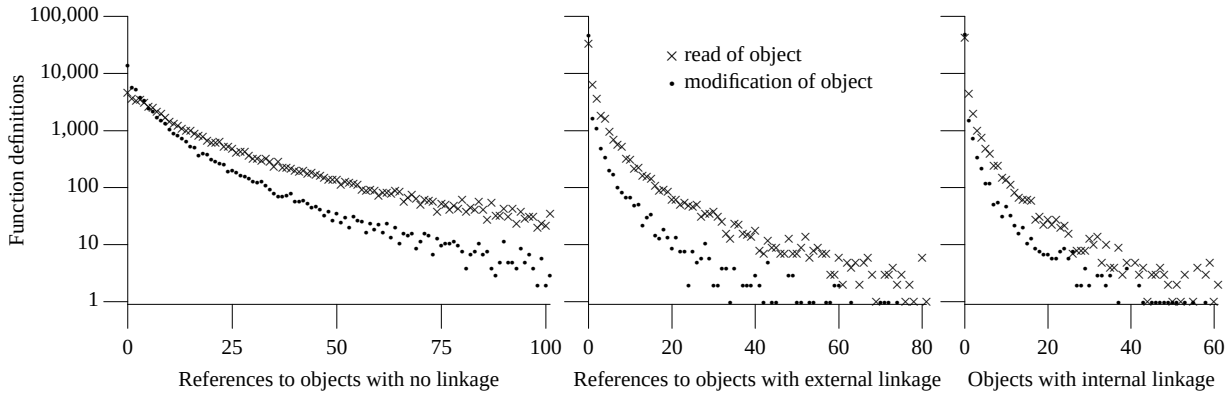

Figure 1821.5: Number of function definitions containing a given number of references (i.e., an access or modification) to all objects, having various kinds of linkage. Based on the translated form of this book's benchmark programs.

Table 1821.4: Mean number of instructions executed per function invocation. Based on Calder, Grunwald, and Zorn.[192]

Program	Mean	Leaf	Non-Leaf	Program	Mean	Leaf	Non-Leaf
burg	61.6	30.6	142.8	eqntott	386.8	402.8	294.2
ditroff	58.6	72.3	56.3	espresso	244.9	151.3	526.5
tex	173.2	44.3	205.4	gcc	96.4	30.1	123.5
xfig	61.9	38.6	74.8	li	42.5	31.9	44.2
xtex	114.9	93.9	136.5	sc	71.1	49.4	80.1
compress	368.4	1,360.2	367.5	Mean	152.8	209.6	186.5

Table 1821.5 gives a breakdown of the overall control flow characteristics of function bodies. One explanation for the larger number of SPECint benchmark functions containing iteration statements is that these programs were selected on the basis of primarily being cpu bound. The only practical way of using lots of cpu time is to iterate and hence this benchmark is biased in favour functions that iterate a lot.

Table 1821.5: Contents of function bodies (as a percentage of all bodies) for embedded `.c` source,[390] SPECint95, and the translated form of this book's benchmark programs.

	Embedded	SPECint95	Book benchmarks
Trivial (one basic block)	32.7	16.2	57.1
Non-looping	47.9	48.1	18.1
Looping	19.4	35.7	24.8

Usage information on the number of objects defined within a function definition is given elsewhere (see Figure 286.1).

Constraints

The identifier declared in a function definition (which is the name of the function) shall have a function type, as specified by the declarator portion of the function definition.[138)] 1822

Commentary

declarator syntax 1547 The syntax for function definitions requires a declarator, which means that the following:

```
1 int x
2 { }
```

is syntactically valid. However, it violates the above constraint. In the following declarations:

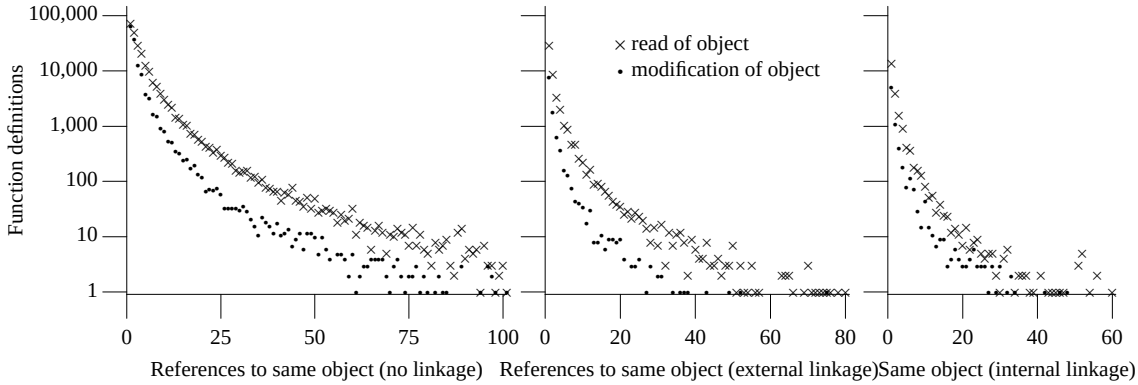

Figure 1821.6: Number of function definitions containing a given number of references (i.e., an access or modification) to the same object, having various kinds of linkage. Based on the translated form of this book's benchmark programs.

```
1  typedef int F(void);
2  F f { /* ... */ }
```

the declarator `f` does not syntactically specify a function type (see the footnote for further discussion). 1830 footnote 138

C++

The C++ Standard specifies the syntax (which avoids the need for a footnote like that given in the C Standard):

The `declarator` *in a* `function-definition` *shall have the form* 8.4p1

D1 (*parameter-declaration-clause*) *cv-qualifier-seq*$_{opt}$ *exception-specification*$_{opt}$

Common Implementations

Many translators use the requirements specified in this constraint to simplify the language grammar they need to process. Consequently the diagnostic message they issue for a violation of this constraint often refers to a violation of syntax.

1823 The return type of a function shall be **`void`** or an object type other than array type. function definition return type

Commentary

This wording is slightly different from that specified for function declarators, but the set of return types supported is the same. While function types are not included, pointers to functions are object types and are therefore permitted. 1592 function declarator return type

Array types are converted to pointer types in many contexts. Given the occurrence of these implicit conversions, writing an expression (e.g., in a **`return`** statement) that has an array type is relatively involved. A special case dealing with objects having an array type in a **`return`** statement would add complications to the language for little obvious benefit (it is possible to declare a function to return a structure type, which has a member having an array type). 729 array converted to pointer

C++

Types shall not be defined in return or parameter types. 8.3.5p6

The following example would cause a C++ translator to issue a diagnostic.

```
enum E {E1, E2} f (void) /* does not change the conformance status of program */
                         // ill-formed
{
return E1;
}
```

Other Languages

A number of languages support functions returning array types and some languages (e.g., those in the functional family of languages) support functions returning function types or even partially evaluated functions. However, some languages further restrict the return type to being a scalar type.

Example

```
int (*g)(void)    /* Constraint violation. */
{ /* ... */ }

int (*h(void))[2] /* Constraint violation. */
{ /* ... * }
```

Usage

Usage information on function return types in the `.c` files is given elsewhere (see Table 1005.1).

Table 1823.1: Occurrence of function return types (as a percentage of all return types; signedness and number of bits appearing in value representation form) appearing in the source of embedded applications (5,597 function definitions) and the SPECint95 benchmark (2,713 function definitions). A likely explanation of the greater use of type **`void`** is the perceived performance issues associated with returning values via the stack causing developers to return values via objects at file scope. Adapted from Engblom.[390]

Type/Representation	Embedded	SPECint95	Type/Representation	Embedded	SPECint95
`void`	59.4	31.2	ptr-to . . .	2.0	17.1
unsigned 32 bit	0.5	2.2	signed 32 bit	0.3	48.4
unsigned 16 bit	3.3	0.0	signed 16 bit	1.6	0.2
unsigned 8 bit	31.6	0.5	signed 8 bit	0.8	0.0

The storage-class specifier, if any, in the declaration specifiers shall be either **`extern`** or **`static`**. 1824

Commentary

In the context of function declarations, storage-class specifiers are used to specify linkage. The two chosen where **`extern`** and **`static`** (representing external and internal linkage respectively), making the appearance of any other storage-class specifier meaningless.

C++

7.1.1p2 *The **`auto`** or **`register`** specifiers can be applied only to names of objects declared in a block (6.3) or to function parameters (8.4).*

A C++ translator is not required to issue a diagnostic if these storage-class specifiers appear in other contexts. Source developed using a C++ translator may contain constraint violations if processed by a C translator.

Common Implementations

One possible interpretation that could be given to the **`register`** storage-class appearing in a function definition, is as a hint to translators that the machine code for the function body be kept in a processor's cache 0 instruction cache. However, support for explicit program control of the cache is only just starting to appear in commercially available processors.

Coding Guidelines

The coding guideline issues associated with function declarations that include the storage-class specifier **static**, **extern**, or no storage-class are discussed elsewhere.

425 static internal linkage
426 extern identifier linkage same as prior declaration
430 function no storage-class

1825 If the declarator includes a parameter type list, the declaration of each parameter shall include an identifier, except for the special case of a parameter list consisting of a single parameter of type **void**, in which case there shall not be an identifier.

Commentary

The syntax for a parameter type list in a function definition is the same as that used for function declarations, where no identifiers need be specified. However, in the case of a function identifiers are required, otherwise there is no mechanism for accessing any argument value passed in that position (use of the ellipsis does not involve the explicit specification of type information)

1601 ellipsis supplies no information

C++

An identifier can optionally be provided as a parameter name; if present in a function definition (8.4), it names a parameter (sometimes called "formal argument"). [Note: in particular, parameter names are also optional in function definitions and . . .

8.3.5p8

[Note: unused parameters need not be named. For example,

```
void print(int a, int)
{
    printf("a = %d\n",a);
}
```

—end note]

8.4p5

Source developed using a C++ translator may contain unnamed parameters, which will cause a constraint violation if processed by a C translator.

1826 No declaration list shall follow.

Commentary

A declaration list can only follow when the form of the function declarator is the old style.

1827 If the declarator includes an identifier list, each declaration in the declaration list shall have at least one declarator, those declarators shall declare only identifiers from the identifier list, and every identifier in the identifier list shall be declared.

identifier list declare at least one declarator

Commentary

The declaration list declares the identifiers that appear in the parameter list and only those identifiers. Standard support for *old style* function definitions was needed because of the existence of a large body source code containing them. This constraint does not prohibit some declarations of doubtful utility. For instance:

```
1  void f_1(p)
2  enum {x, y      /* x & y appear in a declaration-specifier, not in a declarator list. */
3            } p;
4  { /* ... */ }
5
6  void f_2(p)
```

```
7   struct {
8           int z;  /* z is declared, but is not in the declarator list. */
9          } *p;
10  { /* ... */ }
```

C90

The requirement that every identifier in the identifier list shall be declared is new in C99. In C90 undeclared identifiers defaulted to having type **int**.

Source files that translated without a diagnostic being issued by a C90 translator may now result in a diagnostic being generated by a C99 translator.

C++

The declaration list form of function definitions is not supported in C++.

Common Implementations

It is likely that many C99 implementations will offer a C90 compatibility option, that will successfully translate source files containing functions whose parameter definition includes identifiers that are not explicitly declared in the declaration list.

Example

Fortran allows function parameters to be referred to before they are defined and it is established practice to declare an array parameter before the length specified in its array bounds. Translating such Fortran source into C required either that the parameter order be reversed, or old style definitions be used.

```
1   extern void f_proto(int, double [*][*]);
2   extern void f_old();
3
4   /*
5    * C requires identifiers to be declared before they are referenced.
6    */
7   void f_proto(int p_length, double p_1[p_length][p_length])
8   { /* ... */ }
9
10  void f_old(p_1, p_length) /* Parameter order follows Fortran conventions. */
11  int p_length;
12  double p_1[p_length][p_length];
13  { /* ... */ }
14
15  /*
16   * Hanging on to a bit more type information...
17   */
18  void f_alternative(double *p_1, int p_length)
19  {
20  double (*loc_p_1)[p_length] = (double (*)[p_length])p_1;
21  }
```

An identifier declared as a typedef name shall not be redeclared as a parameter. 1828

Commentary

Traditionally C source has been syntactically processed using a parser that only examined the next token in the input stream (i.e., the grammar can be processed using a LALR(1) tool, such as `yacc` and `bison`). This C constraint means that translators are not required to process the following code:

```
1   typedef int I;
2
3   int f(I) /* Constraint violation. */
4   int I;
5   { /* ... */ }
```

which requires more than one token lookahead to answer the question: is `f` an old style function talking a parameter called `I`, or is `f` a declaration of a prototype taking a parameter of type **`int`**, with no identifier name given?

C++

The form of function definition that this requirement applies to is not supported in C++.

1829 The declarations in the declaration list shall contain no storage-class specifier other than **`register`** and no initializations.

function declaration list storage-class specifier

Commentary

Parameters have automatic storage duration and are initialized by the value of the corresponding argument.

1838 parameter automatic storage duration
1004 function call preparing for

C++

The form of function definition that this requirement applies to (i.e., old-style) is not supported in C++.

Other Languages

Those languages (e.g., Ada) that support the use of default values on parameters, as a method of providing default values, usually require that they appear in the function declaration rather than its definition (so they are visible at the points in the source where calls to them occur).

1830 138) The intent is that the type category in a function definition cannot be inherited from a typedef:

footnote 138

```
typedef int F(void);            // type F is "function with no parameters
                                //               returning int"
F f, g;                         // f and g both have type compatible with F
F f { /* ... */ }               // WRONG: syntax/constraint error
F g() { /* ... */ }             // WRONG: declares that g returns a function
int f(void) { /* ... */ }       // RIGHT: f has type compatible with F
int g() { /* ... */ }           // RIGHT: g has type compatible with F
F *e(void) { /* ... */ }        // e returns a pointer to a function
F *((e))(void) { /* ... */ }    // same: parentheses irrelevant
int (*fp)(void);                // fp points to a function that has type F
F *Fp;                          // Fp points to a function that has type F
```

Commentary

This requirement significantly simplifies the creation of grammars that can be processed by commonly available parser generators without any syntactic production rule conflicts occurring.

C++

The C++ Standard specifies this as a requirement in the body of the standard (8.3.5p7).

Semantics

1831 The declarator in a function definition specifies the name of the function being defined and the identifiers of its parameters.

Commentary

Saying in words what is specified in the syntax. The return type is given by some of the *`declaration-specifiers`* and parts of the *`declarator`*.

C++

The C++ Standard does not explicitly make this association about function definitions (8.4).

Usage

Information on argument types is given elsewhere (see Table 1003.1).

Table 1831.1: Occurrence of parameter types in function definitions (as a percentage of the parameters in all function definitions). Based on the translated form of this book's benchmark programs.

Type	%	Type	%	Type	%	Type	%
`struct *`	44.4	`void *`	3.4	`long`	1.6	`struct * *`	1.2
`int`	14.7	`union *`	3.1	`int *`	1.5	`enum`	1.2
other-types	6.8	`unsigned long`	2.7	`unsigned char *`	1.4	`const char *`	1.1
`unsigned int`	5.1	`unsigned int *`	2.0	`char * *`	1.3	`long *`	1.0
`char *`	4.7	`unsigned char`	1.6	`unsigned short`	1.2		

If the declarator includes a parameter type list, the list also specifies the types of all the parameters; 1832

Commentary

Each parameter has the type specified in this list, not the type of the corresponding parameter of any composite type (that may have been created because of the occurrence of previous declarations).

C++

If the parameter list is empty the C++ Standard defines the function as taking no arguments (8.3.5p2).

Example

```
1  extern int glob;
2  extern void f(int);
3
4  void f(const int p)
5  { /* p has type const int in this function body. */ }
6
7  void g(void)
8  {
9  f(glob); /* Composite type of f is function taking a parameter of type int. */
10 }
```

function prototype

such a declarator also serves as a function prototype for later calls to the same function in the same translation unit. 1833

Commentary

compos-ite type 642

If there are any previous declarations of the same function (perhaps from an included header), their types along with the function prototype of the function definition are used to form a composite type. It is this composite type that is used for later calls.

If the declarator includes an identifier list,[139] the types of the parameters shall be declared in a following declaration list. 1834

Commentary

identifier list 1827
declare at least one declarator

This requirement on the program (also covered by a constraint) associates each identifier in the identifier list with the type of the corresponding identifier declared in the declaration list.

C++

The identifier list form of function definition is not supported in C++.

1835 In either case, the type of each parameter is adjusted as described in 6.7.5.3 for a parameter type list;

parameter type adjusted

Commentary

The ordering of this and the following C sentence is important. Both array and function types are converted to pointers to the appropriate respective types before the requirement on being an object type applies.

1598 array type adjust to pointer to
1600 function type adjust to pointer to

1836 the resulting type shall be an object type.

Commentary

This sentence clarifies the relative order in which adjustment of parameter types and checking for an object type occurs. Requirements in other parts of the standard specify that a parameter (which is an object with no linkage) have a complete type by the end of its declarator; so declaring a parameter to have an incomplete type would be a constraint violation.

71 parameter
434 parameter linkage
1361 object type complete by end

C++

The only difference, in parameter types, between a function declaration and a function definition specified by the C++ Standard is:

> *The type of a parameter or the return type for a function declaration that is not a definition may be an incomplete class type.*

8.3.5p6

1837 If a function that accepts a variable number of arguments is defined without a parameter type list that ends with the ellipsis notation, the behavior is undefined.

Commentary

The behavior is undefined if there are either fewer arguments or more arguments, passed in a call, than parameters in the function definition. This C sentence is not specific to the form of function definition (i.e., it could be old-style or prototype) and it is not necessary to access any of the parameters within the function definition. Simply calling the function is sufficient to cause the undefined behavior.

Developers did define functions accepting variable numbers of arguments prior to the availability of prototypes and the ellipsis notation (first specified in the C90 Standard). One technique used to access the additional argument values was to take the address of the last declared parameter and perform pointer arithmetic on it (knowledge of stack layout, such as order of arguments pushed and their alignment, was required to make it point at where the additional arguments were placed).

C++

This C situation cannot occur in C++ because it relies on the old-style of function declaration, which is not supported in C++.

Common Implementations

Because of the unknown, assumed to be significant, amount of existing code that passes variable number of arguments to functions defined using the old-style notation, implementations invariably play safe and do not use any special argument passing conventions (i.e., they are invariably passed on the stack) for such definitions. In the case of function defined using prototype notation, implementations invariably assume that the number of arguments passed equals the number of parameters defined. If these numbers differ the results can be completely unpredictable.

Coding Guidelines

This usage may occur in existing code. The cost/benefit issues involved in modifying existing code are discussed elsewhere. If the guideline recommendation specifying the use of prototypes is followed the usage described by this C sentence will not occur in newly written code.

1810 external declaration syntax
1810.1 function declaration use prototype

parameter automatic storage duration

Each parameter has automatic storage duration. 1838

Commentary

parameter 71
parameter 434 linkage
parameter 1593 storage-class
function declaration list 1829 storage-class specifier
automatic 457 storage duration
parameter 1839 scope begins at

This specification can be deduced from other wording in the standard, i.e., a parameter is an object, whose identifier has no linkage and its declaration may not include the storage-class specifier **static**, therefore it has automatic storage duration.

Coding Guidelines

Some coding guideline documents recommend that function parameters (which are defined to have block scope) be treated as being different from other block scope objects. The recommended differences in treatment arise from conceptual ideas about what parameters represent. For instance, considering them as input only values (which implies that they should not be modified in the function body). The rationale for this view of parameters is often derived from other languages where a pass by address method of argument passing is supported (in this case modifications of a parameters value will affect the value of the corresponding object passed as the argument). There is no obvious benefit in having such a guideline recommendation in C.

parameter scope begins at

Its identifier is an lvalue, which is in effect declared at the head of the compound statement that constitutes the function body (and therefore cannot be redeclared in the function body except in an enclosed block). 1839

Commentary

With the introduction of support for variable length arrays in C99, this description (which was in a footnote in the C90 Standard), is no longer completely accurate.

```
1  void f(int p_length, double p_1[p_length][p_length])
2  { /* ... */ }
```

C++

The C++ Standard does not explicitly specify the fact that this identifier is an lvalue. However, it can be deduced from clauses 3.10p1 and 3.10p2.

3.3.2p2 *The potential scope of a function parameter name in a function definition (8.4) begins at its point of declaration. If the function has a function try-block the potential scope of a parameter ends at the end of the last associated handler, else it ends at the end of the outermost block of the function definition. A parameter name shall not be redeclared in the outermost block of the function definition nor in the outermost block of any handler associated with a function try-block.*

The layout of the storage for parameters is unspecified. 1840

Commentary

In the past there existed a relatively common practice of accessing the values of different parameters by calculating their addresses using pointer arithmetic (this usage causes undefined behavior because pointer arithmetic is only guaranteed to deliver defined results while it remains within the same pointed-to object, or one past the end of the same object). This specification of behavior (there is no equivalent wording for other objects) is intended to explicitly point out to developers that the standard does not guarantee any particular storage layout for parameters.

pointer 1170 arithmetic defined if same object
storage 1354 layout

C++

The C++ Standard does not explicitly specify any storage layout behavior for parameters.

Other Languages

Those languages (e.g., Ada and CHILL) that do provide a mechanism for specifying how objects are laid out in storage do not usually provide support for specifying the relative layout of parameters. BCPL explicitly specifies that the parameters form a contiguous array. However, it is implementation-defined whether the first parameter can be accessed using the lowest or highest subscript.

Common Implementations

Most implementations do the obvious and parameters are laid out in a contiguous area of storage, with addresses either allocated high to low, or low to high. However, some implementations speed up parameter passing by using registers and may not even allocate storage if it is not needed. The alignment of storage used for parameters can be influenced by factors that do not affect object storage layout in other contexts. For instance, the processor may support instructions that manipulate the stack in fixed-sized units (e.g., the natural size of type **int**) and the choice of alignment used for various types is driven by the requirements of these instructions (which do not affect alignment choice in other contexts). Storage allocation issues for parameters are also discussed elsewhere.

39 alignment
1354 storage layout
449 stack

Coding Guidelines

Making use of storage layout information requires that other unspecified or undefined behavior be used, for instance incrementing pointer values so that they no longer point within the original object. The guideline recommendations dealing with making use of representation information is applicable.

1171 pointer arithmetic undefined
569.1 representation information using

1841 On entry to the function, the size expressions of each variably modified parameter are evaluated and the value of each argument expression is converted to the type of the corresponding parameter as if by assignment.

function entry parameter type evaluated

Commentary

This requirement, on implementations, creates a dependency between the evaluation of an argument whose corresponding parameter is used in the evaluation of the size expression of a parameter having a variably modified type and the evaluation of the size expression of that variably modified parameter. For instance, the required evaluation order in the following call to `f`:

```
1  extern int glob_1,
2             glob_2[10][2];
3
4  void f(int n, int a[n][2])
5  { /* ... */ }
6
7  void g(void)
8  {
9  f(glob_1, glob_2);
10 }
```

is to assign the argument `glob_1`, in the call to `f`, to the parameter `n`, evaluate the type of `a`, and then assign the argument `glob_2` to the parameter `a`.

The order of evaluation of the size expressions of parameters having variably modified types is unspecified. For instance, a strictly conforming program has to make worst-case assumptions about the number of elements required in the arrays passed as arguments to the functions `f_1` or `f_2` in the follow example:

```
1  extern int glob;
2
3  int g(void)
4  {
5  return glob++;
6  }
7
8  /*
9   * The order of evaluation of the following variably modified
```

```
 * parameters is not defined, but there is a sequence point
 * between the two modifications of glob.
 */
void f_1(int a_1[const g()], int a_2[const g()]])
{ /* ... */ }

/*
 * The evaluation of the following variably modified parameters causes
 * undefined behavior, because the same object is modifies more than
 * once between sequence points (a full declarator is a sequence point.
 */
void f_2(int a_1[const glob++], int a_2[const glob++]])
{ /* ... */ }
```

If a function prototype is visible at the point of call the values of the arguments will already have been converted to the types of the parameters, before being passed. There is no actual assignment performed on function entry.

default argument promotions 1009

If the only visible declaration is an old style function declaration the arguments will be subject to the default argument promotions, which means they may not have the same type as the parameter. When the type of the parameter is not compatible with its promoted type it is necessary for the value of the argument to be converted, as if by assignment, to the type of the parameter.

```
#include <stdio.h>

int f(p)
unsigned char p;
{
/* Implementations acts as if argument passed is assigned to p here. */
printf("argument passed = %d\n", p);
}

int main(void)
{
/* Output from first three calls should be the same as from the second three. */
f(0x42);                f(0x0142);                f(0x2142);
f((unsigned char)0x42); f((unsigned char)0x0142); f((unsigned char)0x2142);
}
```

function call preparing for 1004

The standard specifies elsewhere that each parameter is assigned the value of the corresponding argument.

C90

Support for variably modified types is new in C99.

C++

Support for variably modified types is new in C99 and is not specified in the C++ Standard.

Common Implementations

Some implementations can optimize away the need to perform an assignment because of the way that they load values from storage, into registers. For instance, a load byte instruction may clear all of the other bits in the register as well as loading a byte into it, removing the need to convert the value passed as an argument (any other, more significant, bits are always ignored).

```
#include <stdio.h>

int f(p)
unsigned char p;
{
/*
 * Accessing the storage allocated to p plus some bytes immediately after it may
```

```
 * access the value of the argument actually passed (provided the implementation
 * does not perform the implicit assignment).  However, such an access also
 * makes use of undefined behavior, so in theory any result could be returned.
 */
printf("parameter value = %d, argument passed may have been = %d\n",
                           p,                              *(int *)&p);
}
```

If the argument value is not representable in the parameter type the behavior of most implementations is the same as that for the same situation in an assignment.

Coding Guidelines

Support for variably modified types is new in C99 and the issue of side effects in their evaluation is one of developer education as well as potentially being coding guideline related. Variable length array declarations can generate side effects, a known problem area. The coding guideline issues for full declarators are discussed elsewhere.

1711 object initializer evaluated when

1842 (Array expressions and function designators as arguments were converted to pointers before the call.)

Commentary

These conversions mirror those that occur for the parameter types.

729 array converted to pointer
732 function designator converted to type
1835 parameter type adjusted

1843 After all parameters have been assigned, the compound statement that constitutes the body of the function definition is executed.

Commentary

That is, after all the parameters have been assigned the value of the corresponding arguments.

The compound body associated with a function definition is treated the same way as a compound body within a nested inner block.

This C statement assumes that the execution environment has sufficient resources to allocate storage for the objects defined in the called function. The C Standard does not provide any mechanism to check whether there are sufficient resources available to call and execute the designated function. Neither does it say anything about what might happen if there are insufficient resources to execute the function definition.

C90

The C90 Standard does not explicitly specify this behavior.

C++

The C++ Standard does not explicitly specify this behavior.

1844 If the `}` that terminates a function is reached, and the value of the function call is used by the caller, the behavior is undefined.

function termination reaching }

Commentary

This case deals with an implicit **`return`** statement without an expression (omitting an expression from an explicit **`return`** statement in a function returning an object type is a constraint violation). There is a body of existing code that omits an explicit **`return`** statement because it is known that the caller does not access a returned value. Rather than specifying this case as a constraint violation, requiring translators to issue a diagnostic, rending a (allegedly large) body of existing code non-conforming the Committee specified undefined behavior (this exact wording also appears in the C90 Standard).

1800 return without expression

C++

Flowing off the end of a function is equivalent to a **return** *with no value; this results in undefined behavior in a value-returning function.*

The C++ Standard does not require that the caller use the value returned for the behavior to be undefined; this behavior can be deduced without any knowledge of the caller.

```
1  int f(int p_1)
2  {
3  if (p_1 > 10)
4     return 2;
5  }
6
7  void g(void)
8  {
9  int loc = f(11);
10
11 f(2); /* does not change the conformance status of the program */
12       // undefined behavior
13 }
```

Other Languages

This behavior is common to many programming languages.

Common Implementations

The usual behavior is for the value of the function call to be whatever happens to be held in the storage location used to hold the return value, when the terminating **}** is reached.

Coding Guidelines

The **}** that terminates a function is reached for one of two reasons:

guidelines 0
not faults

1. it was not intended to occur and the author of the function body has made a mistake. These coding guidelines are not intended to recommend against the use of constructs that are obviously faults,
2. it is intended to occur in certain situations. This intended usage creates a dependency between the calls that do not access the value returned and the control flow in the function definition that results in no defined value being returned in some situations.

Adhering to a guideline recommending that the terminating **}** in a function not be reached may require adding a **return** statement, with an associated expression. Adding such a statement raises various questions, including the following:

- What value should be returned by this statement? On the basis that the statement is never intended to be executed any value will suffice. A case can be made for zero in that this value is more likely to be within the bounds of expected return values and may not have any significant affect on subsequent execution, and a case can be made for returning a value that is likely to have a noticeable affect on subsequent program execution. Returning a fixed value is at least more likely to ensure consistent behavior.
- How will subsequent readers of the function source treat this **return** statement? Without additional information they are likely to assume the value (e.g., a comment or giving it a symbolic name such as `DUMMY_VALUE`) was intended to be returned. The presence of what is essentially a **return** statement has possible costs as well as possible benefits.

Without any obvious cost/benefit for using a **return** statement no guideline recommendation is made here. However, guidelines having other aims (e.g., defensive programming) may recommend the presence of such a statement.

Usage

In the translated source of this book's benchmark programs 0.7% of function definitions contained both `return;` (or the flow of control reached the terminating **}**) and `return expr;`.

1845 EXAMPLE 1 In the following:

```
extern int max(int a, int b)
{
        return a > b ? a : b;
}
```

extern is the storage-class specifier and **int** is the type specifier; **max(int a, int b)** is the function declarator; and

```
{ return a > b ? a : b; }
```

is the function body. The following similar definition uses the identifier-list form for the parameter declarations:

```
extern int max(a, b)
int a, b;
{
        return a > b ? a : b;
}
```

Here **int a, b;** is the declaration list for the parameters. The difference between these two definitions is that the first form acts as a prototype declaration that forces conversion of the arguments of subsequent calls to the function, whereas the second form does not.

Commentary

These two forms of parameter declaration are similar because the type of a and b is compatible with its promoted types

C++

The second definition of max uses a form of function definition that is not supported in C++.

1846 139) See "future language directions" (6.11.7). footnote 139

1847 EXAMPLE 2 To pass one function to another, one might say

```
int f(void);
/* ... */
g(f);
```

Then the definition of **g** might read

```
void g(int (*funcp)(void))
{
        /* ... */
        (*funcp)(); /* or funcp()  ...  */
}
```

or, equivalently,

```
void g(int func(void))
{
        /* ... */
        func(); /* or (*func)()  ...  */
}
```

Other Languages

The second declaration of g is the form often used by other languages.

Coding Guidelines

While the second form of declaration of g may appear more intuitive to many developers, this may be because they have relatively little experience using function pointers. The first declaration of g uses the form needed to declare an object as a pointer to a function type and developers that regularly use pointer to function types will be practiced in reading it.

6.9.2 External object definitions

Semantics

---

object external definition

If the declaration of an identifier for an object has file scope and an initializer, the declaration is an external definition for the identifier. 1848

Commentary

external definition 1817

An external definition is an external declaration that is also a definition. The presence of an initializer turns a declaration into a definition, irrespective of its linkage. The definition of an object causes storage to be reserved for it.

object reserve storage 1354

C++

The C++ Standard does not define the term *external definition*. The object described above is simply called a *definition* in C++.

Other Languages

The conditions under which a declaration is also a definition of an object vary between languages, depending on the model of separate translation they use.

translation unit syntax 1810

Common Implementations

The base document did not support the use of initializers on declarations that included the **extern** storage-class specifier.

Coding Guidelines

Common usage is for developers to use the term *definition*, rather than *external definition*, to refer to such declarations. There does not appear to be a worthwhile benefit in attempting to change this common usage.

---

tentative definition

A declaration of an identifier for an object that has file scope without an initializer, and without a storage-class specifier or with the storage-class specifier **static**, constitutes a *tentative definition*. 1849

Commentary

This defines the term *tentative definition* (which is only used in this, 6.9.2, subclause). Tentative definitions are a halfway house. They indicate that a declaration might be a definition, but the door is left open for a later declaration, in the same translation unit to be the actual definition or simply another tentative definition.

The concept of tentative definition was needed, in C90, because of existing code that contained what might otherwise be considered to be multiple definitions, in the same translation unit, of the same object. Defining and using this concept allowed existing code, containing these apparent multiple definitions of the same object, in the same translation unit (an external definition of the same in more than one translation unit is a constraint violation) to be conforming.

definition one external 1812

With two exceptions all external object declarations are tentative definitions; (1) a declaration that contains an initializer is a definition, and (2) a declaration that includes the storage-class specifier **extern** is not a definition.

C++

The C++ Standard does not define the term *tentative definition*. Neither does it define a term with a similar meaning. A file scope object declaration that does not include an explicit storage-class specifier is treated, in C++, as a definition, not a tentative definition.

A translation unit containing more than one tentative definition (in C terms) will cause a C++ translator to issue a diagnostic.

```
int glob;
int glob; /* does not change the conformance status of program */
          // ill-formed program
```

Coding Guidelines

The term *tentative definition* is not generally used by developers and tends only to be heard in technical discussion by translator writers and members of the C committee. There does not appear to be a worthwhile benefit in educating developers about this term and the associated concepts. Their current misconceptions (e.g., declarations that include the storage-class specifier **`static`** become definitions at the point of declaration) appear to be harmless.

Multiple *`external-declaration`*'s of the same object are redundant (this general issue is discussed elsewhere), but otherwise harmless (a modification of the type of one of them will result in a diagnostic being issued unless all of the declarations have compatible type, i.e., they are similarly modified).

190 redundant code

1850 If a translation unit contains one or more tentative definitions for an identifier, and the translation unit contains no external definition for that identifier, then the behavior is exactly as if the translation unit contains a file scope declaration of that identifier, with the composite type as of the end of the translation unit, with an initializer equal to 0.

object definition implicit

Commentary

This specification requires implementations to create a definition of an object if the translation unit does not contain one (i.e., there is no declaration of the object that includes an initializer). For an object having an incomplete array type the effect of this specification is to complete the type and define an array having a single element. In the case of objects having an incomplete structure or union type the size of the object is needed to define it, which in turn requires a completed type. Thus, the behavior is undefined if an external object definition has an incomplete structure or union type at the end of a translation unit.

1848 object external definition
1853 EXAMPLE tentative array definition
1354 object reserve storage
1465 footnote 109

C++

The C++ Standard does not permit more than one definition in the same translation unit (3.2p1) and so does not need to specify this behavior.

Coding Guidelines

It is common practice to omit the initializer in the declaration of an object. Developers invariably assume that an object declaration that omits a storage-class specifier is a definition (which does eventually become). The fact that an object might not be defined at its point of declaration is purely a technicality.

1851 If the declaration of an identifier for an object is a tentative definition and has internal linkage, the declared type shall not be an incomplete type.

object type for internal linkage

Commentary

This requirement applies at the point of declaration, not at the end of the translation unit. The affect of this difference is illustrated by the following example:

```
static char a[]; /* Internal linkage, undefined behavior.           */
        char b[]; /* External linkage, equivalent to char b[] = {0}; */
```

One consequence of this requirement is that implementations can allocate storage for objects having internal linkage as soon as the declaration has been processed, during translation.

In the case of objects having external linkage the behavior is not undefined if the object has an incomplete array type (see previous C sentence). For objects having no linkage it is a constraint violation if the type of the object is not completed by the end of the declarator.

1361 object type complete by end

Common Implementations

Some implementations (e.g., gcc) support the declaration of objects having a tentative definition and internal linkage, using an incomplete type (which is completed later in the same translation unit).

EXAMPLE linkage

EXAMPLE 1 1852

```
int i1 = 1;         // definition, external linkage
static int i2 = 2;  // definition, internal linkage
extern int i3 = 3;  // definition, external linkage
int i4;             // tentative definition, external linkage
static int i5;      // tentative definition, internal linkage

int i1;             // valid tentative definition, refers to previous
int i2;             // 6.2.2 renders undefined, linkage disagreement
int i3;             // valid tentative definition, refers to previous
int i4;             // valid tentative definition, refers to previous
int i5;             // 6.2.2 renders undefined, linkage disagreement

extern int i1;      // refers to previous, whose linkage is external
extern int i2;      // refers to previous, whose linkage is internal
extern int i3;      // refers to previous, whose linkage is external
extern int i4;      // refers to previous, whose linkage is external
extern int i5;      // refers to previous, whose linkage is internal
```

Commentary

```
1  extern int i1;      // external linkage
2  extern int i2;      // external linkage
3  extern int i3;      // external linkage
4  extern int i4;      // external linkage
5  extern int i5;      // external linkage
6
7  int i1;             // external linkage
8
9  int i1 = 1;         // definition, external linkage
10 static int i2 = 2;  // internal linkage: undefined behavior -> external linkage on previous declaration
11 extern int i3 = 3;  // definition, external linkage
12 int i4;             // external linkage
13 static int i5;      // internal linkage: undefined behavior -> external linkage on previous declaration
```

C++

The tentative definitions are all definitions with external linkage in C++.

EXAMPLE tentative array definition

EXAMPLE 2 If at the end of the translation unit containing 1853

```
int i[];
```

the array `i` still has incomplete type, the implicit initializer causes it to have one element, which is set to zero on program startup.

Commentary

object definition implicit 1850

The implicit initialization (equal to 0), at the end of a translation unit, of the tentative definition of an object describes an effect. In the case of an object declared to be an array of unknown size, the initializer is treated as specifying a single element.

C90

This example was added to the C90 Standard by the response to DR #011.

C++

This example is ill-formed C++.

Coding Guidelines

This usage might be considered suspicious in that declaring an object to have an array type containing a single element is unusual and if it was known that only one element was needed why wasn't this information specified in the declaration. If the usage was unintended it is a fault and these coding guidelines are not intended to recommend against the use of constructs that are obviously faults. Any intended usage is likely to be rare and thus a guideline recommendation (if shown to be cost effective technically) is not cost effective.

0 guidelines not faults

6.10 Preprocessing directives

preprocessor directives syntax

1854

```
preprocessing-file:
                group_opt

```

Commentary

It can be seen from the grammar that most terminals do not match any syntax rules in the other parts of the language. The C language essentially contains two independent languages within it. The preprocessor and what might be called the C language proper.

A *text-line* is the sequence of *pp-tokens* that are scanned for macros to substitute and subsequently processed by the C language syntax.

C90

Support for the following syntax is new in C99:

```
group-part:
        # non-directive
control-line:
        # define  identifier lparen ... ) replacement-list new-line
        # define  identifier lparen identifier-list , ... )
                                                replacement-list new-line
```

The left hand side terms *text-line* and *non-directive* were introduced in C99. Their right-hand side occurred directly in the right-hand side of *group-part* in the C90 Standard.

```
text-line:
        pp-tokens_opt new-line
non-directive:
        pp-tokens new-line
```

The definition of *lparen* in C90 was:

```
lparen:
        the left-parentheses character without preceding white-space
```

C++

The C++ Standard specifies the same syntax as the C90 Standard (16p1).

Other Languages

While most assembly languages support some form of preprocessor, few high-level languages include one (Lisp, PL/1 do).[170] A conditional compilation mechanism was recently added to the Fortran Standard[652] (it is specifically aimed at conditional compilation and does not offer macro processing functionality).

While many versions of Unix include a preprocessor that is independent of the C preprocessor (i.e., `m4`[1392]) it has never achieved wide usage (this reason was given for its exclusion from the POSIX Standard). A few other stand-alone preprocessors (often called *macro processors*) have also been written (e.g., ML/I[169]).

Some non-C preprocessors use the character **$** or **%** rather than **#**.

Common Implementations

Because of the relative simplicity of the preprocessor grammar most implementations do not use a table-driven parser approach, but rather process the directives on an ad hoc basis. Some preprocessors operate at a higher level than individual tokens e.g., taking syntax into account.[507, 1468]

The base document did not support the preprocessing directive **#elif** or **defined**. Support for this functionality was added during the early evolution of C.[1180] Also early implementations supported trailing tokens on the same line as preprocessing directives `#endif MACRO_NAME` and some implementations[1340] continue to provide an option to support this functionality. Some early translators did not permit white-space between **#** and **define** Some also required the **#** to be the first character on the line `gcc` supported `...` in macro definitions prior to C99. The syntax used was to give the varying arguments a (developer chosen) name, for instance in:

```
#define debug(file, format, args...) fprintf(file, format, args)
```

following the parameter `args` with `...` specifies that it takes a variable number of arguments. These variable arguments are substituted wherever the named parameter appears in the replacement list (just like other parameters).

The Unix System V C compiler[1392] (plus `gcc` and others) supports the creation and use of what it calls *assertions*. For instance, (the **#** before an identifier signaling its status as a predicate):

```
/* #assert predicate(token-sequence) */

#assert derek (is_male) /* Associate the answer is_male with the predicate derek. */

/* #if #predicate(token-sequence) */

#if #derek(is_female) /* Evaluates to false. */
#endif
/*
 * Implementations supporting these kinds of assertions usually
 * define the predicates system (with answers such as svr4, mach, posix,
 * hpux, etc.), and cpu (with answers such as i386, sparc, m68k, etc.).
 */
#if #cpu(sparc)
/* ... */
#elif #cpu(i386)
/* ... */
#endif
```

The directive:

```
#ident "version X.Y"
```

is used by a number of translators to include version control information in the source code that is also written out to the generated object file. A common technique is to use a sequence of characters, within the string literal, that are recognized by a source code control system (and which can be updated when a new version is checked in)

The matching directives **#version/#endversion** are available in a Bell-Labs translator. It is claimed[63] that developers were 40% more productive when using a version sensitive editor on a multi million line project having many versions (developed over two decades by more than 5,000 developers).

The Plan 9 C compiler intentionally lacks support for the **#if** directive.[1087]

Coding Guidelines

While lines containing non-preprocessing directives are often visually indented (see Figure 1854.1) developers do not generally indent preprocessing directives (see Figure 1854.1). One possible reason for this difference

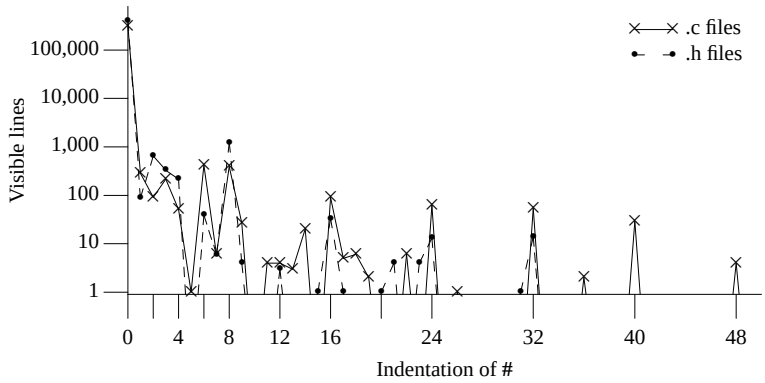

Figure 1854.1: Number of lines containing a preprocessing directive starting at a given indentation from the start of the line (i.e., amount of white space before the first **#** on a line, with the tab character treated as eight space characters). Based on the visible form of `.c` and `.h` files.

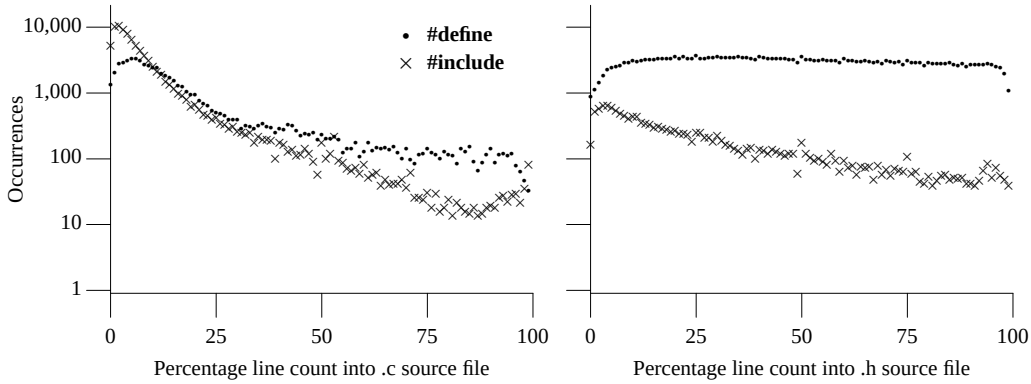

Figure 1854.2: Number of **`#include`** and **`#define`** directives appearing at a relative location (i.e., 100*line_number/lines_in_file) in the source. Based on the visible form of `.c` and `.h` files.

is that indentation of preprocessing directives may not provide a visual edge for readers to run their eyes along (e.g., the visible source between conditional inclusion directives may be statements from the C language whose indentation is driven by factors unrelated to preprocessing; that is there are two indentation schemes operating over the same section of source).

In over 90% of preprocessing directives the **#** character appears at the start of the line. Given that preprocessing directives are usually scattered throughout the source this indentation strategy allows them to generally standout from the surrounding statements.

In general both the **`#include`** and **`#define`** directives appear at the start of a source file (see Figure 1854.2). By their nature the **`#if`** directives are localized at the point when a conditional decision needs to be made.

Usage

A study by Ernst, Badros, and Notkin[396] provides one of the few empirical studies of C preprocessor use.

Table 1854.1: Occurrence of preprocessor directive names and preprocessor operators (as a percentage of all directive names and operators). Based on the visible form of the `.c` and `.h` files.

Directive Name	.c file	.h file	Directive Name	.c file	.h file
`#define`	19.9	75.0	`#if`	6.2	1.5
`#endif`	19.9	7.2	`##`	0.3	0.9
`#include`	28.6	4.1	`#elif`	0.2	0.2
`#ifndef`	2.4	3.2	`#pragma`	0.1	0.1
`#ifdef`	11.3	2.5	`#error`	0.2	0.1
`#else`	4.8	1.7	`#`	0.0	0.1
defined	3.6	1.7	`#line`	1.4	0.0
`#undef`	1.0	1.6			

Description

1855 A ~~preprocessing directive~~ *preprocessingdirective* consists of a sequence of preprocessing tokens that ~~begins with~~ satisfies the following constraints:

preprocessing directive consists of

Commentary

This defines the term *preprocessing directive*. Preprocessor directives are line oriented (the second half of the above sentence requires directive to start on a line and finish on the same line).

The wording was changed and the sentence split up by the response to DR #303.

1856 The first token in the sequence is a # preprocessing token that (at the start of translation phase 4) is either the first character in the source file (optionally after white space containing no new-line characters) or that follows white space containing at least one new-line character ~~,~~ .

Commentary

It is only after preprocessing that the C language becomes is free format. Line splicing occurs prior to translation phase 4 and was created to enable preprocessor directives to span more than one physical source line. Because preprocessing directives are identified at the start of translation phase 4 translators do not treat the output from macro expansion (which occurs during translation phase 4) as possible preprocessing directives (or handle other unusual token sequences as preprocessing directive).

The wording was changed, and this sentence formed, by the response to DR #303.

118 line splicing
129 translation phase 4
1973 expanded token sequence not treated as a directive
1868 EXAMPLE EMPTY #

C90

The C90 Standard did not contain the words "(at the start of translation phase 4)", which were added by the response to DR #144.

C++

Like C90, the C++ Standard does not specify the start of translation phase 4.

1857 ~~and is ended by the next~~ The last token in the sequence is the first new-line character that follows the first token in the sequence. [140)]

Commentary

The wording was changed, and this sentence formed, by the response to DR #303.

1858 A new-line character ends the preprocessing directive even if it occurs within what would otherwise be an invocation of a function-like macro.

preprocessing directive ended by

Commentary

In the following:

```
#define M_1(a, b) ((a) + (b))
#if M_1(1,              /* Syntax violation. */
          2) == 3       /* Different logical line unconnected with the previous one. */
#endif

void f(void)
{
int loc = M_1(1,
                2); /* No end-of-line syntax requirements here. */
}
```

the **#if** preprocessing directive visually spans more than one line. The fact that the macro invocation M_1 is split across two physical lines does not alter the requirements on this preprocessing directive (and a translator required to generate a diagnostic). However, the following example is a rather unusual case:

macro invocation) terminates it 1924

```
#define M_1(a, b) ((a) + (b))
#if M_1(1, /* Comment about the first argument.
              Comment about the second argument */ 2) == 3
#endif
```

in that the comment is replaced by one space character and the new-line character *seen* by translation phase 4 is the one that occurs after the preprocessing token 3 (i.e., the code is conforming).

translation phase 3 124

C90

This wording was not in the C90 Standard, and was added by the response to DR #017.

C++

Like the original C90 Standard, the C++ Standard does not explicitly specify this behavior. However, given that vendors are likely to use a preprocessor that is identical to the one used in their C product (or the one that used to be used, if they nolonger market a C product), it is unlikely that the behaviors seen in practice will be different.

---

footnote 140

140) Thus, preprocessing directives are commonly called “lines”. 1859

Commentary

The common developer usage is for the term *lines* to refer to any sequence of characters terminated by a new-line, i.e., the use is not specific, in the developer community, to preprocessing directives.

Coding Guidelines

Developers are aware of the line-oriented nature of preprocessing directives. However, no terminology (other than *preprocessing directive*, or simply *directive*) is commonly used.

These “lines” have no other syntactic significance, as all white space is equivalent except in certain situations during preprocessing (see the # character string literal creation operator in 6.10.3.2, for example). 1860

Commentary

All source file lines are processed during translation phase 4, either as directives or as token sequences to examine for possible macro replacement. However, the preprocessing directive *lines* are deleted at the end of translation phase 4 and play no further role in translation.

preprocessing directives deleted 132

A text line shall not begin with a # preprocessing token. 1861

Commentary

This is a requirement on the implementation. Syntactically a *text-line* can start with a # (which is a preprocessing token). This requirement disambiguates the syntax by specifying that such an interpretation shall not be made by the implementation.

1862 A non-directive shall not begin with any of the directive names appearing in the syntax.

Commentary

This is a requirement on the implementation. Syntactically any sequence of *pp-tokens* following a # preprocessing token can be a *non-directive*. This requirement disambiguates the syntax by specifying that such an interpretation (if one exists for the given sequence of preprocessing tokens) shall not be made by the implementation where there is another interpretation.

C90

Explicit support for *non-directive* is new in C99.

C++

Explicit support for *non-directive* is new in C99 and is not discussed in the C++ Standard.

1863 When in a group that is skipped (6.10.1), the directive syntax is relaxed to allow any sequence of preprocessing tokens to occur between the directive name and the following new-line character.

Commentary

This C sentence introduces the term *directive name* to describe the preprocessing tokens that occur immediately after the # punctuator (they can be given the status of keywords). 1874 footnote 141

The Committee recognized that the source code contained within a skipped group might still be under development (which is one reason for it being skipped). Given that comments do not nest, it may not be possible, or desirable, to use a comment to prevent translators analyzing the sequence of characters in detail. This relaxation of the syntax allows conditional inclusion directive to be used to bracket a sequence of lines that do not yet form a conforming sequence of *pp-tokens*. 932 footnote 69 1890 directive processing while skipping

```
#if WORKING_ON_IT

#if don't know what condition to put here yet
#endif

#endif
```

The directive name needs to be processed to handle any nested conditional preprocessing directives.

C90

The C90 Standard did not explicitly specify this behavior.

C++

Like C90, the C++ Standard does not explicitly specify this behavior.

Common Implementations

Many implementations attempt to process skipped groups as quickly as possible. By default, many implementors only examine the minimum number of preprocessing tokens necessary to work out where the skipped group ends.

Constraints

1864 The only white-space characters that shall appear between preprocessing tokens within a preprocessing directive (from just after the introducing # preprocessing token through just before the terminating new-line character) are space and horizontal-tab (including spaces that have replaced comments or possibly other white-space characters in translation phase 3). white-space within preprocessing directive

Commentary

white-space characters 778

The use of other white-space characters, (i.e., vertical-tab or form-feed) within preprocessing directives could cause the visual appearance of the source code to suggest that directives are terminated by new-line when in fact they are not. That is the source would be visually confusing and such usage has no obvious benefit. These white-space characters may still appear within preprocessing tokens, e.g., in a character string literal.

white-space sequence replaced by one 128

It is implementation-defined whether other white-space characters are replaced by one space character in translation phase 3.

Common Implementations

Some implementations support the appearance of a carriage return character immediately prior to the end of line (when that character is not part of the end of line sequence). This enables them to handle text files written using the MS-DOS end of line conventions (i.e., end of line is represented by the two characters \r\n).

Coding Guidelines

The presence of white-space within a preprocessing directive may or may not be significant. It is sometimes needed (and invariably appears, whether needed or not) to separate the definition of an object-like macro identifier from its body. For instance, in:

macro object-like 1931

```
1  #define A (x)
2  #define B-y
```

without the intervening white-space the first definition would be for a function-like macro taking a parameter x. No white-space is used in the second definition, but the source would probably be easier to process if some were used.

Semantics

The implementation can process and skip sections of source files conditionally, include other source files, and replace macros. 1865

Commentary

#pragma directive 1994

translation phase 4 129

Preprocessing directives (e.g., **`#pragma`**) can also affect how other phases of translation behave. These operations are performed during translation phase four.

Coding Guidelines

It is possible to completely change the meaning of some C constructs, compared to the behavior that would be deduced purely from their visual appearance in the source code. Constructs can be added, deleted, and modified. All without any indication that these operations will occur, in the source code (or at least the `.c` files). While various criticisms are made about the behavior of the preprocessor (e.g., it performs no semantic checks on the substitutions it makes) the actual problem lies with the people who use it. The preprocessor might be likened to a sharp knife (some people might say a large hammer), being sharp makes the job of cutting easy but don't complain if sloppy use results in the user being cut (or objects near to the hammer being crushed through poor aiming).

In some cases it is possible to provide guideline recommendations that prevent problems occurring, in other cases complexity is intrinsic to the problem being handled. For instance, the heavy use of **`#if`**/**`#endif`** may be the result of having a successful product that runs in many different environments. While some coding guideline documents recommend that preprocessor usage be minimized, such recommendations are really a design issue and as such are outside the scope of these coding guidelines.

---

preprocessing

These capabilities are called *preprocessing*, because conceptually they occur before translation of the resulting translation unit. 1866

Commentary

This defines the term *preprocessing* (the term *macro processing* is sometimes used by developers, perhaps because macro substitution is felt to have the largest impact on the visible form of the source). This is also a generally used term within software engineering that refers to any set of operations that are performed on the input prior to what are considered to be the main operations (in C's case the subsequent phases of translation). Any later operations are sometimes referred to as *post processing*. The component of the translator that performs these operations (independent of whether it is a stand alone program or an integrated part of a larger program) is universally known as the *preprocessor*.

The output from preprocessing is a translation unit.

110 translation unit known as

The C preprocessor is sometimes used to provide macro processing and conditional compilation in non-C language contexts (e.g., other languages and text processing tasks). Members of the C committee have at times born this usage in mind when considering how the preprocessor should behave.

Common Implementations

In many implementations preprocessing is carried out by a stand-alone program, usually known as the *preprocessor*.

120 footnote 5

Coding Guidelines

Developers often think of the output of translation stage four as being the output from the preprocessor. In fact the preprocessor is really only translation phase 4, phases 1–3 would need to be performed even if C did not include a preprocessor (the operations these phases perform are performed by languages that do not include a preprocessor).

Many guideline recommendations are driven by how developers visually process source code. The recommendations that involve preprocessor constructs are often made because the processing that occurs (e.g., macro expansion) is not directly visible to readers of the source.

1867 The preprocessing tokens within a preprocessing directive are not subject to macro expansion unless otherwise stated.

tokens in directive not expanded unless

Commentary

Requiring that macro expansion unconditionally occur within preprocessing directives is not necessarily a desirable requirement (it would also be a change to existing translator behavior that could break existing code). Most preprocessing directives have a form in which macro expansion can occur.

1876 #if macros expanded
1905 #include macros expanded
1991 #line macros expanded
1943 footnote 146

Example

```
#define defined 1 +

#if defined(X) /* Not expanded. */
#endif
```

1868 EXAMPLE In:

EXAMPLE EMPTY #

```
#define EMPTY
EMPTY # include <file.h>
```

the sequence of preprocessing tokens on the second line is *not* a preprocessing directive, because it does not begin with a **#** at the start of translation phase 4, even though it will do so after the macro **EMPTY** has been replaced.

Commentary

This behavior simplifies the job of tools that scan C source (in that they only need to check the first two preprocessing tokens at the start of a line). However, occurrences of EMPTY in other contexts, within a preprocessing directive, may cause complications.

```
#define EMPTY

#include EMPTY <stdio.h>
#include <stdio.h> EMPTY
```

C90

This example was not in the C90 Standard and was added by the response to DR #144.

C++

This example does not appear in the C++ Standard.

6.10.1 Conditional inclusion

conditional inclusion

Constraints

---

conditional inclusion constant expression

The expression that controls conditional inclusion shall be an integer constant expression except that: it shall not contain a cast; 1869

Commentary

An expression occurring in this context has to be evaluated during translation, hence the need for it to be a constant. The additional constraints are designed to allow the preprocessor to operate independently of the subsequent phases of translation.

Coding Guidelines

source file inclusion 1896

Developers do not commonly refer to this construct using the term *conditional inclusion* (which is suggestive of source file inclusion, i.e., the **#include** directive). Some of the terms that are commonly used by developers include *hash if* and *conditionally compiled*. There does not appear to be a worthwhile benefit in attempting to change existing, developer, use of terminology. However, coding guideline documents still need to make it clear what any terms they use might use, refer to.

---

it shall not contain a cast; 1870

Commentary

footnote 141 1874

This constraint is redundant for the reasons pointed out in footnote 141 (there is no constraint given here against **sizeof** appearing in this context). While it is possible to write a cast that will evaluate to a constant expression under the rules applied to conditional inclusion expressions (e.g., `(int * const)+1` will evaluate to 1), in the majority of cases any cast occurring in this context will result in a syntax violation. The preprocessor is not required to have any knowledge of the representation used for any scalar types by subsequent phases of translation. The type of the operands of the constant expression are all defined to have the same rank.

#if operand type uintmax_* 1880

---

identifiers (including those lexically identical to keywords) are interpreted as described below;[141] 1871

Commentary

#if macros expanded 1876
#if identifier replaced by 0 1878

Identifiers are either subject to macro expansion, treated as an operator (see next C sentence), or replaced by 0.

1872 and it may contain unary operator expressions of the form

#if defined

```
defined identifier
```

or

```
defined ( identifier )
```

which evaluate to 1 if the identifier is currently defined as a macro name (that is, if it is predefined or if it has been the subject of a **#define** preprocessing directive without an intervening **#undef** directive with the same subject identifier), 0 if it is not.

Commentary

Semantics in a Constraints clause.

Rationale

The operator **defined** was added to C89 to make possible writing boolean combinations of defined flags with one another and with other inclusion conditions.

The **defined** operator allows more than one test to be made in a single expression. Without this operator it would be necessary to use nested **#ifdef** or **#ifndef** directives, for instance:

```
#ifdef ...
   #ifdef ...
      #ifdef ...
```

Coding Guidelines

The result of the **defined** operator has a boolean role.

476 boolean role
943.1 expression shall be parenthesized

The rationale for using the parenthesized form of the **sizeof** operator is not applicable to the **defined** operator. However, existing practice is to use the parenthesized form (see Table 1872.1). The most common usage of the **defined** operator, in the `.c` files, is equivalent to using the **#ifdef** preprocessing directive.

1884 #ifdef

Example

```
#define X Y

#if defined(X) /* Checks that X is defined, not Y */
#endif
```

Table 1872.1: Occurrence of controlling expressions containing the **defined** operator (as a percentage of all **#if** and **#elif** preprocessing directives). The **#elif** preprocessing directive was followed by the **defined** operator in 66.5% of occurrences of that preprocessing directive— in the .c files (.h 75.5%). Based on the visible form of the .c and .h files.

Preprocessing Directive	%
#if defined **(** identifier **)**	15.7
#if defined **(** identifier **)** **||** defined **(** identifier **)**	5.8
#if defined **(** identifier **)** **&&** defined **(** identifier **)**	2.0
#if **!** defined **(** identifier **)**	1.9
#elif defined **(** identifier **)**	1.9
#if defined **(** identifier **)** **&&** **!** defined **(** identifier **)**	1.3
#if **!** defined **(** identifier **)** **&&** **!** defined **(** identifier **)**	0.9
#if defined **(** identifier **)** **||** defined **(** identifier **)** **||** defined **(** identifier **)**	0.8
#if defined identifier **||** defined identifier	0.5
#if **!** defined **(** identifier **)** **&&** **!** defined **(** identifier **)** **&&** **!** defined **(** identifier **)**	0.3
others	5.3

Each preprocessing token that remains after all macro replacements have occurred shall be in the lexical form of a token (6.4). 1873

preprocessing token shall have lexical form 771

Commentary

This requirement duplicates one given elsewhere.

This sentence was added by the response to DR #304.

footnote 141

141) Because the controlling constant expression is evaluated during translation phase 4, all identifiers either are or are not macro names— there simply are no keywords, enumeration constants, etc. 1874

preprocessing token converted to token 137

Commentary

Preprocessing tokens are converted to tokens during translation phase 7.

Coding Guidelines

#if identifier replaced by 0 1878

A common mistake made by developers is to attempt to use the **sizeof** operator within a controlling constant expression. Once the **sizeof** is replaced by 0 the resulting expression is very likely to contain a syntax violation (i.e., consideration of a guideline recommendation is unnecessary because the syntax violation will cause a diagnostic to be generated).

Semantics

Preprocessing directives of the forms 1875

**if** *constant-expression new-line* $group_{opt}$
**elif** *constant-expression new-line* $group_{opt}$

check whether the controlling constant expression evaluates to nonzero.

Commentary

Unlike the controlling expression of an **if** statement it is not necessary to enclose the expression in parentheses. Also the **elif** form does not exist in C language. There is no **#switch** to handle a sequence of **#if**/**#else** or **#elif** preprocessor directives (although such a construct has been proposed as a worthwhile extension, the C Committee continues to turn it down).

Rationale **#elif** was added to minimize the stacking of **#endif** directives in multi-way conditionals.

Other Languages

Some languages (e.g., Algol 68 and Ada) also include support for the **elif** keyword.

Common Implementations

Snelting[1261] applied concept analysis to conditional inclusion directives to produce a visualization of the structure and properties of possible program build configurations.

1821 concept analysis

Coding Guidelines

The coding guideline issues that are applicable to the **if** statement are also applicable to conditional inclusion directives.

1739 selection statement syntax

Experience suggests that developers do not always use the **#elif** form in contexts where it could be used. The following are possible reasons for this behavior:

- Developers having a mental model of conditionals that does not include this construct (an equivalent construct is not available within an **if** statement).
- Developers treating **#if**/**#endif** pairs as conceptually independent of any preprocessing directives they may be nested within.
- The result of cut-and-paste operations from other parts of the source.
- Portability. One common reason why source code contains many nested conditional directives is to handle the behavior of many different translators and environments that is has been ported to. Given that historically some translators have not supported the **#elif** directive, of necessity the source may have had any use of this directive removed.

At the time of this writing there is insufficient information available to make a cost/benefit decision on a guideline recommendation and none is given here.

form of representation mixing

The *constant-expression* in a **#if** directive is sometimes evaluated by readers of the source. The expression may contain integer constants represented using a variety of different forms (e.g., decimal, hexadecimal, character constant, etc.).

A study by Gonzalaz and Kolers[505] investigated how subject's performance on an arithmetic problem was affected by the notational system used to represent values. Subjects were shown an equation of the form $p + q = n$ and had to respond true/false as quickly as possible (e.g., does $2 + 3 = 6$?). The numeric values were presented using either Arabic or Roman digits (e.g., $V + 3 = IX$, $4 + II = 6$, etc.). The results were not consistent with a model that translated the numerals into a single representation system before adding and comparing them. Others[1404] have suggested that the difference in performance can be explained by the time taken to encode the different representations.

Mixed notation can occur in C source. For instance, an expression can contain integer constants represented using decimal, hexadecimal, and octal lexical forms. The results of these studies show that there is a cognitive cost associated with mixing different representations in the same expression. There is no obvious guideline recommendation for trading off this cost against the benefit of using different representations (for different expressions).

Usage

The visible form of the `.c` files contained 12,277 (`.h` 4,159) **`#else`** directives.

Table 1875.1: Common **`#if`** preprocessing directive controlling expressions (as a percentage of all **`#if`** directives). Where *`integer-constant`* is an integer constant expression, and *function-call* is an invocation of a function-like macro. Based on the visible form of the `.c` files.

others	6.1

#if macros expanded

Prior to evaluation, macro invocations in the list of preprocessing tokens that will become the controlling constant expression are replaced (except for those macro names modified by the **`defined`** unary operator), just as in normal text. 1876

Commentary

The following quote from DR #258 has had some lines and quotes (from the C Standard) removed.

#258 ***Problem***

Consider the code:

```
#define repeat(x) x && x    // Line 1
#if repeat(defined fred)    // Line 2
```

and the code:

```
#define forget(x) 0         // Line 3
#if forget(defined fred)    // Line 4
```

Does line 2 "generate" a ***defined*** *operator? Is line 4 strictly conforming code, or does the fact that macro expansion "forgets" the* ***defined*** *operator cause a problem ?*

I would guess that the original intention was that any `defined X` *pair in the original source worked correctly. The proposed change would resolve this.*

In addition, given the order of events, it is unsuitable to say that a `defined X` *expression is "evaluated". Rather it should be described as a textual substitution.*

Proposed Committee Response

The standard does not clearly specify what happens in this case, so portable programs should not use these sorts of constructs.

1877 If the token **defined** is generated as a result of this replacement process or use of the **defined** unary operator does not match one of the two specified forms prior to macro replacement, the behavior is undefined.

Commentary

Some implementations support this form and there is existing code that makes use of it. However, the C committee did not want to require this usage to be supported. The behavior is also undefined if the **defined** operator is the subject of a **#define** directive.

2026 predefined macros not #defined

Common Implementations

Implementations vary in the order in which they process the sequence of preprocessing tokens in the constant expression. Some perform a pass that handles any **defined** operators, while others perform all processing (e.g., including macro replacement) in a single pass.

10 implementation single pass

Coding Guidelines

Intentional use of this behavior is likely to involve a directive that is either successfully translated or causes a diagnostic to be issued. This largely removes one rationale for a guideline recommendation. Occurrences of uses of this behavior (which may involve developers needing to comprehend what is occurring) are considered to be rare. Which removes the other rationale for a guideline recommendation.

Example

```
#if DEF
#define FOO defined
#else
#define FOO 1 +
#endif

#if FOO BAR
#endif

#define PAREN_PLUS ) + 1

#if defined(X PAREN_PLUS
#endif

#define M(a) defined(a)

#if M(X)
#endif
```

#if identifier replaced by 0

After all replacements due to macro expansion and the **defined** unary operator have been performed, all remaining identifiers (including those lexically identical to keywords) are replaced with the pp-number **0**, and then each preprocessing token is converted into a token. 1878

Commentary

Requiring that all identifiers appearing in this context be defined as a macro has the potential for introducing a great deal of complexity. Zero has several useful arithmetic properties that enable it to occur with no, or a canceling, affect. Being able to use it as an implicit initial value, for identifiers that may be defined as macros, reduces the number of possibilities that developers need to consider.

preprocessing token converted to token 137

The conversion of a preprocessing token to a token mirrors that which occurs in translation phase 7. The sequencing rules mean that any remaining identifiers are converted to the pp-number **0** before token conversion occurs.

The wording was changed by the response to DR #305.

C++

In the C++ Standard **true** and **false** are not identifiers (macro names), they are literals:

16.1p4 *. . . , except for* ***true*** *and* ***false****, are replaced with the pp-number 0, . . .*

If the character sequence `true` is not defined as a macro and appears within the constant-expression of a conditional inclusion directive, when preprocessed by a C++ translator this character sequence will be treated as having the value one, not zero.

Coding Guidelines

The analogy might be made between an identifier that has not been defined as a macro and an object that has not been explicitly initialized. However, use of this analogy requires a choice to be made, (1) for static storage duration an implicit value of zero is provided, and (2) while for automatic and allocated storage duration the value of the object is indeterminate. If the usage was unintentional, it is a fault and considered to be outside the scope of these coding guidelines. An intentional usage may cause subsequent readers to spend more time deducing that the affect of the usage is to produce the value zero, than if they had been able to find a definition that explicitly specified a zero value.

guidelines 0 not faults

The simplest way of adhering to a guideline recommending that all identifiers appearing in the controlling expression of a conditional inclusion directive be defined would be to insert the following (replacing `X` by the undefined identifier) on the lines before it:

```
#ifndef X
#define X 0
#endif
```

However, given these potential usage patterns there does not appear to be a worthwhile benefit in a guideline recommendation covering this issue.

Example

In the following the developer may be expecting `M` to be replaced by the body of some previously defined macro. If no such macro exists `M` will be replaced by 0.

```
#if M == 2
#endif
```

Usage

Approximately 15% of all conditional inclusion directives, in the translated form of this book's benchmark programs, contained an identifier that was replaced by 0 (i.e., they contained an identifier that was neither the operand of **defined** or defined as macro names).

1879 The resulting tokens compose the controlling constant expression which is evaluated according to the rules of 6.6, ~~except that all signed integer types and all unsigned integer types act as if they have the same representation as, respectively, the types **intmax_t** and **uintmax_t** defined in the header **<stdint.h>**~~.

Commentary

The wording was changed by the response to DR #265.

#if operand type uintmax_*

1880 For the purposes of this token conversion and evaluation, all signed integer types and all unsigned integer types act as if they have the same representation as, respectively, the types **intmax_t** and **uintmax_t** defined in the header **<stdint.h>**.[142)]

Commentary

The preprocessor has to evaluate constant expressions using one or more integer type representations. Limiting the representations used to integer types having the same rank minimizes the number of dependencies between the preprocessor and the translator (this requirement also creates a dependency between the processor and the contents of the header **<stdint.h>** used by the implementation).

The types `intmax_t` and `uintmax_t` are the signed or unsigned version of the greatest-width integer type supported by the implementation (and have rank at least equal to that of the type **long long**). Any differences in the representation the types `intmax_t` and `uintmax_t` used by the preprocessor and the typedef names defined (if any, through the appropriate **#include**) in a translation unit would mean that an implementation was not conforming (the situation is the same as that between the type of **sizeof** and the `size_t` used from **<stddef.h>**, see DR #017q7).

The wording was changed by the response to DR #265.

C90

The resulting tokens comprise the controlling constant expression which is evaluated according to the rules of 6.4 using arithmetic that has at least the ranges specified in 5.2.4.2, except that ***int*** *and* ***unsigned int*** *act as if they have the same representation as, respectively,* ***long*** *and* ***unsigned long****.*

The ranks of the integer types used for the operands of the controlling constant expression differ between C90 and C99 (although in both cases the rank is the largest that an implementation is required to support). Those cases where the value of the operand exceeded the representable range in C90 (invariably resulting in the value wrapping) are likely to generate a very large value in C99.

C++

The C++ Standard specifies the same behavior as C90 (see the C90 subsection above).

Common Implementations

While a number of C90 implementations supported the type **long long** they still performed preprocessor arithmetic using the types **long** and **unsigned long** (as specified by the C90 requirements). Fear of breaking existing source code means that vendors are likely to offer some form of C90 compatibility option that will continue to perform preprocessor arithmetic using the types specified in C90.

Coding Guidelines

There are a number of possible coding guideline issues associated with the value of a constant expression in a **#if** directive, including:

- The value may be different from the value of an identical sequence of tokens in other contexts in the source file (e.g., the right operand of an assignment statement).
- The value may depend on the implementation used (this problem is not preprocessor-specific, the representation used for the operands in an expression can depend on the implementation).

- The specification has changed between C90 and C99.

The problem with any guideline recommendation is that the total cost is likely to be greater than the total benefit (a cost is likely to be incurred in many cases and a benefit obtained in very few cases). For this reason no recommendation is made here. The discussion on suffixed integer constants is also applicable in the context of a conditional inclusion directive.

integer constant 835
type first in list

Example

In the following the developer may assume that unwanted higher bits in the value of `C` will be truncated when shifted left.

```
#define C 0x1100u
#define INT_BITS 32

#define TOP_BYTE (C << (INT_BITS-8))

#if TOP_BYTE == 0
/* ... */
#endif

void f(void)
{
if (TOP_BYTE == 0)
   /* ... */ ;
}
```

This includes interpreting character constants, which may involve converting escape sequences into execution character set members. 1881

#if escape sequences

Commentary

This conversion also occurs in translation phase 5.

translation phase 5 133

Whether the numeric value for these character constants matches the value obtained when an identical character constant occurs in an expression (other than within a **#if** or **#elif** directive) is implementation-defined.[143] 1882

Commentary

The C committee recognized that developers may choose to perform different phases of translation on different hosts. For instance, source files may be preprocessed and then distributed for further translation on other, different, hosts.

Common Implementations

Differences between the numeric values in these two cases is rare (although cases involving Ascii and EBCDIC character sets do occur).

EBCDIC 3

Coding Guidelines

Making use of the numeric value of character constants is making use of representation information, which is covered by a guideline recommendation. However, there are cases where deviations may occur.

representation information 569.1
representation information using 569.1
using

Example

See footnote 141.

footnote 141 1874

Also, whether a single-character character constant may have a negative value is implementation-defined. 1883

basic character set may be negative

Commentary

The guarantee on the value being nonnegative does not apply during preprocessing. For instance, a preprocessing using the EBCDIC character set and acting as if the type **char** was signed. In other contexts the value of a character constant containing a single-character that is not a member of the basic execution character set is implementation-defined.

478 basic character set positive if stored in char object

885 character constant more than one character

Coding Guidelines

The discussion on the possibility of character constants having other implementation-defined values is applicable here.

885 character constant more than one character

1884 Preprocessing directives of the forms

#ifdef #ifndef

```
# ifdef  identifier new-line group_opt
# ifndef identifier new-line group_opt
```

check whether the identifier is or is not currently defined as a macro name.

Commentary

There is no **#elifdef** form (although over half of the uses of the **#elif** directive are followed by a single instance of the **defined** operator— Table 1872.1).

1885 Their conditions are equivalent to **#if defined** *identifier* and **#if !defined** *identifier* respectively.

Commentary

The **#ifdef** and **#ifndef** forms are rather like the unary **++** and **--** operators in that they provide a short hand notation for commonly used functionality.

Coding Guidelines

The **#ifdef** forms are the most common form of conditional inclusion directive. Measurements (see Table 1872.1) also show that nearly a third of the uses of the **defined** operator could be replaced by one of these forms. There are advantages (e.g., most common form suggests most practiced form for readers, and ease of visual scanning down the left edge of the source) and disadvantages (e.g., requires more effort to add additional conditions to the single test being made) to using the **#ifdef** forms, instead of the **defined** operator. However, there does not appear to be a worthwhile cost/benefit to recommending one of the possibilities.

1886 142) Thus on an implementation where INT_MAX is 0x7FFF and UINT_MAX is 0xFFFF, the constant 0x8000 is signed and positive within a #if expression even though it is unsigned in translation phase 7.

Commentary

The wording was changed by the response to DR #265.

1887 143) Thus, the constant expression in the following **#if** directive and **if** statement is not guaranteed to evaluate to the same value in these two contexts.

footnote 143

```
#if 'z' - 'a' == 25
if ('z' - 'a' == 25)
```

Commentary

This situation could occur, for instance, if the Ascii representation were used during the preprocessing phases and EBCDIC were used during translation phase 5.

133 translation phase 5

1888 Each directive's condition is checked in order.

Commentary

The order is from the lowest line number to the highest line number.

Coding Guidelines

selection statement 1739 syntax

It may be possible to obtain some translation time performance advantage (at least for the original developer) by appropriately ordering the directives. Unlike developer behavior with **if** statements, developers do not usually aim to optimize speed of translation when deciding how to order conditional inclusion directives (experience suggests that developers often simply append new directive to the end of any existing directives).

Recognizing a known pattern in a sequence of directives has several benefits for readers. They can make use of any previous deductions they have made on how to interpret the directives and what they represent, and the usage highlights common dependencies in the source. In the following code fragment more reader effort is required to spot similarities in the sequence that directives are checked than if both sequences of directives had occurred in the same order.

```
1   #ifdef MACHINE_A
2   /* ... */
3   #else
4   #ifdef MACHINE_B
5   /* ... */
6   #endif
7   #endif
8
9   #ifdef MACHINE_B
10  /* ... */
11  #else
12  #ifdef MACHINE_A
13  /* ... */
14  #endif
15  #endif
```

guideline recommendation 0 enforceable

Given the lack of attention from developers on the relative ordering of directives and the benefits of using the same ordering, where possible, a guideline recommendation appears worthwhile. However, a guideline recommendation needs to be automatically enforceable and determining when two sequences of directives have the same affect, during translation, may be infeasible because information that is not contained within the source may be required (e.g., dependencies between macro names that are likely to be defined via translator command line options).

Rev 1888.1

Where possible the visual order of evaluation of expressions within different sequences of nested conditional inclusion directives shall be the same.

If it evaluates to false (zero), the group that it controls is skipped: directives are processed only through the name that determines the directive in order to keep track of the level of nested conditionals; 1889

Commentary

if statement 1744 operand compare against 0

A parallel can be drawn with the behavior of **if** statements, in that if their controlling expression evaluates to zero, during program execution, any statements in the associated block are skipped.

---

directive processing while skipping

directives are processed only through the name that determines the directive in order to keep track of the level of nested conditionals; 1890

Commentary

The preprocessor operates on a representation of the source written by the developer, not translated machine code. As such it needs to perform some processing on its input to be able to deduce when to stop skipping.

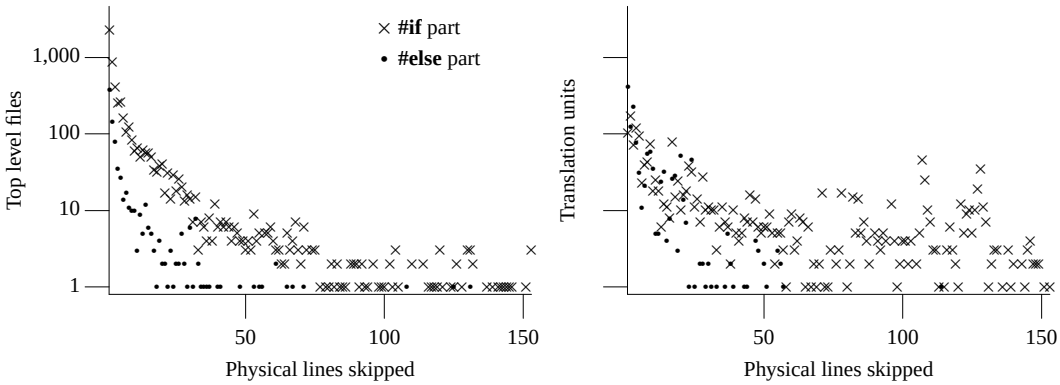

Figure 1889.1: Number of top-level source files (i.e., the contents of any included files are not counted) and (right) complete translation units (including the contents of any files **#include**d more than once) having a given number of lines skipped during translation of this book's benchmark programs.

Directives need to be processed to keep track of the level of nesting of conditionals and translation phases 1–3 still need to be performed (line splicing could affect what is or is not the start of a line) and characters within a comment must not be treated as directives.

116 translation phase 1

The intent of only requiring a minimum of directive processing, while skipping, is to enable partially written source code to be skipped and to allow preprocessors to optimize their performance in this special case, speeding up the rate at which the input is processed.

Example

```
#if 1
extern int ei;

#elif " an unmatched quote character, undefined behavior

extern int foo_bar;
#endif

#if 0
printf("\
#endif \n");

#endif

#if 0
/*
#endif
*/
#endif
```

1891 the rest of the directives' preprocessing tokens are ignored, as are the other preprocessing tokens in the group.

Commentary

There is no requirement that any directive be properly formed, according to the preprocessor syntax. However, preprocessing tokens still need to be created, before they are ignored (as part of translation phase 3).

1854 preprocessor directives syntax
124 translation phase 3

Example

In the following the **#define** directive is not well formed. But because this group is being skipped the translator is required to ignore this fact.

```
#if 0
#define M(e
#endif
```

Only the first group whose control condition evaluates to true (nonzero) is processed. 1892

Commentary

This group is processed exactly as-if it appeared in the source outside of any group.

If none of the conditions evaluates to true, and there is a **#else** directive, the group controlled by the **#else** is processed; 1893

Commentary

A semantic rule to associate **#else** with the lexically nearest preceding **#if** (or similar form) directive, like the one given for **if** statements, is not needed because conditional inclusion is terminated by a **#endif** directive.

else 1747 binds to nearest if

Like the matching **#if** (or similar form) directive case, all preprocessing tokens in the group are treated as if they appeared outside of any conditional inclusion directive. Processing continues until the first **#endif** is encountered (which must match the opening directive).

Coding Guidelines

The arguments made for **if** statements always containing an **else** arm might be thought to also apply to conditional inclusion. However, the presence of a matching **#endif** directive reduces the likelihood that readers will confuse which preprocessing directive any **#else** associates with (although other issues, such as lack of indentation or a large number of source lines between directives can make it difficult to visually associate matching directives).

else 1745

---

lacking a **#else** directive, all the groups until the **#endif** are skipped.[144)] 1894

Commentary

The affect of this specification mimics the behavior of **if** statements.

else 1747 binds to nearest if

Forward references: macro replacement (6.10.3), source file inclusion (6.10.2), largest integer types (7.18.1.5). 1895

6.10.2 Source file inclusion

Constraints

---

source file inclusion

A **#include** directive shall identify a header or source file that can be processed by the implementation. 1896

Commentary

There is no requirement that a header be represented using a source file. It could be represented using prebuilt information within the translator that is enabled only when the appropriate **#include** directive is encountered during preprocessing (but not in a group that is skipped). Also there is no requirement that the spelling of the header in the C source file be represented by a source file of the same spelling. The C Standard has no explicit knowledge of file systems and is silent on the issue of directory structures. Minimum required limits on the implementation processing of a header name are specified elsewhere.

footnote 2018 153

#include 1909 mapping to host file

Failure to locate a header or source file that can be processed by the implementation (e.g., a file of the specified name does not exist, at least along the places searched) is a constraint violation.

Other Languages

Most languages do not specify a **#include** mechanism, although many of their implementations provide one. The approach commonly used by C implementations is popular, but not universal. Some languages explicitly state that a **#include** directive denotes a file of the given name in the translators host environment.

Common Implementations

For most implementations the header name maps to a file name of the same spelling. It is quite common for the translation environment to ignore the case of alphabetic letters (e.g., MS-DOS and early versions of Microsoft Windows), or to limit the number of significant characters in the file name denoted by a header name (the remaining characters being ignored). Use of the / character in specifying a full path to a file is sufficiently common usage that even host environments where this character is not normally associated with a directory separator support such usage in header names (many Microsoft windows translators support this character, as well as the \ character, as a directory separator).

In the majority of implementations **#include** directives specify files containing source in text form. However, some implementations support what are known as *precompiled headers*.

121 source file representation
121 header precompiled

It is not uncommon (over 10% of **#include**s in Figure 1896.1) for the same header to be **#include**d more than once when translating a source file (it is a requirement that implementations support this usage for standard headers). The following are some of the techniques implementations use to reduce the overhead of subsequent **#include**s.

- A common convention is to bracket the contents of a header, starting with the preprocessing token sequence `#ifndef __H_file_name__/#define __H_file_name__` and ending with `#endif`. The processing of subsequent **#include**s of the same header is then reduced to the minimal processing needed to skip to the matching **#endif**. Some implementations (e.g., `gcc`) go one step further and detect headers that contain such bracketing the first time they are processed, and completely skips opening and processing the header if it is subsequently encountered again in a **#include** directive.
- Support the preprocessing directive **#import**.[353] This directive is equivalent to the **#include** directive except that if the specified header has already been included it is not included again.

Coding Guidelines

Some coding guideline documents recommend that implementation supplied headers appear before developer written headers, in a source file. Such recommendations overlook the possibility that a developer written header might itself **#include** an implementation header.

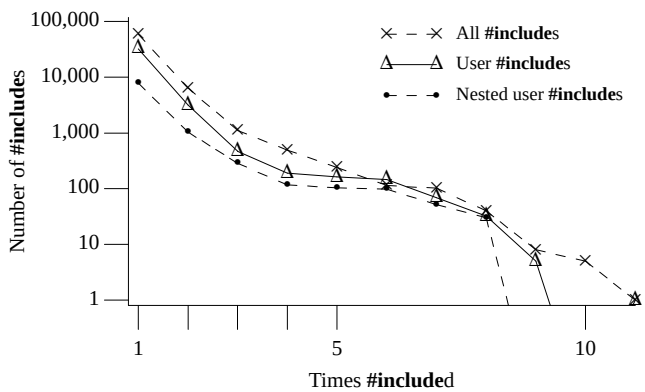

Figure 1896.1: Number of times the same header was **#include**d during the translation of a single translation unit. The crosses denote all headers (i.e., all systems headers are counted), triangles denote all headers delimited by quotes (i.e., likely to be user defined headers) and bullets denote all quote delimited headers **#include** nested at least three levels deep. Based on the translated form of this book's benchmark programs.

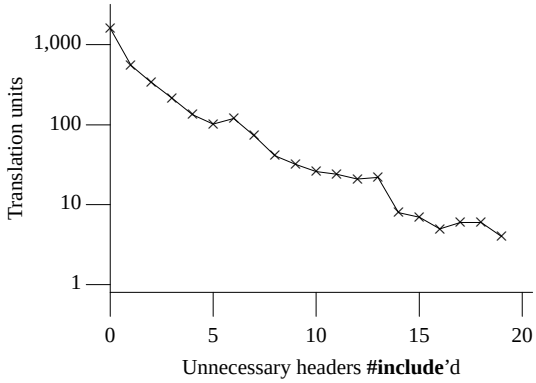

Figure 1896.2: Number of preprocessing translation units (excluding system headers) containing a given number of **#include**s whose contents are not referenced during translation (excludes the case where the same header is **#include**d more than once, see Figure 1896.1). Based on the translated form of this book's benchmark programs.

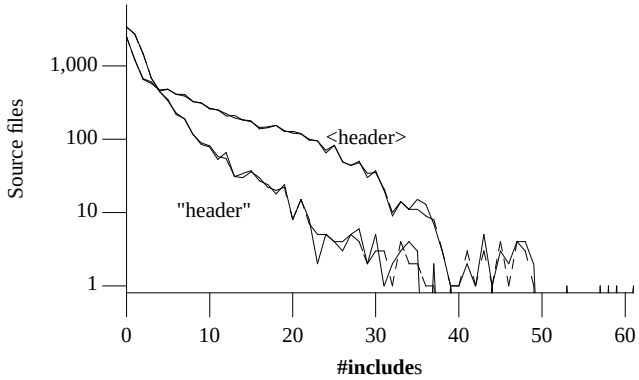

Figure 1896.3: Number of `.c` source files containing a given number of **#include** directives (dashed lines represent number of unique headers). Based on the visible form of the `.c` files.

Experience suggests that once a **#include** directive appears in a source file it is rarely removed (see Figure 1896.2) and that new **#include** directives are simply added after the last one. The issue of redundant code is discussed elsewhere.

redundant code 190

There does not appear to be a worthwhile benefit in ordering **#include** directives in any way (apart from any relative ordering dictated by dependencies between headers).

Table 1896.1: Occurrence of two forms of *header-name*s (as a percentage of all **#include** directives), the percentage of each kind that specifies a path to the header file, and number of absolute paths specified. Based on the visible form of the `.c` files.

Header Form	% Occurrence	% Uses Path	Number Absolute Paths
<h-char-sequence>	75.0	86.4	0
"q-char-sequence"	25.0	17.2	0

Semantics

#include h-char-sequence

A preprocessing directive of the form

```
# include <h-char-sequence> new-line
```

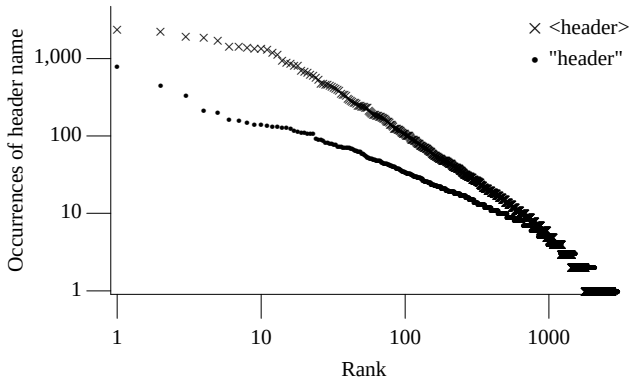

Figure 1896.4: *header-name* rank (based on character sequences appearing in **#include** directives) plotted against the number of occurrences of each character sequence. Also see Figure 792.26. Based on the visible form of the `.c` files.

searches a sequence of implementation-defined places for a header identified uniquely by the specified sequence between the < and > delimiters, and causes the replacement of that directive by the entire contents of the header.

Commentary

File systems invariably provide a unique method of identifying every file they contain (e.g., a *full path name*). The base document recognized the disadvantages of requiring that the full path name be specified in each **#include** directive and permitted a substring of it to be given. The implementation-defined places are usually additional character sequences (e.g., directory names) added to the *h-char-sequence* in an attempt to create a full path name that refers to an existing file.

918 header name syntax

Rationale

The file search rules used for the filename in the **#include** directive were left as implementation-defined. The Standard intends that the rules which are eventually provided by the implementor correspond as closely as possible to the original K&R rules. The primary reason that explicit rules were not included in the Standard is the infeasibility of describing a portable file system structure. It was considered unacceptable to include UNIX-like directory rules due to significant differences between this structure and other popular commercial file system structures.

Nested include files raise an issue of interpreting the file search rules. In UNIX C a **#include** directive found within an included file entails a search for the named file relative to the file system *directory* that holds the outer **#include**. Other implementations, including the earlier UNIX C described in K&R, always search relative to the same *current directory*. The C89 Committee decided in principle in favor of K&R approach, but was unable to provide explicit search rules as explained above.

Other Languages

Other languages (or an extension provided by their implementations) commonly use the double-quote delimited form.

Common Implementations

The character sequence between the < and > delimiters is invariably treated as the name of a file, possibly including a path. The ordering of the search sequence used for directives having the form *<h-char-sequence>* is often different from that used for the form *"q-char-sequence"*. For instance, in the *<h-char-sequence>* case the contents of `/usr/include` might be searched first, followed by the contents of the directory containing the `.c` file, while in *"q-char-sequence"* case the contents of the directory containing the `.c` file might be searched first, followed by other places.

1909 #include mapping to host file

The environment in which a translator executes may also affect the sequence of places that are searched. For instance, the affect of relative path names (e.g., `../proj/abc.h`) on the identity of the current directory.

gcc searches two directories, /usr/include and another directory that holds very machine specific files, such as stdarg.h (e.g., /usr/lib/gcc-lib/i386-redhat-linux/egcs-2.91.66/include on your authors computer). gcc supports the **#include_next** directive. This directive causes the search algorithm to skip some of the initial implementation-defined places that would normally be searched. The initial places that are skipped are those that were searched in locating the file containing the **#include_next** directive (including the place where the search succeeded).

Tzerpos and Holt[1383] describe a well-formedness theory of header inclusion that enables unnecessary **#include** directives to be deduced.

Coding Guidelines

The standard does not specify the order in which the implementation-defined places are searched. This is a potential coding guideline issue because it is possible that a *h-char-sequence* will match in more than one of the places (i.e., there is a file having the same name along several of the different possible search paths). The behavior is thus dependent (i.e., it is assumed that the contents of the different headers will be different) on the order in which the places are searched.

Experience suggests that the affect of a translator locating an **#include**d file different from the one expected to be located by the developer has one of two consequences— (1) when the contents of the file accessed is similar to the one intended (e.g., a different version of the intended file) the source file may be successfully translated, and (2) when the contents of the file accessed has no connection with the intended file the source is rarely successfully translated. The problem might therefore be considered to be one of version management, rather than the choice of characters used in a *h-char-sequence*. There are a number of reasons why a solution to this issue is to not use *h-char-sequence*s at all, including the following:

#include 1898 places to search for

- For the < > delimited form, implementations usually look in a predefined location first (as described in the Common implementation section above and in the following C sentence). Ensuring that the names chosen by developers for the headers they create are different from those of system headers is an almost impossible task. While it might be possible to enumerate the set of names of existing file names of system headers contained in commercially important environments, members are likely to be added to this set on a regular basis. Rather than trying to avoid using file names likely to match those of system headers, developers could ensure that places containing system headers are searched last.

- The < > delimited form is often considered to denote *externally* supplied headers (e.g., provided by the implementation or translator environment vendor). What constitutes a system supplied header is open to interpretation. One distinction that can be made between system and developer headers is that developers do not control of the contents of system headers. Consequently, it can be argued that their contents are not subject to coding guidelines. Headers whose contents have been written by developers are subject to coding guidelines. The convention generally adopted to indicate this status is to use the double-quote character delimit form of **#include**.

Rev 1897.1 Developer written headers in a **#include** directive shall not be delimited by the < and > characters.

Developers sometimes specify full path names in headers (see Table 1896.1). This is a configuration management issue and is not considered to be within the scope these coding guidelines.

Table 1897.1: Number of various kinds of identifiers declared in the headers contained in the `/usr/include` directory of some translation environments. Information was automatically extracted and represents an approximate lower bound. Versions of the translation environments from approximately the same year (mid 1990s) were used. The counts for ISO C assumes that the minimum set of required identifiers are declared and excludes the type generic macros.

Information	Linux 2.0	AIX on RS/6000	HP/UX 9	SunOS 4	Solaris 2	ISO C
Number of headers	2,006	1,514	1,264	987	1,495	24
macro definitions	10,252	18,637	13,314	11,987	10,903	446
identifiers with external linkage	1,672	1,542	1,935	616	1,281	487
identifiers with internal linkage	80	34	2012	0	5	0
tag declaration	716	1,088	899	1,208	945	3
typedef name declared	1,024	828	15	493	1,027	55

1898 How the places are specified or the header identified is implementation-defined.

#include places to search for

Commentary

The differences between the environments in which translation occurs has narrowed over the years. However, even although there may be much common practice, such are issues are considered to be outside the scope of the C Standard.

10 program transformation mechanism

Common Implementations

Implementations invariably search one or more predefined locations first (e.g., `/usr/include`), followed by a list of alternative places. A number of techniques are used to allow developers to specify a list of alternative places to be searched for files corresponding to the headers specified in a **`#include`** directive. For instance, the alternative places may be specified via a translator command line option (e.g., `-I`), in a translator configuration file (e.g., `gcc` version 2.91.66 hosted on RedHat Linux reads many default from the file `/usr/lib/gcc-lib/i386-redhat-linux/egcs-2.91.66/specs`, although the path `/usr/include` is still hard coded in the translator sources), or an environment variable (e.g., several Microsoft windows based translators use `INCLUDE`).

The directory separator used in Unix and MS-DOS slants in different directions. Many implementations, in both environments, recognize both characters as directory delimiters. One consequence of this is that escape sequences are not recognized as such (something that is unlikely to be a problem in header names).

The RISCOS environment does not support filenames ending in `.h`. The implementation-defined behavior for this host is to look in a directory called `h`, for a file of the given name with the `.h` removed.

Coding Guidelines

The implementation-defined behavior associated with how the places are specified occurs outside of the source code and is the remit of configuration management guidelines. For this reason nothing further is said here.

1899 A preprocessing directive of the form

#include q-char-sequence

```
# include "q-char-sequence" new-line
```

causes the replacement of that directive by the entire contents of the source file identified by the specified sequence between the " delimiters.

Commentary

The commonly accepted intent of this form of the **`#include`** directive is that it is used to reference source files created by developers (i.e., headers that are not provided as part of the implementation or host environment). The only syntactic difference between *`q-char-sequence`* and *`h-char-sequence`* is that neither sequence may contain their respective delimiters.

918 header name syntax

Most *`q-char-sequence`*s end with one of two character sequences (i.e., `.c` or `.h`). The character sequences before these suffixes is often called the *header name*.

Other Languages

The use of double-quote as the delimiter is the almost universal form used in other languages (although some use the ' character because that is what is used to delimit string literals).

Coding Guidelines

The term commonly used to refer to these source files is *header*. The context of the conversation often being used to distinguish any other intended usage. The intent is that the contents of these source files is controlled by developers and as such they are subject to coding guidelines.

The named source file is searched for in an implementation-defined manner. 1900

Commentary

While this "implementation-defined manner" might be the same as that for the < > delimited form. The intent is for it to be sufficiently different that developers do not need to be concerned about the name of a header created by them matching one provided as part of the implementation (and therefore potentially found by the translator when searching for a matching header). For instance, your author does not know the names of most of the 304 files (e.g., `compface.h`) contained in `/usr/include` on his software development computer. The discussion on the < > delimited form is applicable here.

#include 1897 h-char-sequence

Common Implementations

The search algorithm used invariably differs from that used for the < > delimited form (otherwise there would be little point in distinguishing the two cases). The search algorithm used by some implementations is to first look in the directory containing the source file currently being translated (which may itself have been included). If that search fails, and the current source file has itself been included, the directory containing the source file that **`#include`** it is then searched. This process continuing back through any nested **`#include`** directives. For instance, in:

file_1.c
```
#include "abc.h"
```

file_2.c
```
#include "/foo/file_1.c"
```

file_3.c
```
#include "/another/path/file_2.c"
```

(assuming the translation environment supports the path names used), translating the source file `file_3.c` causes `file_2.c` to be included, which in turn includes `file_3.c`. The source file `abc.h` will be searched for in the directories `/foo`, `/another/path` and then the directory containing `file_3.c`.

Some implementations use the double-quote delimited form within their system headers, to change the default first location that is searched. For instance, a third-party API may contain the header `abc.h`, which in turn needs to include `ayx.h`. Using the form `"ayx.h"` means that the implementation will search in the directory containing `abc.h` first, not `/usr/include`. This usage can help localize the files that belong to specific APIs. Other implementations use a search algorithm that starts with the directory containing the original source file being translated.

If the source file is not found after these places have been searched, some implementations then search other places specified via any translator options. Other implementations simply follow the behavior described by the following C sentence (which has the consequence of eventually checking these other places).

#include 1898 places to search for

If this search is not supported, or if the search fails, the directive is reprocessed as if it read 1901

`#` **`include`** <*h-char-sequence*> *new-line*

with the identical contained sequence (including > characters, if any) from the original directive.

Commentary

The previous search can fail in the sense that it does not find a matching source file.

Some existing code uses the double-quote delimited form of **#include** directive to include headers provided by the implementation (rather than the < > delimited form). This requirement ensures that such code continues to be conforming.

1902 144) As indicated by the syntax, a preprocessing token shall not follow a **#else** or **#endif** directive before the terminating new-line character.

footnote 144

Commentary

Saying in words what is specified in the syntax.

Common Implementations

Many early implementations (and some present days ones, for compatibility with existing source) treated any sequence of characters following one of these directives as a comment, e.g., `#endif X == 1`.

1903 However, comments may appear anywhere in a source file, including within a preprocessing directive.

Commentary

A comment is replaced by a single space character prior to preprocessing.

126 comment replaced by space
1858 preprocessing directive ended by

1904 A preprocessing directive of the form

```
# include pp-tokens new-line
```

(that does not match one of the two previous forms) is permitted.

Commentary

This form permits the < > or double-quote delimited forms to be generated via macro expansion. However, it is rarely used (11 instances in over 60,000 **#include** directives in the visible source of the `.c` files). Whether this is because developers are unaware of its existence, or because it has little utility is not known.

1914 #include example 2

1905 The preprocessing tokens after **include** in the directive are processed just as in normal text. (Each identifier currently defined as a macro name is replaced by its replacement list of preprocessing tokens.)

#include macros expanded

Commentary

To be exact, the preprocessing tokens after **include** in the directive up to the first new-line character are processed just as in normal text.

1906 (Each identifier currently defined as a macro name is replaced by its replacement list of preprocessing tokens.)

Commentary

This C sentence provides explicitly clarification that macro replacement occurs in this case (the same clarification is also given elsewhere).

1991 #line macros expanded

1907 The directive resulting after all replacements shall match one of the two previous forms.[145)]

Commentary

It is not a violation of syntax if the directive does not match one of the two previous forms, because the syntax of this form has been matched. It is a violation of semantics and therefore the behavior is undefined.

1908 The method by which a sequence of preprocessing tokens between a < and a > preprocessing token pair or a pair of " characters is combined into a single header name preprocessing token is implementation-defined.

Commentary

This implementation-defined behavior may take a number of forms, including:

1958 operator
1963 if result not valid

- The ## operator can be used to glue preprocessing tokens together. However, the behavior is undefined if the resulting character sequence is not a valid preprocessing token. For instance, the five preprocessing tokens {{} {string} {.} {h} {}} cannot be glued together to form a valid preprocessing token without going through intermediate stages whose behavior is undefined.

1950 operator

- Creating a preprocessing token, via macro expansion, having the double-quote delimited form (i.e., a string preprocessing token) need not depend on any implementation-defined behavior. The stringize operator can be used to create a string preprocessing token.

- Other implementation-defined behaviors might include the handling of space characters. For instance, in the following:

```
1  #define bra <
2  #define ket >
3  #include bra stdio.h ket
```

  does the implementation strip off the space character at the ends of the delimited character sequence?

Coding Guidelines

Given the rarity of use of this form of **#include** no guideline recommendations are given here.

Example

```
1  #define mk_sys_hdr(name) < ## name ## >
2
3  #if BUG_FIX
4  #define VERSION 2a /* works because pp-numbers include alphabetics */
5  #else
6  #define VERSION 2
7  #endif
8
9  #define add_quotes(a) # a
10 #define mk_str(str, ver) add_quotes(str ## ver)
11
12 #include mk_str(Version, VERSION)
```

#include mapping to host file

The implementation shall provide unique mappings for sequences consisting of one or more ~~letters or digits (as defined in 5.2.1)~~ nondigits or digits (6.4.2.1) followed by a period (.) and a single ~~letter~~ nondigit. 1909

Commentary

This C sentence and the following ones in this C paragraph are a specification of the minimum set of requirements that an implementation must meet. For sequences outside of this set the implementation mapping may be non-unique (like, for instance, the Microsoft Windows technique of mapping files ending in .html to .htm). The handling of character sequences that resemble UCNs may also differ, e.g., "\ubada\file.txt" (Ubada is a city in Tanzania and BADA is the Hangul symbol 붚 in ISO 10646). The standard does not permit any number of period characters because many operating systems do not permit them (at least one, RISCOS, does not permit any).

The wording was changed by the response to DR #302 to extend the specification to be more consistent with C++.

C++

The implementation provides unique mappings for sequences consisting of one or more nondigits (2.10) followed by a period (.) and a single nondigit. 16.2p5

Other Languages

Other languages either specified to operate within the same operating systems and file systems limitations as C and as such have to deal with the same issues, or require an integrated development environment to be created before they can be used.

Common Implementations

Implementations invariably pass the sequence of characters that appear between the delimiters (when searching other places a directory path may be added) as an argument in a call to `fopen` or equivalent system function. The called library function will eventually call some host operating system function that interfaces to the host file system. The C translator's behavior is thus controlled by the characteristics of the host file system and how it maps character sequences to file names. The handling of the period character varies between file systems, known behaviors include:

- Unix based file systems permit more than one period in a file name.
- MS-DOS based file systems only permit a single period in a file name.
- RISCOS, an operating system for the Acorn ARM processor does not support filenames that contain a period. For this host file names, that contained a period, specified in a **`#include`** directive were mapped using a directory structure. All file names ending in the characters `.h` were searched for in a directory called `h`.

Coding Guidelines

Because an implementation is not required to provide a unique mapping for all sequences it is possible that an unintended header or source file will be accessed, or the translator will fail to identify a known header or source file. The possible consequences of an unintended access are discussed elsewhere, while failure to identify known header or source file will cause a diagnostic to be issued. The cost/benefit issues associated with using character sequences having a unique mapping in the different environments that the source may be translated in is outside the scope of these coding guidelines.

1897 #include h-char-sequence
1896 source file inclusion

1910 The first character shall ~~be a letter~~ not be a digit.

Commentary

This requirement only applies to the first character of the sequence that implementations are required to provide a unique mapping for.

The wording was changed by the response to DR #302.

C90

The requirement that the first character not be a digit is new in C99. Given that it is more restrictive than that required for existing C90 implementations (and thus existing code) it is unlikely that existing code will be affected by this requirement.

C++

This requirement is new in C99 and is not specified in the C++ Standard (the argument given in the C90 subsection (above) also applies to C++).

Common Implementations

Most implementations support a first character that is not a letter.

header name significant characters

The implementation may ignore the distinctions of alphabetical case and restrict the mapping to eight significant characters before the period. 1911

Commentary

These permissions reflect known characteristics of file systems in which translators are executed.

C90

The limit specified by the C90 Standard was six significant characters. However, implementations invariably used the number of significant characters available in the host file system (i.e., they do not artificially limit the number of significant characters). It is unlikely that a header of source file will fail to be identified because of a difference in what used to be a non-significant character.

C++

The C++ Standard does not give implementations any permissions to restrict the number of significant characters before the period (16.1p5). However, the limits of the file system used during translation are likely to be the same for both C and C++ implementations and consequently no difference is listed here.

Common Implementations

All file systems place some limits on the number of characters in a source file name— for instance:

- Most versions of the Microsoft DOS environment ignore the distinction of alphabetic case and restrict the mapping to eight significant characters before any period (and a maximum of three after it).
- POSIX requires that at least 14 characters be significant in a file name (it also requires implementations to support at least 255 characters in a pathname). Many Linux file systems support up to 255 characters in a filename and 4095 characters in a pathname.

Coding Guidelines

The potential problems associated with limits on sequences characters that are likely to be treated as unique is a configuration management issue that is outside the scope of these coding guidelines.

A **#include** preprocessing directive may appear in a source file that has been read because of a **#include** directive in another file, up to an implementation-defined nesting limit (see 5.2.4.1). 1912

Commentary

Thus **#include** directives can be nested within source files whose contents have themselves been **#include**d. This issue is discussed elsewhere. While this permission only applies to source files, an implementation using some form of precompiled headers (which are not source files within the standard's definition of the term) that did not support this functionality would not be popular with developers.

limit 295
#include nesting
header 121
precompiled
source files 108

EXAMPLE 1 The most common uses of **#include** preprocessing directives are as in the following: 1913

```
#include <stdio.h>
#include "myprog.h"
```

Other Languages

Some languages only have a single form of **#include** directive for all headers.

#include example 2

EXAMPLE 2 This illustrates macro-replaced **#include** directives: 1914

```
#if VERSION == 1
        #define INCFILE  "vers1.h"
#elif VERSION == 2
        #define INCFILE  "vers2.h"   // and so on
```

```
#else
        #define INCFILE  "versN.h"
#endif
#include INCFILE
```

Commentary

This example does not illustrate any benefit compared to that obtained from placing separate **#include** directives in each arm of the conditional inclusion directive.

1915 **Forward references:** macro replacement (6.10.3).

1916 145) Note that adjacent string literals are not concatenated into a single string literal (see the translation phases in 5.1.1.2);

footnote 145

Commentary

String concatenation occurs in translation phase 6 and so it is not possible to join together two existing strings to form another string within a **#include** directive.

135 translation phase 6

1917 thus, an expansion that results in two string literals is an invalid directive.

Commentary

It is an invalid directive in that it violates a semantic requirement and thus the behavior is undefined. It is not a syntax violation.

6.10.3 Macro replacement

Constraints

macro replacement

1918 Two replacement lists are identical if and only if the preprocessing tokens in both have the same number, ordering, spelling, and white-space separation, where all white-space separations are considered identical.

replacement list identical if

Commentary

This is actually a definition in a Constraints clause (it is used by two constraints in this C subsection).

The check against same spelling only needs to take into account the significant characters of an identifier. Considering all white-space separations to be identical removes the need for developers to be concerned about use of different source layout (e.g., indentation) and method of spacing (e.g., space character vs. horizontal tab).

282 internal identifier significant characters

Rationale

The specification of macro definition and replacement in the Standard was based on these principles:

- Interfere with existing code as little as possible.
- Keep the preprocessing model simple and uniform.
- Allow macros to be used wherever functions can be.
- Define macro expansion such that it produces the same token sequence whether the macro calls appear in open text, in macro arguments, or in macro definitions.

Preprocessing is specified in such a way that it can be implemented either as a separate text-to-text prepass or as a token-oriented portion of the compiler itself. Thus, the preprocessing grammar is specified in terms of tokens.

object-like macro redefinition

An identifier currently defined as an object-like macro shall not be redefined by another **#define** preprocessing directive unless the second definition is an object-like macro definition and the two replacement lists are identical. 1919

Commentary

There was an existing body of code, containing redefinitions of the same macro, when the C Standard was first written. The C committee did not want to specify that existing code containing such usage was non-conforming, but they did consider the case where the bodies of any subsequent definitions differed to be an erroneous usage.

EXAMPLE 1983
macro redefinition

C90

The wording in the C90 Standard was modified by the response to DR #089.

Common Implementations

#define/#undef stack

Some translators permit multiple definitions of a macro, independently of the contents of the contents of the bodies. The behavior is for a new definition to cause the previous body to be pushed, in a stack-like fashion. Any subsequent **#undef** of the macro name popping this stacked definition and to make it the current one.

Coding Guidelines

C permits more than one definition of the same macro name, with the same body, and more than one external definition of the same object, with the same type and the coding guideline issues are the same for both (in both cases translators are not always required to issue a diagnostic if the definitions are considered to be different).

linkage 420
identifier 422.1
declared in one file

In both cases a technique for avoiding duplicate definitions, during translation but not in the visible source, is to bracket definitions with `#ifndef MACRO_NAME/#endif` (in the case of the file scope object a macro name needs to be created and associated with its declaration). Using this technique has the disadvantage that it prevents the translator checking that any subsequent redeclarations of an identifier are the same (unless the bracketing occurs around the only textual declaration that occurs in any source file used to build a program).

function-like macro redefinition

Likewise, an identifier currently defined as a function-like macro shall not be redefined by another **#define** preprocessing directive unless the second definition is a function-like macro definition that has the same number and spelling of parameters, and the two replacement lists are identical. 1920

Commentary

object-like 1919
macro redefinition

The issues are the same as for object-like macros, with the addition of checks on the parameters. Requiring that the parameters be spelled the same, rather than, for instance, that they have an identical effect, simplifies the similarity checking of two macro bodies. For instance, in:

```
1  #define FM(foo) ((foo) + x)
2  #define FM(bar) ((bar) + x)
```

a translator is not required to deduce that the two definitions of `FM` are structurally identical.

There shall be white-space between the identifier and the replacement list in the definition of an object-like macro. 1921

Commentary

extended 216
character set

In the following (assuming `$` is a member of the extended character set and permitted in an identifier preprocessing token):

```
1  #define A$ x
```

an object-like macro with the name `A$` and the body `x` is defined, not macro with the name `A` and the body `$ x`.

There is no requirement that there be white-space following the **)** in a function-like macro definition.

C90

The response to DR #027 added the following requirements to the C90 Standard.

DR #027

Correction

Add to subclause 6.8, page 86 (Constraints):

*In the definition of an object-like macro, if the first character of a replacement list is not a character required by subclause 5.2.1, then there shall be white-space separation between the identifier and the replacement list.**

*[Footnote *: This allows an implementation to choose to interpret the directive:*

```
#define THIS$AND$THAT(a, b) ((a) + (b))
```

as defining a function-like macro THISANDTHAT, rather than an object-like macro THIS. Whichever choice it makes, it must also issue a diagnostic.]

However, the complex interaction between this specification and UCNs was debated during the C9X review process and it was decided to simplify the requirements to the current C99 form.

```
#define TEN.1 /* Define the macro TEN to have the body .1 in C90. */
              /* A constraint violation in C99. */
```

C++

The C++ Standard specifies the same behavior as the C90 Standard.

Common Implementations

HP–was DEC– treats $ as part of the spelling of the macro name.

1922 If the identifier-list in the macro definition does not end with an ellipsis, the number of arguments (including those arguments consisting of no preprocessing tokens) in an invocation of a function-like macro shall equal the number of parameters in the macro definition.

Commentary

This requirement is the macro invocation equivalent of the one for function calls.

998 function call arguments agree with parameters

C90

If (before argument substitution) any argument consists of no preprocessing tokens, the behavior is undefined.

The behavior of the following was discussed in DR #003q3, DR #153, and raised against C99 in DR #259 (no committee response was felt necessary).

```
#define foo() A
#define bar(B) B

foo() // no arguments
bar() // one empty argument?
```

What was undefined behavior in C90 (an empty argument) is now explicitly supported in C99. The two most likely C90 translator undefined behaviors are either to support them (existing source developed using such a translator will may contain empty arguments in a macro invocation), or to issue a diagnostic (existing source developed using such a translator will not contain any empty arguments in a macro invocation).

C++

The C++ Standard contains the same wording as the C90 Standard.

C++ translators are not required to correctly process source containing macro invocations having any empty arguments.

Common Implementations

Some C90 implementations (e.g., `gcc`) treated empty arguments as an argument containing no preprocessing tokens, while others (e.g., Microsoft C) treated an empty argument as being a missing argument (i.e., a constraint violation).

... arguments macro

Otherwise, there shall be more arguments in the invocation than there are parameters in the macro definition (excluding the `...`). 1923

Commentary

Rationale

There must be at least one argument to match the ellipsis. This requirement avoids the problems that occur when the trailing arguments are included in a list of arguments to another macro or function. For example, if `dprintf` had been defined as

```
#define dprintf(format,...) \
        dfprintf(stderr, format, __VA_ARGS__)
```

and it were allowed for there to be only one argument, then there would be a trailing comma in the expanded form. While some implementations have used various notations or conventions to work around this problem, the Committee felt it better to avoid the problem altogether.

C90

Support for the form `...` is new in C99.

C++

Support for the form `...` is new in C99 and is not specified in the C++ Standard.

Common Implementations

`gcc` allowed zero arguments to match a macro parameter defined using the `...` form.

Coding Guidelines

While some developers may be confused because the requirements on the number of arguments are different from functions defined using the ellipsis notation, passing too few arguments is a constraint violation (i.e., translators are required to issue a diagnostic that a developer then needs to correct).

---

macro invocation) terminates it

There shall exist a `)` preprocessing token that terminates the invocation. 1924

Commentary

While this requirement is specified in the syntax, it is interpreted as requiring the `)` preprocessing token to occur before any macro replacement of the identifiers following the matching `(` preprocessing token. For instance, in:

```
1  #define R_PAREN )
2
3  #define FUNC(a) a
4
5  static int glob = (1 + FUNC(1 R_PAREN );
```

the invocation is terminated by the `)` preprocessing token that occurs immediately before `;`, not the expanded form of `R_PAREN`.

1925 The identifier **__VA_ARGS__** shall occur only in the replacement-list of a function-like macro that uses the ellipsis notation in the ~~arguments~~parameters.

Commentary

This requirement simplifies a translators processing of occurrences of the identifier **__VA_ARGS__**.

This typographical correction was made by the response to DR #234.

C90

Support for **__VA_ARGS__** is new in C99.

Source code declaring an identifier with the spelling __VA_ARGS__ will cause a C99 translator to issue a diagnostic (the behavior was undefined in C90).

C++

Support for **__VA_ARGS__** is new in C99 and is not specified in the C++ Standard.

Common Implementations

gcc required developers to give a name to the parameter that accepted a variable number of arguments. This parameter name appeared in the replacement list wherever the variable number of arguments were to be substituted.

Example

```
1  /*
2   * The following are constraint violations.
3   */
4  #define __VA_ARGS__
5  #define jparks __VA_ARGS__
6  #define jparks(__VA_ARGS__)
7  #define jparks(__VA_ARGS__, ...) __VA_ARGS__
8
9  #define jparks(x) x
10       jparks(__VA_ARGS__)
11
12 #define jparks(x, ...) x
13       jparks(__VA_ARGS__,1)
14 /*
15  * The following break the spirit, if not the wording
16  * of this constraint.
17  */
18 #define jparks(x, y) x##y
19       jparks(__VA, _ARGS__)
20
21 #define jparks(x, y, ...) x##y
22       jparks(__VA, _ARGS__, 1)
```

1926 A parameter identifier in a function-like macro shall be uniquely declared within its scope.

macro parameter unique in scope

Commentary

This constraint is the macro equivalent of the one given for objects with no linkage. Its scope is the list of parameters in the macro definition and the body of that definition. This scope ends at the new-line that terminates the directive. Macro parameters are also discussed elsewhere.

1350 declaration only one if no linkage
1934 macro parameter scope extends
396 identifier macro parameter

Semantics

1927 The identifier immediately following the **define** is called the *macro name*.

macro name identifier

Commentary

This defines the term *macro name*. This term is generically used in software engineering to refer to this kind of entity.

---

macro one name space

There is one name space for macro names. 1928

Commentary

Object-like and function-like macro names exist in the same name space. However, an identifier defined as a function-like macro is only treated as such when its name is followed by an opening parenthesis. Name spaces are also discussed elsewhere.

function-like macro followed by (1935
name space 438

---

white-space before/after replacement list

Any white-space characters preceding or following the replacement list of preprocessing tokens are not considered part of the replacement list for either form of macro. 1929

Commentary

Specifying that such white-space should be considered to part of the replacement list has potential maintenance and comprehension costs (it restricts how the start of the replacement list may be indented and white-space following the replacement list is not immediately visible to readers) for no obvious benefit.

Example

In the following the string literal "_ _" is assigned to p.

```
#define str_ize(a)  #a
#define M  _ _

char *p = str_ize(M);
```

If a # preprocessing token, followed by an identifier, occurs lexically at the point at which a preprocessing directive could begin, the identifier is not subject to macro replacement. 1930

Commentary

tokens in directive not expanded unless 1867

This is a special case of a more general specification given elsewhere.

Common Implementations

Some preprocessors used to perform this kind of replacement (some past entries in the Obfuscated C contest[43] relied on such translator behavior).

Example

In the following, even although the identifier `define` is defined as a macro, the line starting **`#define`** still processed as a macro definition directive, and not as a **`#undef`** directive.

```
#define define undef

#define X Y
```

---

macro object-like

A preprocessing directive of the form 1931

`#` **`define`** *identifier replacement-list new-line*

defines an *object-like macro* that causes each subsequent instance of the macro name[146)] to be replaced by the replacement list of preprocessing tokens that constitute the remainder of the directive.

Commentary

This defines the term *object-like* macro. This term is not commonly used by developers, who tend to use the generic term *macro* for all macro definitions and when a distinction needs to be made use the term *function macro* (rather than the technically correct term *function-like macro*) to refer to the case of a macro defined to have parameters. A macro's replacement list is commonly known as a *macro body*, or simply its *body*.

The preprocessing tokens in a `text-line` are unconditional scanned for instances of macro names to expand, as are preprocessing tokens in some preprocessing directives.

1854 preprocessor directives syntax

The standard lists a few restrictions on identifiers that can be defined as macro names. The issue of implementation limits on the number of macros that may be defined in one preprocessing translation unit is discussed elsewhere.

2026 predefined macros not #defined
287 limit macro definitions

Other Languages

Some languages use **`def`** rather than **`define`**.

Common Implementations

Some preprocessors have a maximum limit on the number of characters that can occur in a replacement list (e.g., an early version of Microsoft C[932] had a 512 byte limit; a limit of 4096 is still seen in some preprocessors).

Implementations invariably provide a mechanism that is external to the source code for defining macros, e.g., the `-D` command line option.

Coding Guidelines

Macros can be defined to serve a variety of purposes (see Table 1931.1 for measurements of actual usage) including:

- Giving a symbolic name to a constant or expression. The issue of symbolic names is discussed elsewhere, as are the advantages of using enumeration types for related identifiers.
- Representing an expression without the overhead of a function call. Having made the decision to represent an expression with a symbolic name the decision on whether to use a function call or macro then needs to be made, the human decision making factors involved are discussed elsewhere.
- Parameterized code duplication. This kind of usage occurs because a function definition does not provide the necessary flexibility (for instance, the parameterization may involve constructs other than expressions).
- Parameterizing the definition of a type. This issue is discussed in more detail under typedef names.
- Controlling conditional inclusion. In this case their status as a macro definition is used as a flag.

822 symbolic name
517 enumeration set of named constants
0 agenda effects decision making
1629 typedef name syntax
476 boolean role

Some coding guideline documents recommend against what are sometimes known as *syntax changing* macro names. This terminology comes from the fact that uses of such macro names change the syntax, at least visually, of C. For instance, a developer familiar with Pascal might define the macro names `begin` and end to represent the C punctuators **`{`** and **`}`** respectively (this existing usage was one reason these macro names were not used as alternative spellings, in **`<iso646.h>`**, for these punctuators; it could have rendered existing conforming code nonconforming), or a developer wanting to modify existing code to use greater floating-point precision might define the macro name `float` to be **`double`**.

The growth in the usage languages with C-like syntax over the last 10 years means that these days it is rare for developers to attempt to change the visual appearance of C source to be closer to a language they are more familiar with. While a macro name that maps to a C token may be surprising to readers of the source, it is unlikely to conflict with their existing C knowledge, and therefore might be considered at worse a minor inconvenience (i.e., cost).

Defining a macro whose name is the same as a keyword means that the behavior of translated source can be very different from that expected from its visual appearance (such usage also results in undefined behavior

if the definition occurs prior to the inclusion of any library header). The presence of such a definition requires that readers substitute their existing, default response, knowledge of behavior for a new behavior (assuming that they had noticed the definition of the macro). Experience suggests that the short-term benefit of defining and using such macro names is less than the longer term (which may be only a few days) costs associated with comprehension and miscomprehension of the affected source.

Cg 1931.1 A source file shall not define a macro name to have the spelling of a keyword.

Replacement lists may look innocuous enough when viewed in isolation. However, in the context in which they occur the expanded form may interact in unexpected ways with adjacent tokens. For instance, looking at the components of the following source in isolation:

```
1  #define SUM  a + b
2
3  extern int glob;
4
5  void f(void)
6  {
7  int loc = glob * SUM;
8  }
```

the appearance of the replacement list of `SUM` suggests that `a` will be added to `b` and looking at the use of `SUM` in the initialization of `loc` suggests that it will be multiplied by the value of `glob`. However, the token sequence after macro replacement is `glob*a+b`, which has a very different interpretation.

The visual appearance of a replacement list containing statements can also be misleading. For instance, in:

```
1  #define INIT c=0; d=0;
2
3  extern int glob;
4
5  void f(void)
6  {
7  if (glob == 0)
8     INIT;
9  }
```

the assignment to `d` is not dependent on the value of `glob`. Which is counter to what the visual appearance of the source suggests.

A general solution to both of these problems is to bracket the replacement list, ensuring that the visually expected behavior is the same as the behavior that occurs after macro replacement.

Cg 1931.2 A replacement list having the form of an expression containing one or more binary operators shall be bracketed with parentheses, unless the binary operators are only those included in the production of a *postfix-expr*.

Cg 1931.3 A replacement list consisting of more than one statement shall be completely enclosed in a pair of braces (which make take the form of a **do** statement).

The visual appearance of declarations can also be deceptive when macro replacements are involved. For instance, in:

```
#define INFO_PTR int *

INFO_PTR glob_1,
         glob_2;
```

`glob_1` is declared to have a pointer type, while `glob_2` is declared to have an integer type.

The bracketing technique cannot be used with a replacement list that represents a type (it would violate C syntax). However, using a typedef name is not a general solution, it is possible to use macro names in situations where a typedef name cannot be used. For instance, in:

```
#define X_TYPE int

unsigned X_TYPE glob;
```

it is possible to modify the type denoted by `X_TYPE` because the macro expanded form represents a valid integer type when preceded by **`unsigned`**. However, the type denoted by a typedef name cannot be so modified.

1382 type specifiers possible sets of

Cg 1931.4

A replacement list shall not consist of a sequence of preprocessing tokens that has, after expansion, the syntax of a pointer type.

The replacement list of a macro definition has to appear on a single logical source line. Experience suggests that constructs that appear on separate lines in other contexts often appear on the same line within a replacement list. The developer cost (typing the characters) of using splicing, to give the replacement list a visible form that closely resembles that seen when it appears in other contexts is small. The benefit for subsequent readers is the ability to use the same strategies to read source constructs as they use in other contexts.

118 logical source line

118 physical source line

There are a number of ways in which token sequences appearing in various contexts might visually resemble each other. For instance, in the following definitions both `ZERO_ARRAY_1` and `ZERO_ARRAY_2` visually associate preprocessing tokens in the macro body, while in `ZERO_ARRAY_3` preprocessing tokens in the macro body visual interacts with the preprocessing tokens in the preprocessing directive.

```
#define ZERO_ARRAY_1(a, n) for (int i = 0; i < (n); i++) \
                               (a)[i]=0;
#define ZERO_ARRAY_2(a, n)       \
   for (int i = 0; i < (n); i++) \
       (a)[i]=0;
#define ZERO_ARRAY_3(a, n) for (int i = 0; i < (n); i++) \
   (a)[i]=0;
```

The following guideline recommendation leaves the decision on what constitutes *the same visual layout* to developers.

Rev 1931.5

Token sequences shall have the same visual layout in the replacement list of a macro definition as they do in other contexts.

Usage

Usage information on the number of macro names defined in source files is given elsewhere.

287 limit macro definitions

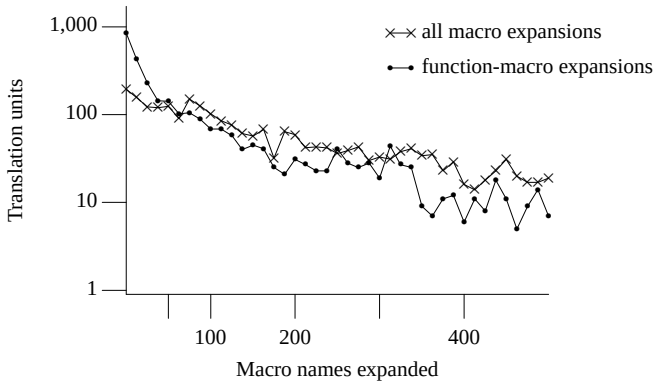

Figure 1931.1: Number of translation units containing a given number of macro names which were macro expanded, excluding expansions that occurred while processing the contents of system headers. Based on the translated form of this book's benchmark programs.

Table 1931.1: Detailed breakdown of the kinds of replacement lists occurring in macro definitions. Adapted from Ernst, Badros, and Notkin.[396]

Replacement List	%	Example
constant	42	`#define ARG_MAX 1000`
expression	33	`#define SHFT_UP(x) ((x) << 8)`
empty	6.9	`#define DUMMY`
unknown identifier	6.9	`#define INTERN_BUF buffer`
statement	5.1	`#define TERMINATE goto func_end`
type	2.1	`#define NODE_PTR void *`
other	1.9	`#define OPTION -X=23`
symbol	1.4	`#define ALLOC_STORAGE malloc`
syntactic	0.5	`#define begin {`

Table 1931.2: Common macro definitions listed with an abstracted form of their replacement list (as a percentage of all macro definitions). Note that *function-call* may also be a macro invocation. Based on the visible form of the `.c` and `.h` files.

Kind of Macro Defined and Abstract Form of its Replacement List	%
object-like macro *integer-constant*	50.7
object-like macro identifier	5.9
object-like macro expression	5.8
function-like macro function-call	4.7
object-like macro function-call	3.7
object-like macro *string-literal*	3.4
function-like macro expression	3.4
object-like macro	3.4
object-like macro *constant-expression*	2.0
function-like macro	1.7
others	15.4

The replacement list is then rescanned for more macro names as specified below. 1932

Commentary

This sentence was added by the response to DR #306 and removes the possibility of a reader interpreting the rescanning clause as only applying to function-like macros.

rescanning 1968
macro 1933
function-like

macro
function-like

A preprocessing directive of the form 1933

```
# define identifier lparen identifier-list_opt ) replacement-list new-line

# define identifier lparen ... ) replacement-list new-line
# define identifier lparen identifier-list , ... ) replacement-list new-line
```

defines a *function-like macro* with ~~arguments,~~ parameters, whose use is similar syntactically to a function call.

Commentary

This defines the term *function-like* macro. This term is commonly used by developers. Function-like macro definitions do not contain any type information. Replacement is based solely on matching preprocessing token spellings.

Limits on the number of parameters a function-like macro definition may contain are discussed elsewhere. [290] limit macro parameters

The wording was changed by the response to DR #307.

C90

Support for the `...` notation in function-like macro definitions is new in C99.

C++

Support for the `...` notation in function-like macro definitions is new in C99 and is not specified in the C++ Standard.

Common Implementations

`gcc` supported a form of `...` notation in its implementation of the C90 Standard.

Coding Guidelines

The guideline recommendations given in the C sentence for describing object-like macros are written in a general form, i.e., they also apply to function-like macro definitions. [1931] macro object-like

The visual appearance of a function-like macro's replacement list can be misleading in suggesting that an operation is performed on a parameter. For instance, in:

```
1  #define FUNC(x)  x * glob_1
2
3  extern int glob_1,
4             glob_2;
5
6  void f(void)
7  {
8  int loc = FUNC(2 + glob_2);
9  }
```

a reader looking at the replacement list for `FUNC` might believe that the macro expanded argument will be multiplied by `glob_1`. In fact the expanded token sequence has very different behavior, i.e., `2+glob_2*glob_1`.

A general solution is to use parenthesis to ensure that the actual behavior matches that expected from the visual appearance of the source.

Cg 1933.1

Any parameter of a function-like macro appearing as an operand in an expression shall be parenthesized, unless it is the operand of the # or ## operators.

macro parameter scope extends

The parameters are specified by the optional list of identifiers, whose scope extends from their declaration in the identifier list until the new-line character that terminates the **#define** preprocessing directive. 1934

Commentary

The visibility of the parameters also extends over the entire replacement list and is not affected by any identifiers declared within the replacement list (they are simply treated as a sequence of preprocessing tokens until later phases of translation). Scope is extensively discussed elsewhere.

scope 390 of identifiers

Usage

Usage information on the number of parameters in function-like macro definitions is given elsewhere.

limit 290 macro parameters

function-like macro followed by (

Each subsequent instance of the function-like macro name followed by a **(** as the next preprocessing token introduces the sequence of preprocessing tokens that is replaced by the replacement list in the definition (an invocation of the macro). 1935

Commentary

No formal syntax is specified for the sequence of preprocessing tokens that form an invocation of a function-like macro. However, in some contexts the sequence of preprocessing tokens in an invocation of a function-like macro may result in undefined behavior (e.g., preprocessing tokens having the form of a preprocessing), or the context in which the invocation occurs may have its own syntax (e.g., preprocessing directives are terminated by a new-line).

argument 1940 resemble preprocessing directive

preprocessing directive 1858 ended by

It is possible to suppress the expansion of a *function-like* macro by ensuring that it is not followed by a **(** preprocessing token (e.g., by enclosing the macro name in parenthesis):

```
#define FUNC(a) (a+1)

void f(void)
{
(FUNC)(3);     /* Final token sequence is (FUNC)(3) */
}
```

even if a **(** preprocessing token occurs in the sequence of preprocessing tokens at some point (DR #017q21):

```
#define L_PAREN (
#define F_M(a) a

char *p = F_M L_PAREN "abc" ); /* Expands to F_M("abc") not "abc" */
```

Coding Guidelines

Some implementations provide both function and macro definitions of some library functions. Developers wanting to ensure that the function's definitions are invoked parenthesize the name of the function to prevent it being treated as a function-like macro. An occurrence of an identifier currently defined as a function-like macro and not followed by a **(** preprocessing token could be a fault (in which case a translator diagnostic is likely to be generated because of a reference to an undeclared identifier), or the same identifier is used to define different entities (this issue is discussed elsewhere).

identifier 792 syntax

The replaced sequence of preprocessing tokens is terminated by the matching **)** preprocessing token, skipping intervening matched pairs of left and right parenthesis preprocessing tokens. 1936

Commentary

The syntax of function-like macros does not specify which right parentheses terminates an argument list. Hence the need for this wording. Skipping intervening matched pairs of left and right parentheses preprocessing tokens allows arbitrary expressions, which may containing parentheses, to be passed as arguments. Any preprocessing tokens between the matched parentheses are treated as belonging to the argument and not part of the syntax of the macro invocation. For instance:

```
#define EXPR(x, y) x * y

int glob = EXPR( (a - b), (c == d) );
```

The) preprocessing token is searched for in the source file without performing macro expansion (DR #017q21):

```
#define i(x) 3
#define a i(yz
#define b )

a b ) ;
/*
 * Expands via the following stages:

 i(yz b )  ) delimits the argument list before b is expanded
 i(yz ) )  the argument to i is the two preprocessing tokens yz )
 3
 */
```

1937 Within the sequence of preprocessing tokens making up an invocation of a function-like macro, new-line is considered a normal white-space character.

Commentary

This specification only applies outside of preprocessing directives. The intent is for function-like macro invocations to have the same flexibility in their visual layout as function calls.

1858 preprocessing directive ended by

Coding Guidelines

The issues associated with laying out source code are driven by its visible form, not its expanded form.

770 words white space between
940 expression visual layout
1348 declaration visual layout
1707 statement visual layout
1810 translation unit syntax

1938 The sequence of preprocessing tokens bounded by the outside-most matching parentheses forms the list of arguments for the function-like macro.

Commentary

This introduces the common usage term *arguments* to refer to these preprocessing token sequences. Limits on the number of arguments that may appear in an invocation of function-like macro are discussed elsewhere.

macro arguments
291 limit arguments in macro invocation

1939 The individual arguments within the list are separated by comma preprocessing tokens, but comma preprocessing tokens between matching inner parentheses do not separate arguments.

macro arguments separated by comma

Commentary

The syntax of function-like macros does not specify which commas delimit the arguments. Hence the need for this wording. Skipping commas occurring between matched parentheses preprocessing tokens allows function call, which may themselves contain arguments, to be passed as arguments.

Coding Guidelines

An argument whose evaluation causes a side effect can sometimes result in program behavior that is surprising to developers (because they failed to take account of the argument being evaluated more than once). For instance, in the following fragment:

```
#define M(a, b)  ((a)*(b) + (a))

int glob = M(i++, j);
```

the object `i` is incremented twice. There are a number of possible guideline recommendations that prevent these surprises occurring, these include recommending that:

- The evaluation of arguments to macros not have side effects. Such a recommendation would require that developers be aware of whether an identifier followed by a left parentheses results in a macro replacement or a function call. At some future time a function call may be replaced by a macro invocation, which could then require that existing code be changed to ensure that arguments did not cause side effects (this goes against the aim that adherence to guideline recommendations not require an amount of effort that is out of proportion to the changes made to existing source). Side effect related issues in other language constructs are discusses elsewhere.

guideline recommendation 0
adherence has a reasonable cost
controlling expression 1740
if statement

- The expansion of a macro not result in a sequence of tokens that evaluate any of its arguments more than once. Syntactically it is possible to create a replacement list that follows this recommendation. However, semantically temporary variables of the correct type need to be visible and invoking the same macro twice in the same full expression is likely to result in undefined behavior.

```
1  #define M(a, b)  (t1=(a), t2=(b), (t1)*(t2) + (t1))
2
3  int glob = M(i++, j) + M(k, l);
```

  When using `gcc` this problem can be solved by making use of two extensions, (1) the **`typeof`** operator and (2) using the **`({ })`** punctuators to create an expression from a sequence of declarations and statements. For instance:

```
1  #define min(X, Y)               \
2          ({                      \
3          typeof (X) __x = (X),   \
4                     __y = (Y);   \
5          (__x < __y) ? __x : __y; \
6          })
```

The costs associated with both of these possible recommendations would be incurred for all function-like macros, while a benefit would only be obtained for a few uses. It would seem that neither of them has sufficient cost/benefit to make a guideline recommendation worthwhile.

Both of the previous possible recommendations treated the macro definition and its invocation in isolation. Recommending that an argument causing a side effect not be passed to a macro whose corresponding parameter is evaluated more than once is equivalent to one recommending that programs not contain faults, an issue that is discussed elsewhere.

guidelines 0
not faults

Example

```
1  #define M(x, y) /* ... */
2
3  M( f(1, 2), g((x=y++, y)))
4  M( {a=1 ; b=2;} ) /* A semicolon is not a comma         */
5  M( <, [ )         /* Passes the arguments < and [       */
6  M( (,), (...) )   /* Passes the arguments (,) and (...) */
7
8  #define START_END(start, end) start c=3; end
9
10 START_END( {a=1 , b=2;} ) /* braces are not parentheses */
11
12 /*
13  * To pass a comma token as an argument it is
14  * necessary to write:
15  */
16
17 #define COMMA ,
18
19 M(a COMMA b, (a, b))
```

1940 If there are sequences of preprocessing tokens within the list of arguments that would otherwise act as preprocessing directives[147], the behavior is undefined.

argument resemble preprocessing directive

Commentary

In the following code fragment:

```
#define FUNC_MACRO(x) /* ... */

FUNC_MACRO(
#define M 44

#if VAL == 1
          3
#else
          4
#endif
          )
```

possible behaviors include:

- Treating the sequence of preprocessing tokens between the matches parentheses treated as its argument.
- Treating those sequences of preprocessing tokens that have the form of a preprocessing directive as such a directive, i.e., defining `M` an object-like macro and passing either `3` or `4` as the argument to `FUNC_MACRO`.
- Issuing a diagnostic and failing to translate the source file.

Preprocessing directives can occur within the list of arguments in automatically generated, or processed, code. For instance, an expression original written by a developer may be expanded or split over several lines (source is often emailed and some email programs have a lower limit on the number of characters on a line than the C Standard).

Suppose line number 123 of a source file contained

```
dgay(some_very_long_and_complicated_expression_that_I + will_not_provide_in_full_detail, but_you_can_well_imagine
```

a tool that converted C source into a form suitable for emailing might convert this to one of several forms:

- Splitting long lines is the simplest approach:

```
#line 123
dgay(some_very_long_and_complicated_expression_that_I
                + will_not_provide_in_full_detail,
                but_you_can_well_imagine__that_such_messy_things_ +
                can_easily_arise + in_scientific_computation);
```

  Using line splicing would not help because the method of counting line numbers is not altered by the presence of line splices. 118 line splicing 1986 line number

- Splitting long lines and adding **`#line`** directives so that any diagnostic messages can be related back to the original source might be more developer friendly:

```
#line 123
dgay(some_very_long_and_complicated_expression_that_I
#line 123
         + will_not_provide_in_full_detail,
#line 123
         but_you_can_well_imagine__that_such_messy_things_ +
#line 123
         can_easily_arise + in_scientific_computation);
```

However, if dgay is defined as a macro the behavior will be undefined.

Rationale A new proposal for C99 to allow the **#line** directive to appear within macro invocations was considered. The Committee decided to not allow any preprocessor directives to be recognized as such inside of macros.

predefined macros not #defined 2026

This C specification covers preprocessing directives, not preprocessing operators (such as **defined**, which is discussed elsewhere).

This footnote was added by the response to DR #250.

Common Implementations

As of version 3.3, gcc treats directives within arguments the same as if they had not occurred within macro arguments.

Coding Guidelines

Measurements and experience show that this usage is rare and consequently no guideline recommendations is discussed here.

If there is a **...** in the identifier-list in the macro definition, then the trailing arguments, including any separating comma preprocessing tokens, are merged to form a single item: the *variable arguments*. 1941

Commentary

This defines the term *variable arguments*. The same term is also used to refer to the arguments corresponding to the ellipsis notation in a function definition. It would be more exact for the specification to say "after the" rather than "in the".

macro replacement

The C preprocessor model of macro expansion is one of performing (potentially recursive) token substitution, not of interpreting sequences of commands (e.g., there is no method of iterating). This model has no existing framework for walking through a list of variable arguments, like statements in a function definition. Without completely rewriting the preprocessor specification there is little scope for anything other than solution adopted by the C Committee. Because all of the variable arguments are formed into a single item they be used in a context that treats them as a single sequence of preprocessing tokens.

C90

Support for **...** in function-like macro definitions is new in C99.

C++

Support for **...** in function-like macro definitions is new in C99 and is not specified in the C++ Standard.

Coding Guidelines

These guideline recommendations are driven by common developer behaviors in dealing with constructs. This construct is new in C99 and as yet no significant experience has been gained about how developers interact with it. The specification of behavior is sufficiently different from the use of ellipsis in function prototype definitions that drawing parallels, with the aim of framing an applicable guideline recommendation, does not look possible.

EXAMPLE 1984 variable macro arguments

The number of arguments so combined is such that, following merger, the number of arguments is one more than the number of parameters in the macro definition (excluding the **...**). 1942

Commentary

This argument specification differs from that for function definitions, in that for macros at least one argument is required to match the **...** notation. If it is possible that a single argument may be passed then the definition of the macro needs to include **...** as the only parameter in its definition.

```
1  #define ONE(...)
2  #define TWO(p1, ...)
```

The function-like macro ONE requires at least one argument and the macro TWO requires at least two arguments.

1943 146) Since, by macro-replacement time, all character constants and string literals are preprocessing tokens, not sequences possibly containing identifier-like subsequences (see 5.1.1.2, translation phases), they are never scanned for macro names or parameters.

footnote 146

Commentary

This issue is discussed in more detail elsewhere.

1951 # stringize operand

Other Languages

Some early implementations had preprocessors that were character based and scanned character constants and string literals for macro names to expand.

Example

```
#define X marks the spot

char *str = "Xmas"; /* Not expanded to "marks the spotmas". */
```

1944 147) Despite the name, a non-directive is a preprocessing directive.

footnote 147

Commentary

This footnote was added by the response to DR #250. In the following example `#nonstandard` has the status of a preprocessing directive and the behavior is undefined:

```
#define nothing(x)

nothing (
#nonstandard
)
```

6.10.3.1 Argument substitution

1945 After the arguments for the invocation of a function-like macro have been identified, argument substitution takes place.

argument substitution

Commentary

The term *argument substitution* is also commonly used by developers to refer to this process.

How a sequence of preprocessing tokens within a source file are split into the arguments that belong to a particular function-like macro invocation is discussed elsewhere.

1939 macro arguments separated by comma

Coding Guidelines

Experience suggests that many developers do not have accurate knowledge of the sequence of operations that occur during argument substitution. In many cases this lack of knowledge is not significant because the final result is as expected. In more subtle cases the results may be surprising. However, your author is not aware of any pattern to these developer misconceptions and so is unable to word any guideline recommendation. Given that there are few cases where a detailed knowledge of the sequence of operations is needed education may not help (i.e., without practice developers are unlikely to remember what they learned some time ago). Developer uncertainty about the sequence of events may lead them to select the most likely behavior from among a range of possibilities they consider to be plausible in the given context. There are no obvious guideline recommendations covering this pattern of usage.

1939 macro arguments separated by comma

parameter argument macro expanded

A parameter in the replacement list, unless preceded by a # or ## preprocessing token or followed by a ## preprocessing token (see below), is replaced by the corresponding argument after all macros contained therein have been expanded. 1946

Commentary

That is, parameters occurring in the replacement list are replaced after their corresponding arguments have been macro expanded. The # and ## operator contexts are the only situations where any macros appearing in a parameter's corresponding argument are not considered for replacement. In the following the expanded form of PARAM is not examined for preprocessing tokens that have the same spelling as a parameter of F.

```
1  #define PARAM param
2  #define F(param) param + PARAM
3
4  int glob = F(1); /* Expands to 1+param, rather than 1+1 */
```

Before being substituted, each argument's preprocessing tokens are completely macro replaced as if they formed the rest of the preprocessing file; 1947

Commentary

Each argument is expanded in isolation (i.e., there is no interaction between arguments or any other preprocessing tokens in the source file).

Example

In the following the argument in the invocation of FM2 is expanded to the two tokens {FM1} and {(}.

```
1  #define L_PAREN (
2  #define FM1(a) a
3  #define FM2(b) b 23)
4
5  void f1(void)
6  {
7  FM2(FM1 L_PAREN);
8  }
```

Completely expanding the argument requires that FM1 then be expanded (it is followed by an opening parentheses). However, this expansion does not succeed because there is no matching closing parentheses, in the sequence of preprocessing tokens for that argument. The behavior is undefined. Continuing on from the above source:

```
1  void f2(void)
2  {
3  FM2(FM1(L_PAREN));
4  }
```

FM2 expands to (23). The following definition achieves what may have been intended:

```
1  #define FM3(c, d) c d 23)
2
3  void f3(void)
4  {
5  FM3(FM1, L_PAREN);
6  }
```

the invocation of FM3 expands to 23 (the argument FM1 is not expanded further, as an argument, because it is not followed by an opening parentheses).

1948 no other preprocessing tokens are available.

Commentary

In particular any subsequent preprocessing tokens from the source file, or any preprocessing tokens following the parameter in the replacement list.

1949 An identifier **__VA_ARGS__** that occurs in the replacement list shall be treated as if it were a parameter, and the variable arguments shall form the preprocessing tokens used to replace it.

Commentary

This is a requirement on the implementation.

This is replaced by all the arguments that match the ellipsis, including the commas between them. Rationale

The extent to which the arguments corresponding to the parameter **__VA_ARGS__** are replaced may be affected by the presence of commas. For instance, in:

```
#define LPAREN (
#define RPAREN )
#define F(x, y) x + y
#define ELLIP_FUNC(...) __VA_ARGS__

ELLIP_FUNC(F, LPAREN, 'a', 'b', RPAREN); /* 1st invocation */
ELLIP_FUNC(F  LPAREN  'a', 'b'  RPAREN); /* 2nd invocation */
```

the argument in the second invocation of `ELLIP_FUNC` expands to `F('a', 'b')` which in turn expands to `'a'+'b'`. This expansion sequence does not occur in the first invocation because of the comma separating `F` from `(` (and other preprocessing tokens).

C90

Support for **__VA_ARGS__** is new in C99.

C++

Support for **__VA_ARGS__** is new in C99 and is not specified in the C++ Standard.

6.10.3.2 The # operator

Constraints

1950 Each # preprocessing token in the replacement list for a function-like macro shall be followed by a parameter as the next preprocessing token in the replacement list. # operator

Commentary

Within a replacement list the **#** preprocessing token is a unary operator. It is commonly called the *stringize* operator.

This operator is intended to be applied to the unexpanded form of the corresponding argument. Other preprocessing tokens in the replacement list can be *stringized* by simply delimiting them in double-quotes. Occurrences of a **#** preprocessing token that are not followed by a parameter are probable unintended and this constraint requirement ensures that translators will issue a diagnostic.

Usage

Based on the visible form of the `.c` files 0.26% (0.09% `.h` files) of the replacement lists of macro definitions contained a **#** operator. There were no obvious patterns to the usage.

Semantics

stringize operand

If, in the replacement list, a parameter is immediately preceded by a # preprocessing token, both are replaced by a single character string literal preprocessing token that contains the spelling of the preprocessing token sequence for the corresponding argument. 1951

Commentary

Rationale

Some pre-C89 implementations decided to replace identifiers found within a string literal if they matched a macro argument name. The replacement text is a "stringized" form of the actual argument token sequence. This practice appears to be contrary to K&R's definition of preprocessing in terms of token sequences. The C89 Committee declined to elaborate the syntax of string literals to the point where this practice could be condoned; however, since the facility provided by this mechanism seems to be widely used, the C89 Committee introduced a more tractable mechanism of comparable power.

In the following example:

```
#define HASH #

#define M(a) HASH a /* Expands to # a */
```

the # preprocessing token exists in the expanded replacement list, rather than the replacement list and is considered to be a punctuator rather than an operator.

Common Implementations

Microsoft C supports the preprocessor operator `#@` (call the *charizing* operator) as an extension. It converts its operand to a character constant.

Example

```
#define mkstr(a) # a

char *p_1 = mkstr("mnp\a");    /* Assigns "\"mnp\\a\"" */
char *p_2 = mkstr(000);        /* Assigns "000"        */
char *p_3 = mkstr(0);          /* Assigns "0"          */
char *p_4 = mkstr(0004);       /* Assigns "0004"       */
char *p_5 = mkstr(0.001E+000); /* Assigns "0.001E+000" */
char *p_6 = mkstr(x\
yz);                           /* No new-line in created string, i.e., "xyz" */
char *p_7 = mkstr(0
K);                            /* Assigns "0 K" */
```

white space between macro argument tokens

Each occurrence of white space between the argument's preprocessing tokens becomes a single space character in the character string literal. 1952

Commentary

white-space 128 sequence replaced by one

Whether multiple white space between preprocessing tokens has already been converted to a single white space before this conversion is discussed elsewhere. Also there is no white space added where none existed in the source file.

Rationale

One problem with defining the effect of stringizing is the treatment of white space occurring in macro definitions. Where this could be discarded in the past, now upwards of one logical line may have to be retained. As a compromise between token-based and character-based preprocessing disciplines, the C89 Committee decided to permit white space to be retained as one bit of information: none or one. Arbitrary white space is replaced in the string by one space character.

Coding Guidelines

Any misconceptions about the white space will appear between preprocessing tokens that have been stringized is a developer education issue, not a coding guideline issue.

Example

The following assigns the string literal "x y \\a+ 1" to p.

```
#define mkstr(a) # a

char *p = mkstr(x y   \a+
                          1);
```

Your author cannot think of a way to generate multiple, adjacent, space characters in a stringized sequence of preprocessing tokens.

1953 White space before the first preprocessing token and after the last preprocessing token composing the argument is deleted.

Commentary

This specification mirrors the one given for the replacement list and it is given for the same reasons.

1929 white-space before/after replacement list

1954 Otherwise, the original spelling of each preprocessing token in the argument is retained in the character string literal, except for special handling for producing the spelling of string literals and character constants: a \ character is inserted before each " and \ character of a character constant or string literal (including the delimiting " characters), except that it is implementation-defined whether a \ character is inserted before the \ character beginning a universal character name.

escape sequence handling

Commentary

This specification is intended to ensure that the output produced by passing the string produced by the stringize operator as an argument to `printf`, for instance, is the same as the visible form (with white-space characters reduced to a single space character) of the preprocessing token sequence immediately prior to being stringized (although this sequence may not exist in the visible source). In the following example:

```
#define mkstr(s) #s

char *at = mkstr(\u0040);
```

if UCNs are mapped in translation phase 1 and @ is a supported character then the invocation of `mkstr` expands to "@". Otherwise the conversion occurs in translation phase 5 and the invocation expands to "\\u0040".

116 translation phase 1
133 translation phase 5

C90

Support for universal character names is new in C99.

C++

Support for universal character names is available in C++. However, wording for this clause of the C++ Standard was copied from C90, which did not support universal character names. The behavior of a C++ translator can be viewed as being equivalent to another C99 translator, in this regard. A C++ translator is not required to document its handling of a \ character before a universal character name.

Example

The # operator provides a mechanism for producing defined behavior from what appears to be a sequence of preprocessing tokens having no guaranteed interpretation within the C Standard.

776 character ' or " matches

```
#define mkstr(x) #x

char *p = mkstr(');  /* A single quote might, subject to undefined behavior, be given a meaning. */
```

If the replacement that results is not a valid character string literal, the behavior is undefined. 1955

Commentary

string literal 895 syntax

For instance, syntactically, occurrences of the backslash character in string literals are limited to escape sequences. In the following example:

```
#define mkstr(x) # x

char *p = mkstr(a \ b); /* "a \ b" violates the syntax of string literals */
```

the result of the # operator need not be `"a \ b"`.

Common Implementations

translation phase 133 5

Most implementations simply create a sequence of characters. However, processing in subsequent phases of translation (e.g., conversion of escape sequences) may also result in undefined behavior.

The character string literal corresponding to an empty argument is `""`. 1956

Commentary

This specification is more consistent than the stringize operator not returning any preprocessing token for this case.

C90

An occurrence of an empty argument in C90 caused undefined behavior.

C++

Like C90, the behavior in C++ is not explicitly defined (some implementations e.g., Microsoft C++, do not support empty arguments).

and ## evaluation order

The order of evaluation of # and ## operators is unspecified. 1957

Commentary

The C committee chose not to specify the relative precedence of these operators. In:

```
#define STR_GLUE(a, b) # a ## b

char *p = STR_GLUE(1, 2);
```

if `{1}` is glued to `{2}` and then stringised the resulting preprocessing token is defined. However, stringizing `{1}` and then attempting to glue it to `{2}` does not yield a defined preprocessing token (the behavior is undefined).

When both operators occur in a replacement list, performing token gluing first would appear to give the highest probability of having a defined result, when a stringize operator is also present. However, there is no requirement that implementations use this order. There is no need to specify an evaluation order for the # operator because it is unary (the evaluation order or the ## operator is discussed elsewhere).

1965 evaluation order

Coding Guidelines

full expression 1712

An order dependency on the evaluation of the # and ## operators only exists when either of them could be applied to the same preprocessing token in a replacement list. Unlike full expression evaluation it is not possible to use parentheses to group operands with preprocessor operators. These operators have to be adjacent to the preprocessing tokens they operate on. However, this combination of events rarely occurs (there are no occurrences in the `.c` files) and thus a guideline recommendation is not considered worthwhile.

Example

It is possible to specify an ordering by breaking the operations out into separate macro definitions.

```
#define MK_STR(a) #a
#define GLUE(a, b) a ## b

char *p_1 = MK_STR(GLUE(1, 2));

#define STR_GLUE(a, b) MK_STR(a ## b)

char *p_2 = STR_GLUE(1, 2);
```

6.10.3.3 The ## operator

Constraints

1958 A ## preprocessing token shall not occur at the beginning or at the end of a replacement list for either form of macro definition. ## operator

Commentary

The ## preprocessing token is a binary operator, requiring two operands. This operator is often called the *token gluing*, *glue*, or *token pasting* operator. Unlike the # operator, there is no requirement that the ## operator only be applied to preprocessing tokens that are parameters.

Common Implementations

gcc supports an additional use for the ## preprocessing operator. If a macro parameter accepting a variable number of arguments is passed no arguments and a ## appears before its use in the replacement list, the preceding comma punctuator is removed from the expanded replacement list. For instance, in:

```
#define eprintf(format, args...)         \
      fprintf (stderr, format , ## args)

/* The invocation */

eprintf("failure!\n");

/* is expanded to:
 *
 *    fprintf(stderr, "failure!\n");
 *
 * rather than to:
 *
 *    fprintf(stderr, "failure!\n" , );
 */
```

The Plan 9 C compiler intentionally lacks support for the ## operator.[1087]

Example

Readers might like to work out which of the following two assignments to max relies on undefined behavior and which is strictly conforming.

file_1.c

```
#define __CONCAT__(_A, _B) _A ## _B
#define __CONCAT_U__(_A) _A ## u
#define ULONG32_C(__c)  __CONCAT__(__CONCAT_U__(__c), l)
#define ULONG32_MAX   ULONG32_C(4294967295)

unsigned long max = ULONG32_MAX;
```

file_2.c
```
#define __XXCONCAT__(_A, _B) _A ## _B
#define __CONCAT__(_A, _B) __XXCONCAT__(_A, _B)
#define __XCONCAT_U__(_A) _A ## u
#define __CONCAT_U__(_A) __XCONCAT_U__(_A)
#define ULONG32_C(__c)  __CONCAT__(__CONCAT_U__(__c), l)
#define ULONG32_MAX   ULONG32_C(4294967295)

unsigned long max = ULONG32_MAX;
```

Table 1958.1: Occurrence of the ## preprocessor operator (as a percentage of all occurrences of that operator). The form , ## identifier is a gcc extension (described in the Common implementations subclause). Based on the visible form of the .c and .h files.

Preprocessing Token Sequence	%
identifier ## identifier	70.2
, ## identifier	24.2
identifier ## identifier ## identifier	15.7
others	4.8
integer-constant ## identifier	1.8
integer-constant ## identifier ## *integer-constant*	1.0
identifier ## *integer-constant*	1.0

Semantics

If, in the replacement list of a function-like macro, a parameter is immediately preceded or followed by a ## preprocessing token, the parameter is replaced by the corresponding argument's preprocessing token sequence; 1959

Commentary

parameter 1946
argument macro expanded

In this case the argument will not have been macro expanded before this replacement occurs (so if it consists of more than one preprocessing token only the first, and/or the last, are operated on).

Rationale

Another facility relied on in much current practice but not specified in K&R is "token pasting," or building a new token by macro argument substitution. One pre-C89 implementation replaced a comment within a macro expansion by no characters instead of the single space called for in K&R . The C89 Committee considered this practice unacceptable.

As with "stringizing," the facility was considered desirable, but not the extant implementation of this facility, so the C89 Committee invented another preprocessing operator. The ## operator within a macro expansion causes concatenation of the tokens on either side of it into a new composite token.

The specification of this pasting operator is based on these principles:

- Paste operations are explicit in the source.
- The ## operator is associative.
- A formal parameter as an operand for ## is not expanded before pasting. The actual parameter is substituted for the formal parameter; but the actual parameter is not replaced. Given, for example

  ```
  #define a(n) aaa ## n
  #define b    2
  ```

  the expansion of a(b) is aaab, not aaa2 or aaan.
- A normal operand for ## is not expanded before pasting.

- Pasting does not cross macro replacement boundaries.
- The token resulting from a paste operation is subject to further macro expansion.

These principles codify the essential features of prior art and are consistent with the specification of the stringizing operator.

Example

```
#define GLUE(a, b) a ## b

double d = GLUE(3.4e, -3); /* surprise! -3 is two preprocessing tokens */
```

1960 however, if an argument consists of no preprocessing tokens, the parameter is replaced by a *placemarker* preprocessing token instead.[148)]

argument no tokens replaced by placemarker token

Commentary

This defines the term *placemarker*. The standard uses placemarker preprocessing tokens to describe an effect, an implementation need not represent them internally. The need for a placemarker preprocessing token occurs because the **##** operator does not cross replacement boundaries.

C90

The explicitly using the concept of a placemarker preprocessing token is new in C99.

C++

The explicit concept of a placemarker preprocessing token is new in C99 and is not described in C++.

Coding Guidelines

In C90, an argument that consisted of no preprocessing tokens resulted in undefined behavior. The extent to which developers made use of such arguments and the behavior they expected from such usage is not known. Whether the definition of a behavior, in C99, and the introduction of the placemarker concept is something that developers need to be made aware of is not known.

1961 For both object-like and function-like macro invocations, before the replacement list is reexamined for more macro names to replace, each instance of a ## preprocessing token in the replacement list (not from an argument) is deleted and the preceding preprocessing token is concatenated with the following preprocessing token.

Commentary

The preprocessing token **##** is only recognized as an operator when it appears in the replacement list of the macro definition. When it appears anywhere else it is a punctuator.

1966 EXAMPLE # ## #
1980 EXAMPLE reexamination
1981 EXAMPLE # and ##

Table 1961.1: Possible results of concatenating, using the **##** operator, pairs of preprocessing tokens (the one appearing in the left column followed by the one appearing in the top row) where the result might be defined (*undefined* denotes undefined behavior).

	identifier	*pp-number*	*punctuator*	*string-literal*	*character-constant*
identifier	identifier	identifier or undefined	undefined	string-literal or undefined	character-constant or undefined
pp-number	pp-number	pp-number	pp-number or undefined	undefined	undefined
punctuator	pp-number or undefined	pp-number or undefined	punctuator or undefined	undefined	undefined
everything else	undefined	undefined	undefined	undefined	undefined

placemarker preprocessor

Placemarker preprocessing tokens are handled specially: concatenation of two placemarkers results in a single placemarker preprocessing token, and concatenation of a placemarker with a non-placemarker preprocessing token results in the non-placemarker preprocessing token. 1962

Commentary

EXAMPLE 1982 placemarker

This specification handles the special case of an argument containing no preprocessing tokens.

C90

The concept of placemarker preprocessing tokens is new in the C99 Standard. The behavior of concatenating an empty argument with preprocessing token was not explicitly defined in C90, it was undefined behavior.

C++

Like C90, the behavior of concatenating an empty argument with preprocessing token is not explicitly defined in C++, it is undefined behavior.

Example

N418.c

```
#define PI 3.1416
#define  F f
#define  D     /* Expands into no preprocessing tokens. */
#define LD L
#define  glue(a, b) a ## b
#define xglue(a, b) glue(a, b)

/*
 * The following:
 */
float        f = xglue(PI, F);
double       d = xglue(PI, D);
long double ld = xglue(PI, LD);
/*
 * should expand into:
 */
float        f = 3.1416f;
double       d = 3.1416;
long double ld = 3.1416L;
```

if result not valid

If the result is not a valid preprocessing token, the behavior is undefined. 1963

Commentary

translation phase 136, preprocessing token 7 771 shall have lexical form

While behavior in later phases is also likely to be undefined (e.g., when the preprocessing token is converted to a token) and a constraint violation, this specification applies during preprocessing and removes the need to define the behavior of any subsequent operations involving the result.

Common Implementations

Many implementations allow invalid preprocessing tokens to be created and to subsequently be operands of the ## operator. This behavior enables the creation of preprocessing tokens that need to be built out of three separate preprocessing tokens, where the result of concatenating any two of them is not a valid preprocessing token.

Coding Guidelines

This situation is not sufficiently commonly for a guideline recommendation to be worthwhile.

Example

```
#define GLUE(a, b, c) a ## b ## c

extern void f(int p, GLUE(. , . , .));

#include GLUE(< , header, >)
```

1964 The resulting token is available for further macro replacement.

Commentary

However, it is not available for use as a preprocessing operator. The result of concatenating two preprocessing tokens is not treated any differently than other preprocessing tokens. 1966 EXAMPLE # ### #

1965 The order of evaluation of ## operators is unspecified. ## evaluation order

Commentary

If all intermediate results are defined for all orders of evaluation, the final result will always be the same. However, in some cases the result is not defined for some orders of evaluation.

Coding Guidelines

It is not possible to use parentheses to define an order of evaluation (the operators have to be adjacent to the preprocessing tokens that they operate on). The only solution is to break the replacement list up into separate macro definitions, each performing a single operation.

Example

```
#define GLUE_3(x, y, z) x ## y ## z

GLUE_3(>, >, =)    /* Behavior defined for all orders of evaluation.         */
GLUE_3(1, . , e10) /* Behavior only defined if left most ## performed first. */
/* There are no cases where the behavior is only defined if right most ## performed first. */
```

1966 EXAMPLE In the following fragment: EXAMPLE # ## #

```
#define hash_hash # ## #
#define mkstr(a) # a
#define in_between(a) mkstr(a)
#define join(c, d) in_between(c hash_hash d)

char p[] = join(x, y); // equivalent to
                       // char p[] = "x ## y"
```

The expansion produces, at various stages:

```
join(x, y)

in_between(x hash_hash y)

in_between(x ## y)

mkstr(x ## y)

"x ## y"
```

In other words, expanding **hash_hash** produces a new token, consisting of two adjacent sharp signs, but this new token is not the ## operator.

Commentary

This example was created by the response to DR #017q22.

C++

This example is the response to a DR against C90. While there has been no such DR in C++, it is to be expected that WG21 would provide the same response.

---

footnote 148

148) Placemarker preprocessing tokens do not appear in the syntax because they are temporary entities that exist only within translation phase 4. 1967

Commentary

function-like macro followed by (1935

The standard does not specify any formal syntax for function-like macro invocations, let alone placemarker preprocessing tokens.

C90

Support for the concept of placemarker preprocessing tokens is new in C99.

C++

Support for the concept of placemarker preprocessing tokens is new in C99 and they are not described in the C++ Standard.

6.10.3.4 Rescanning and further replacement

---

rescanning

After all parameters in the replacement list have been substituted and # and ## processing has taken place, all placemarker preprocessing tokens are removed. 1968

Commentary

The concept of placemarkers is only needed during the processing of the **##** operator.

C90

Support for the concept of placemarker preprocessing tokens is new in C99.

C++

Support for the concept of placemarker preprocessing tokens is new in C99 and does not exist in C++.

---

rescanned along with subsequent tokens

Then, the resulting preprocessing token sequence is rescanned, along with all subsequent preprocessing tokens of the source file, for more macro names to replace. 1969

Commentary

Unlike argument substitution, and **#** and **##** operator processing, the replacement list is not processed in isolation from the rest of the source code. For instance, in:

```
#define M1(a) (a+1)
#define M2(b) b

int ei_1 = M2(M1)(17);   /* becomes int ei_1 = (17+1);   */
int ei_2 = (M2(M1))(17); /* becomes int ei_2 = (M1)(17); */
```

after the invocation of `M2` is expanded, the resulting sequence is `M1`. The rest of the source code is `(17);`. Rescanning including this sequence of preprocessing tokens, in the assignment to `ei_1`, results in an invocation of the macro `M1`.

Rationale

The rescanning rules incorporate an ambiguity. Given the definitions

```
#define  f(a)  a*g
#define  g     f
```

it is clear (or at least unambiguous) that the expansion of `f(2)(9)` is `2*f(9)`, the `f` in the result being introduced during the expansion of the original `f`, and so is not further expanded.

However, given the definitions

```
#define f(a)  a*g
#define g(a)  f(a)
```

the expansion will to be either `2*f(9)` or `2*9*g`: there are no clear grounds for making a decision whether the `f(9)` token string resulting from the initial expansion of `f` and the examination of the rest of the source file should be considered as nested within the expansion of `f` or not. The C89 Committee intentionally left this behavior ambiguous as it saw no useful purpose in specifying all the quirks of preprocessing for such questionably useful constructs.

Coding Guidelines

There are situations where it is intended that a replacement list include preprocessing tokens from the rest of the source file. For instance, if the name of a function needs to be unconditionally mapped to another name an object-like macro needs to be used. However, after expansion the mapped name might invoke a function-like macro:

```
1  #define isprint __PRINT_PROPERTY
2  #define __PRINT_PROPERTY(x) (((x < 0) || (x > 127)) ? 0 : __IS_PRINT[x])
3  int (__PRINT_PROPERTY)(int);
4
5  void f(void)
6  {
7  _Bool a_printable = isprint('a');
8  }
```

1970 If the name of the macro being replaced is found during this scan of the replacement list (not including the rest of the source file's preprocessing tokens), it is not replaced.

macro being replaced found during rescan

Commentary

A problem faced by many pre-C89 preprocessors is how to use a macro name in its expansion without suffering "recursive death." The C89 Committee agreed simply to turn off the definition of a macro for the duration of the expansion of that macro. Rationale

Coding Guidelines

Whether or not a macro expansion that depends on this recursion-breaking rule requires significantly greater effort to comprehend than other macro expansions, involving similar numbers of preprocessing tokens but no recursion breaking, is not known. Neither is it known whether an alternative set of macros, that did not depend on recursion breaking, would require less effort. Without this information it is not possible to estimate the cost/benefit of any guideline recommendations and none are made here.

Example

```
1  extern int M_1,
2             M_2;
```

```
3
4   #define M_1 M_2
5   #define M_2 M_1
6
7   void f(void)
8   {
9   M_1 = M_2; /* Macros do not alter the behavior, i.e., M_2 is still assigned to M_1 */
10  }
```

```
1   #define short static short
2
3   short si; /* Expands to static short si; */
```

EXAMPLE 1980 reexamination Also see elsewhere for examples.

Furthermore, if any nested replacements encounter the name of the macro being replaced, it is not replaced. 1971

Commentary

Indirect recursion, via other macro definitions, is treated the same as direct recursion.

Coding Guidelines

The reasoning here is the same as for the case of direct recursion.

Example

```
1   static int M_0 = 0;
2
3   #define M_0(x)     M_ ## x
4   #define M_1(x) x + M_0(0)
5   #define M_2(x) x + M_1(1)
6   #define M_3(x) x + M_2(2)
7   #define M_4(x) x + M_3(3)
8   #define M_5(x) x + M_4(4)
9
10  int f_1(void)
11  {
12  return M_0(1)(2)(3)(4)(5); /* Expands to:
13                                          2 + M_0(3)(4)(5)
14                                              or
15                                          2 + M_0(0)(3)(4)(5) */
16  }
17
18  int f_2(void)
19  {
20  return M_0(5)(4)(3)(2)(1); /* Expands to: 4 + 4 + 3 + 2 + 1 + M_0(3)(2)(1) */
21  }
```

These nonreplaced macro name preprocessing tokens are no longer available for further replacement even if they are later (re)examined in contexts in which that macro name preprocessing token would otherwise have been replaced. 1972

Commentary

The C preprocessor model is one where the incoming preprocessing tokens are processed and then output. It is not intended that the preprocessor have to hold on to all preprocessing tokens it has processed, until the end of the source file is reached.

```
#define F(a) a
#define FUNC(a) (a+1)

void f(void)
{
/*
 * The preprocessor works successively through the input without
 * backing up through previous processed preprocessing tokens.
 */
F(FUNC) FUNC (3); /* final token sequence is FUNC(3+1) */
}
```

This rule allows implementations to mark preprocessing tokens with a single bit (this bit is often referred to using the term *blue paint*, after the marking ink used by engineers, by members of the C committee), indicating that they are no longer available for replacement.

Example

```
#define A   A B C
#define B   B C A
#define C   C A B

A
/*
 * Using the notation:
 *    X={ }       the result of expanding X.
 *    lowercase   an identifier that has been 'painted blue'.
 * 'simplify'
   expand    A={ A B C }
   paint     A={ a B C }
   rescan    A={ a B={ B C A } C }
   paint     A={ a B={ b C a } C }
   rescan    A={ a B={ b C={ C A B } a } C }
   paint     A={ a B={ b C={ c a b } a } C }
             A={ a B={ b c a b a } C }
             A={ a b c a b a C }
   rescan    A={ a b c a b a C={ C A B }}
   paint     A={ a b c a b a C={ c a B }}
   rescan    A={ a b c a b a C={ c a B={ B C A }}}
   paint     A={ a b c a b a C={ c a B={ b c a }}}
             A={ a b c a b a C={ c a b c a }}
             A={ a b c a b a c a b c a }

   simplify  a b c a b a c a b c a

 * Final tokens output:

   A B C A B A C A B C A
 */
```

1973 The resulting completely macro-replaced preprocessing token sequence is not processed as a preprocessing directive even if it resembles one, but all pragma unary operator expressions within it are then processed as specified in 6.10.9 below.

expanded token sequence not treated as a directive

Commentary

As described elsewhere, a preprocessing directive is a particular sequence of preprocessing tokens at the start of translation phase 4. Macro-replaced preprocessing tokens don't exist until after the start of translation

1855 preprocessing directive consists of

argument 1940 resemble preprocessing directive
_Pragma 2030 operator

phase 4. The issue of arguments that resemble preprocessing directives is discussed elsewhere. The **_Pragma** unary operator is discussed elsewhere.

C90

Support for **_Pragma** unary operator expressions is new in C99.

C++

Support for **_Pragma** unary operator expressions is new in C99 and is not available in C++.

Example

```
#define H #
#define D define

#define DEFINE(a, b) H D a b

DEFINE(X, 3)
```

the invocation results in the sequence of preprocessing tokens:

{#} {define} {X} {3}

which are not treated as a preprocessing directive.

6.10.3.5 Scope of macro definitions

---

macro definition lasts until

A macro definition lasts (independent of block structure) until a corresponding **#undef** directive is encountered or (if none is encountered) until the end of the preprocessing translation unit. 1974

Commentary

There is no requirement that macros with the same names in different translation units have the same replacement lists, or both be object-like or function-like (neither linkage or scope apply to macro names).

linkage 420 scope 390 of identifiers

Common Implementations

Very few implementations write information on macro definitions out to the generated object file. Although some static analysis tools save this information for later cross translation unit consistency checking.

Coding Guidelines

The issue of having the definition of macro names exist over some kind of restricted scope is discussed elsewhere.

macro definition 408 emulate block scope

---

macro definition no significance after

Macro definitions have no significance after translation phase 4. 1975

Commentary

All preprocessing directives are deleted at the end of translation phase 4.

preprocessing directives 132 deleted

C90

This observation is new in C99.

C++

This observation is not made in the C++ document.

#undef

A preprocessing directive of the form 1976

```
# undef identifier new-line
```

causes the specified identifier no longer to be defined as a macro name.

Commentary

The relatively high percentage of macro definitions that do not include a replacement list (see Table 1931.1) shows the degree to which the status of being defined as a macro name is sufficient information for developer use. The **#undef** directive provides additional control over which identifiers are defined as macro names.

The standard specifies a few identifiers that cannot be **#undef**ed.

2026 predefined macros not #defined

Common Implementations

Some translators support a `-U` translator option that can be used to override any predefined macros (either defined using the `-D` option or internally generated by the translator). Some prestandard translators handled **#define**/**#undef** in a stack-like fashion.

1919 #define/#undef stack

Coding Guidelines

Discussion of the **#undef** directive, in guideline documents or between developers, is relatively rare. Whether this is because use of this directive rare, or simply innocuous is not known.

Usage

Approximate 5% of all **#undef** directives occur before a **#include** directive (based on the visible form of the `.c` files).

Table 1976.1: Occurrence of various sequences of preprocessing directives (as a percentage of all such sequences) that follow a **#undef** and reference the same identifier (e.g., 2.7% of the first occurrence of **#undef** are followed by one or more **#define**s followed by one or more **#undef**s). **#define** represents one or more **#define** preprocessing directives. **#undef** represents one or more **#undef** preprocessing directives. **#if[n]def** represents two or more **#if**s and **#ifndef**s, in any order. **#und-def** represents one or more pairs of **#undef** **#define** preprocessing directives. Based on the visible form of the `.c` files.

Following Directive Sequences	%
	53.0
#ifdef	20.4
#define	16.2
others	4.8
#define #undef	2.7
#if(n)def	1.5
#define #undef-#define **#undef**	1.4

1977 It is ignored if the specified identifier is not currently defined as a macro name.

Commentary

This behavior simplifies the process of using **#undef** by removing the need to check the status of the identifier (e.g., by using **#ifdef**) before evaluating the directive.

Coding Guidelines

The issue of redundant code is discussed elsewhere. Whether or not a **#undef** is redundant, or simply providing a fail safe backup is outside the scope of these guidelines.

190 redundant code

1978 EXAMPLE 1 The simplest use of this facility is to define a “manifest constant”, as in

```
#define TABSIZE 100
int table[TABSIZE];
```

Commentary

Defining an object-like macro to have an integer constant replacement list is one of the most commonly given examples of the use of the preprocessor.

EXAMPLE macro argument side effects

EXAMPLE 2 The following defines a function-like macro whose value is the maximum of its arguments. It has the advantages of working for any compatible types of the arguments and of generating in-line code without the overhead of function calling. It has the disadvantages of evaluating one or the other of its arguments a second time (including side effects) and generating more code than a function if invoked several times. Also it cannot have its address taken, as it has none. 1979

```
#define max(a, b) ((a) > (b) ? (a) : (b))
```

The parentheses ensure that the arguments and the resulting expression are bound properly.

Commentary

macro 1939 arguments separated by comma

The issue of side effects in the evaluation of macro arguments is discussed elsewhere.

EXAMPLE reexamination

EXAMPLE 3 To illustrate the rules for redefinition and reexamination, the sequence 1980

```
#define x      3
#define f(a)   f(x * (a))
#undef  x
#define x      2
#define g      f
#define z      z[0]
#define h      g(~
#define m(a)   a(w)
#define w      0,1
#define t(a)   a
#define p()    int
#define q(x)   x
#define r(x,y) x ## y
#define str(x) # x

f(y+1) + f(f(z)) % t(t(g)(0) + t)(1);
g(x+(3,4)-w) | h 5) & m
       (f)^m(m);
p() i[q()] = { q(1), r(2,3), r(4,), r(,5), r(,) };
char c[2][6] = { str(hello), str() };
```

results in

```
f(2 * (y+1)) + f(2 * (f(2 * (z[0])))) % f(2 * (0)) + t(1);
f(2 * (2+(3,4)-0,1)) | f(2 * (~ 5)) & f(2 * (0,1))^m(0,1);
int i[] = { 1, 23, 4, 5,  };
char c[2][6] = { "hello" "" };
```

Commentary

Analyzing a part of the example, we get:

```
1  #define f(a)   f(x * (a))
2  #define x      2
3  #define z      z[0]
4
5  f(f(z));
```

the sequence of expansions are (preprocessing tokens bracketed by {} are no longer available for further replacement):

```
1  f(f(z))
```

replacing the argument z:

```
1  f(f({z}[]))
```

substituting and expanding the nested function-like macro:

```
f({f}(2 * ({z}[0])))
```

the argument has been fully expanded and can now be substituted into the replacement list:

```
f(2 * ({f}(2 * ({z}[0]))))
```

and expanding the replacement list we get:

```
{f}(2 * ({f}(2 * ({z}[0]))))
```

so the final sequence of preprocessing tokens is:

```
f(2 * (f(2 * (z[0]))))
```

1981 EXAMPLE 4 To illustrate the rules for creating character string literals and concatenating tokens, the sequence EXAMPLE # and ##

```
#define str(s)      # s
#define xstr(s)     str(s)
#define debug(s, t) printf("x" # s "= %d, x" # t "= %s" \
                        x ## s, x ## t)
#define INCFILE(n)  vers ## n
#define glue(a, b)  a ## b
#define xglue(a, b) glue(a, b)
#define HIGHLOW     "hello"
#define LOW         LOW ", world"

debug(1, 2);
fputs(str(strncmp("abc\0d" "abc", '\4') // this goes away
      == 0) str(: @\n), s);
#include xstr(INCFILE(2).h)
glue(HIGH, LOW);
xglue(HIGH, LOW)
```

results in

```
printf("x" "1" "= %d, x" "2" "= %s", x1, x2);
fputs(
  "strncmp(\"abc\\0d\", \"abc\", '\\4') == 0" ": @\n",
  s);
#include "vers2.h"    (after macro replacement, before file access)
"hello";
"hello" ", world"
```

or, after concatenation of the character string literals,

```
printf("x1= %d, x2= %s", x1, x2);
fputs(
  "strncmp(\"abc\\0d\", \"abc\", '\\4') == 0: @\n",
  s);
#include "vers2.h"    (after macro replacement, before file access)
"hello";
"hello, world"
```

Space around the # and ## tokens in the macro definition is optional.

Commentary

The characters "(after macro replacement, before file access)" are commentary and are not generated by macro replacement.

EXAMPLE placemarker

EXAMPLE 5 To illustrate the rules for placemarker preprocessing tokens, the sequence 1982

```
#define t(x,y,z) x ## y ## z
int j[] = { t(1,2,3), t(,4,5), t(6,,7), t(8,9,),
           t(10,,), t(,11,), t(,,12), t(,,) };
```

results in

```
int j[] = { 123, 45, 67, 89,
            10, 11, 12,  };
```

Commentary

1965 evaluation order

Although the order of evaluation of the **##** operator is unspecified, in the above example all orders return the same result.

C90

This example is new in the C99 Standard and contains undefined behavior in C90.

C++

The C++ Standard specification is the same as that in the C90 Standard,

EXAMPLE macro redefinition

EXAMPLE 6 To demonstrate the redefinition rules, the following sequence is valid. 1983

```
#define OBJ_LIKE      (1-1)
#define OBJ_LIKE      /* white space */ (1-1) /* other */
#define FUNC_LIKE(a)   ( a )
#define FUNC_LIKE( a )(        /* note the white space */ \
                         a /* other stuff on this line
                            */ )
```

But the following redefinitions are invalid:

```
#define OBJ_LIKE    (0)     // different token sequence
#define OBJ_LIKE    (1 - 1) // different white space
#define FUNC_LIKE(b) ( a )  // different parameter usage
#define FUNC_LIKE(b) ( b )  // different parameter spelling
```

Commentary

The preprocessor is not required to have any knowledge of how subsequent phrases of translation treated sequences of preprocessing tokens (i.e., the fact that they become an integer constant expression that has the same value as the replacement list of another macro definition).

EXAMPLE variable macro arguments

EXAMPLE 7 Finally, to show the variable argument list macro facilities: 1984

```
#define debug(...)        fprintf(stderr, __VA_ARGS__)
#define showlist(...)        puts(#__VA_ARGS__)
#define report(test, ...) ((test)?puts(#test):\
                printf(__VA_ARGS__))
debug("Flag");
debug("X = %d\n", x);
showlist(The first, second, and third items.);
report(x>y, "x is %d but y is %d", x, y);
```

results in

```
fprintf(stderr,  "Flag" );
fprintf(stderr,  "X = %d\n", x );
puts( "The first, second, and third items." );
((x>y)?puts("x>y"):
                printf("x is %d but y is %d", x, y));
```

C90

Support for macros taking a variable number of arguments is new in C99.

C++

Support for macros taking a variable number of arguments is new in C99 and is not supported in C++.

6.10.4 Line control

Constraints

1985 The string literal of a **#line** directive, if present, shall be a character string literal. #line

Commentary

This requirement that character string literals be used (i.e., no wide string literals) is more restrictive than that for the **#include** directive (which specifies implementation-defined handling of the sequence of characters). 1899 #include q-char-sequence

Semantics

1986 The *line number* of the current source line is one greater than the number of new-line characters read or introduced in translation phase 1 (5.1.1.2) while processing the source file to the current token. line number

Commentary

This defines the term *line number*. Counting new-line characters read or introduced in translation phase 1 means that line splicing does not affect the line number. The first line of the source file has a line number of 1. 116 translation phase 1

1987 A preprocessing directive of the form #line digit-sequence

```
# line digit-sequence new-line
```

causes the implementation to behave as if the following sequence of source lines begins with a source line that has a line number as specified by the digit sequence (interpreted as a decimal integer).

Commentary

Developers point of reference for diagnostic messages is invariably the contents of the untranslated source file. The **#line** directive can simplify the implementations of tools that modify this source during translation, such as a preprocessor. Using this directive removes the need for them (in those cases where a mapping back to the original line number is desirable) to ensure that modifications to the source maintain line number information.

Common Implementations

Some implementations supported the following as an equivalent form:

```
# digit-sequence new-line
```

In some cases this token sequence is generated by translation phase 4 to provide line number information to subsequent phases of translation (to enable them to provide accurate line number information in any diagnostics issued).

1988 The digit sequence shall not specify zero, nor a number greater than 2147483647.

Commentary

The syntax of the directive does not permit a minus sign to appear before the digits. 1854 preprocessor directives syntax

C90

The limit specified in the C90 Standard was 32767.

C++

Like C90, the limit specified in the C++ Standard is 32767.

Common Implementations

Many existing C90, and C++, implementations supported the C99 value.

#line
digit-sequence
s-char-sequence

A preprocessing directive of the form 1989

```
# line digit-sequence "s-char-sequence_opt" new-line
```

sets the presumed line number similarly and changes the presumed name of the source file to be the contents of the character string literal.

Commentary

Hiding the implementation details about the name of the file containing generated, or preprocessed, source can have a variety of advantages (e.g., the contents of a **#include**d file may refer to the name of the source file from which it was generated). This option provides such functionality.

Common Implementations

Some early implementations supported the following as an equivalent form:

```
# digit-sequence "s-char-sequence_opt" new-line
```

A preprocessing directive of the form 1990

```
# line pp-tokens new-line
```

(that does not match one of the two previous forms) is permitted.

Commentary

This form provides some flexibility in allowing the line number and source filename to be specified via macro replacement.

#line
macros expanded

The preprocessing tokens after **line** on the directive are processed just as in normal text (each identifier currently defined as a macro name is replaced by its replacement list of preprocessing tokens). 1991

Commentary

To be exact, the preprocessing tokens after **line** on the directive up to the first new-line character are processed just as in normal text.

The directive resulting after all replacements shall match one of the two previous forms and is then processed as appropriate. 1992

Commentary

However, preprocessing tokens having the form of a constant expression are not evaluated to create an integer constant. For instance, the following will not cause the current line number to be incremented by 10.

```
1  #line __LINE__+10
```

C++

The C++ Standard uses different wording that has the same meaning.

16.4p5

If the directive resulting after all replacements does not match one of the two previous forms, the behavior is undefined; otherwise, the result is processed as appropriate.

6.10.5 Error directive

Semantics

1993 A preprocessing directive of the form #error

```
# error pp-tokens_opt new-line
```

causes the implementation to produce a diagnostic message that includes the specified sequence of preprocessing tokens.

Commentary

The **#error** directive was introduced in C89 to provide an explicit mechanism for forcing translation to fail under certain conditions. Formally, the Standard can require only that a diagnostic be issued when the **#error** directive is processed. It is the intent of the Committee, however, that translation cease immediately upon encountering this directive if this is feasible in the implementation. Further diagnostics on text beyond the directive are apt to be of little value. Rationale

C++

. . . , and renders the program ill-formed. 16.5p1

Both language standards require that a diagnostic be issued. But the C Standard does not specify that the construct alters the conformance status of the translation unit. However, given that the occurrence of this directive causes translation to terminate, this is a moot point. 89 #error terminate translation

Common Implementations

Most implementation issue the diagnostic and then stop translation. However, a few implementations do continue translating after this directive is encountered. Some implementations also support the preprocessing directives **#inform**[353] and **#warning**.[1278] As their identifier name suggests they generate informational messages and warnings respectively. The translation does not fail. #warning

Example

```
1  #include <limits.h>
2
3  #if CHAR_BIT != 9
4  #error This program only runs on a host where CHAR_BIT == 9
5  #endif
```

6.10.6 Pragma directive

Semantics

#pragma directive

A preprocessing directive of the form 1994

 # pragma *pp-tokens*$_{opt}$ *new-line*

where the preprocessing token **STDC** does not immediately follow **pragma** in the directive (prior to any macro replacement)[149] causes the implementation to behave in an implementation-defined manner.

Commentary

Rationale The **#pragma** directive was added in C89 as the universal method for extending the space of directives.

The word *pragma* is from the Greek word meaning *action*. The term *compiler directive* or simply *directive* is often used to refer to **pragma** directives.

In the following example the preprocessing token **STDC** does not immediately follow **pragma** (prior to macro replacement) and implementation-defined behavior can occur.

```
#define GLOBAL_FP_CONTRACT STDC FP_CONTRACT ON

#pragma GLOBAL_FP_CONTRACT
```

C90

The exception for the preprocessing token **STDC** is new in C99.

C++

The exception for the preprocessing token **STDC** is new in C99 and is not specified in C++.

Other Languages

A common implementation mechanism, across all languages, is for certain sequences of characters within a comment to be given a special meaning. A few languages (e.g., Ada and Algol 68) have pragma directives defined in their specification. A larger number of language implementations provide some form of **pragma** directive (although the identifier used to denote it varies). A study by Fowler[439] examined implementation-dependent pragmas in Ada compilers. He found that:

1. fewer than 5% of the implementations support all the language-defined pragmas,
2. fewer than 30% of the implementations documented their support for language-defined pragmas,
3. fewer than 45% of the implementations gave more than a perfunctory description of implementation-defined pragmas and attributes.

Common Implementations

Many implementations include support for one or more **pragma** directive, some have extensive support.[614, 1314] The commercial pressure on vendors is to support the **pragma** directives specified by the market leader in their niche. Some implementations support a preprocessing directive of the form *#pack pp-tokens new-line*. It is used to specify information about how storage allocation, for various types, is to be performed. An equivalent form using a **pragma** directive might be `#pragma pack(2)`. The OpenMP API[42] for shared-memory parallelism in C makes extensive use of **#pragma**.

It is possible for the implementation-defined behavior to replace the **pragma** directive with an executable statement. For instance:

```
if (cond)
   {
#pragma vendor_X_library_call
   }
```

might expand to (when using a preprocessor that recognizes the **pragma** directive):

```
if (cond)
   {
__X_go_faster_stripes();
   }
```

or to (when using a preprocessor that does not recognize the **pragma** directive):

```
if (cond)
   {
   }
```

Some implementations and tools embed directives in comments. For instance, Lint[672] uses the form `/*UPPERCASEKEYWORD*/`, while Splint[400] uses the form `/*@information@*/`.

Coding Guidelines

The **pragma** directive is one of several possible methods that are usually available to a developer to influence how a translator performs its job (another one is command line options). However, one difference that usually exists between **pragma** directives and other methods is that the former might be applied to part of a source file, rather than all of it. For instance, the second **pragma** in a source file may change the behavior switched on by the first directive. There are a number of potential coding guideline issues associated with **#pragma** directives, including:

- The rationale for the appearance of a **pragma** directive, in source code, is to change a translator's default behavior. Any occurrences of this directive thus require readers to remember and take into account special case information, that differs from their knowledge of the default behavior, about the constructs affected by the directive. The amount of information they will need to remember will depend on whether the directive applies to all or parts of a source file.
- The visibility of the directive to readers. Other methods of altering translator behavior may also be visibly opaque (e.g., command line options in make-files). However, readers are generally aware of the places to look for translator configuration information and while readers may look at the first few lines of a source file for translator options they tend not to look at other places in a source file.
- Cutting and pasting is a relatively common method of editing source. One of the dangers of this technique is that **#pragma** directives may be unintentionally copied.

On method of minimizing many of these problems is to place all **pragma** directives near the start of source files. However, this rather defeats the flexibility offered by this directive in being selectively applied to parts of a source file. If directives apply to complete declarations it may be worthwhile placing those declarations in a separate source file (the issues involved in deciding which declarations to put in which source file are discussed elsewhere).

1810 declarations in which source file

There is no obvious, worthwhile, guideline recommendation that can be made about how to structure the use of **pragma** directives and so nothing more is said about the issue here.

1995 The behavior might cause translation to fail or cause the translator or the resulting program to behave in a non-conforming manner.

Commentary

The definition of implementation-defined behavior does not include these possibilities. The permissive behaviors of the **pragma** directive are thus all those permitted by the definition of implementation-defined behavior plus those listed in this C sentence.

42 implementation-defined behavior

C90

These possibilities were not explicitly specified in the C90 Standard.

C++

These possibilities are not explicitly specified in the C++ Standard.

---

pragma unrecognized ignored

Any such **pragma** that is not recognized by the implementation is ignored. 1996

Commentary

The standard does not delimit the extent to which a pragma needs to be "not recognized" by an implementation (such questions are invariably regarded as being quality-of-implementation issues that are outside the scope of the standard).

```
1   #pragma DING DUNG /* Only valid second pp-token is DONG */
```

Other Languages

Ada specifies similar behavior.

Coding Guidelines

redundant code 190

A **pragma** that is not recognized by the implementation is redundant code. It may not be recognized for a number of reasons, including the following:

- It is not support by the implementation. This usage might be considered harmless.
- The developer has misspelled a directive that is supported by the implementation. This is a fault and these coding guidelines are not intended to recommend against the use of constructs that are obviously faults.

guidelines 0 not faults

The extent to which it is cost effective for the author to provide information about the likelihood of a particular **pragma** being supported by various implementations (by, for instance, using a comment or conditional inclusion) is difficult to estimate for the general case. At the time the **pragma** directive is written its author will be aware of the use of implementation-defined behavior but may not have any idea of what other implementations, if any, the source will be ported to (e.g., writers of open source often give no thought to the possibility that a translator other than `gcc` might be used). For these reasons no guideline recommendations are considered here.

If the preprocessing token **STDC** does immediately follow **pragma** in the directive (prior to any macro replacement), then no macro replacement is performed on the directive, and the directive shall have one of the following forms[150)] whose meanings are described elsewhere: 1997

```
#pragma STDC FP_CONTRACT on-off-switch
#pragma STDC FENV_ACCESS on-off-switch
#pragma STDC CX_LIMITED_RANGE on-off-switch
on-off-switch:  one of
                ON        OFF        DEFAULT
```

Commentary

The identifier **STDC** is not reserved in other contexts and a source file may define a macro name that has this spelling. The term *standard pragmas* is commonly used by members of the C committee to refer to these **pragma** directives (it also appears in a footnote).

footnote 150 2002

The behavior of these **pragma** directives are specified in the library section.

The purpose of these pragmas is to inform the implementation that during translation code appearing after an occurrence of one of them is to be treated in some special way (e.g., certain floating-point optimizations can/cannot be performed). In many implementations the floating-point environment is dynamic (i.e., it can be reconfigured during program execution). The effect of any instances of these pragmas is static (i.e., it only has any effect during translation) and it is the developers responsibility to ensure that the dynamic behavior matches that specified statically.

C90

Support for the preprocessing token **STDC** in **pragma** directives is new in C99.

C++

Support for the preprocessing token **STDC** in **pragma** directives is new in C99 and is not specified in the C++ Standard.

Other Languages

Although Ada defines 38 standard pragmas it does not use a prefix to introduce them.

Common Implementations

Some vendors and other standards specify that a specific identifier follow **#pragma**. For instance, the IBM C compiler for AIX[618] uses the identifier **ibm** and the OpenMP[42] uses **omp**.

Some processors only provide static control of floating-point modes, i.e., the rounding direction must be encoded as part of the bit pattern of a generated machine code instruction.

1998 **Forward references:** the **FP_CONTRACT** pragma (7.12.2), the **FENV_ACCESS** pragma (7.6.1), the **CX_LIMITED_RANGE** pragma (7.3.4).

1999 149) An implementation is not required to perform macro replacement in pragmas, but it is permitted except for in standard pragmas (where **STDC** immediately follows **pragma**). footnote 149

Commentary

Specifying that macro replacement does not occur within standard pragmas gives the implementation the freedom to use them within the headers it supplies. A macro name, with the same spelling as a preprocessing token occurring in a standard pragma, defined before a header is included will not affect a translator's interpretation of that pragma.

C90

This footnote is new in C99.

C++

This footnote is new in C99 and is not specified in the C++ Standard.

Common Implementations

This behavior is another aspect of the implementation-defined nature of **pragma** directives. If the market leaders perform macro replacement then it is very likely that other vendors will also perform it.

Those preprocessors that support macro replacement within **pragma** directives only need to examine the preprocessing token following a `#pragma` to know whether or not to perform macro replacement.

Coding Guidelines

1996 pragma unrecognized ignored

Given that unrecognized **pragma** directives are ignored by translators it may take developers some time before they notice a difference in implementation behavior (between the cases when macro replacement occurs and does not occur).

Example

The following example illustrates one technique for effectively performing macro replacement in **pragma** directives:

```
#define wanted ON
#define not_wanted OFF

#define Pragma(...) _Pragma(#__VA_ARGS__)
#define xPragma(...) Pragma(__VA_ARGS__)

xPragma(STDC FP_CONTRACT wanted)
xPragma(STDC FENV_ACCESS not_wanted)
```

If the result of macro replacement in a non-standard pragma has the same form as a standard pragma, the behavior is still implementation-defined; 2000

Commentary

The standard only guarantees a standard **pragma** directive to be treated as such is when the specified sequence of preprocessing tokens appears in the source.

C90

Support for standard pragmas is new in C99.

C++

Support for standard pragmas is new in C99 and is not specified in the C++ Standard.

Example

```
#if HAS_FAST_FLOAT_POINT_UNIT
#define DO_CONTRACT STDC FP_CONTRACT ON
#else
#define DO_CONTRACT NULL_PRAGMA
#endif

#pragma DO_CONTRACT
```

an implementation is permitted to behave as if it were the standard pragma, but is not required to. 2001

Commentary

This combination of behavior is subsumed within the definition of implementation-defined behavior and is specified here to clarify that it is permitted in a conforming program.

footnote 150

150) See "future language directions" (6.11.8). 2002

6.10.7 Null directive

Semantics

A preprocessing directive of the form 2003

```
# new-line
```

has no effect.

Commentary

Rationale The existing practice of using empty # lines for spacing is supported in the Standard.

null statement syntax 1731

The preprocessor equivalent of the null statement.

Coding Guidelines

The null directive differs from am empty line in that it contains a visible character. This character may be used to held maintain a distinctive visible edge to any indented directives in the source.

6.10.8 Predefined macro names

2004 The following macro names[151)] shall be defined by the implementation:

macro name predefined

Commentary

This is a requirement on the implementation. These macro names are commonly referred to as the *predefined macros*. There is no clause header (i.e., Description, Semantics, Constraints) given for the requirements in this clause.

Some of the macros specified in the following C sentences expand to string literals. These string literals do not have any special properties associated with them (e.g., there is no requirement that any of them share the same storage).

908 string literal distinct array

Other Languages

Many languages (e.g., Ada and Fortran) support a large number of predefined identifiers (which may be intrinsic or part of a predefined library) supplying a variety of information.

Common Implementations

Most implementations also define macros, internally within the translator (i.e., not in headers), that provide information on the identity of the translator (e.g., a representation of the vendor name) and the host environment (particularly those vendors that supply implementations on a number of environment and host processors).

Table 2004.1: Occurrence of predefined macro names (as a percentage of all predefined macro names; a total of 1,826). Based on the visible form of the `.c` and `.h` files.

Predefined Macro	.c files	.h files	Predefined Macro	.c files	.h files	Predefined Macro	.c files	.h files
__LINE__	42.17	43.47	__TIME__	2.52	0.00	__STDC_IEC_559__	0.00	0.00
__FILE__	36.31	37.77	__STDC_VERSION__	0.00	0.00	__STDC_HOSTED__	0.00	0.00
__STDC__	15.77	18.11	__STDC_ISO_10646__	0.00	0.00			
__DATE__	3.23	0.65	__STDC_IEC_559_COMPLEX__	0.00	0.00			

2005 **__DATE__** The date of translation of the preprocessing translation unit: a character string literal of the form **"Mmm dd yyyy"** , where the names of the months are the same as those generated by the **asctime** function, and the first character of **dd** is a space character if the value is less than 10.

__DATE__ macro

Commentary

129 translation phase 4

This string literal specifies the date when translation phase 4 executed, not when later phases of translation were executed (e.g., the output of this phase may be written to a file for subsequent processing on another day). A change of date during the translation process does not affect the character sequence contained in the string literal. The standard does not specify any accuracy requirements on the value returned by the __DATE__ macro.

2025 predefined macros constant values during translation

Specifying that a space character is to be used if the day value is less than 10 the standard guarantees that the string literal always has the same width.

The discussion given for the __TIME__ macro is applicable here.

Common Implementations

Many translators unconditionally create the value to be used as the result of the __DATE__ macro once, when the translator is first started. This value is then used for all occurrences of __DATE__ during that translation. Translators generally rely on the accuracy of the date available in the environment in which they execute. Microsoft C supports the __TIMESTAMP__ macro as an extension. It expands to a string literal containing the date and time of the last modification of the current source file.

A single call to the `time` library function returns all of the information needed to create the values of the __TIME__ and __DATE__ macros.

__DATE__ date not available

If the date of translation is not available, an implementation-defined valid date shall be supplied. 2006

Commentary

The C Standard cannot require that the environment in which a translator executes be capable of knowing the current date. However, it can require that a value always be supplied by the translator.

Common Implementations

The `time` library function, assuming this is how the translator obtains the current date, returns the value `(time_t)-1` if the current calendar time is not available.

__FILE__ macro

__FILE__ The presumed name of the current source file (a character string literal).[152)] 2007

Commentary

It is only the presumed name because the value may have previously been changed, earlier in the source file being translated, using a **#line** directive, or may have to be guessed (e.g., if the source was read from standard input). #line 1985

Other Languages

Perl supports both the special variable `$PROGRAM_NAME` and the global special constant `__FILE__`.

__LINE__ macro

__LINE__ The presumed line number (within the current source file) of the current source line (an integer constant).[152)] 2008

Commentary

It is only the presumed name because the value may have previously been changed, earlier in the source file being translated, using a **#line** directive. #line 1985

Other Languages

Perl supports the global special constant `__LINE__`.

__STDC__ macro

__STDC__ The integer constant **1**, intended to indicate a conforming implementation. 2009

Commentary

Rationale

The macro `__STDC__` allows for conditional translation on whether the translator claims to be standard-conforming. It is defined as having the value 1. Future versions of the Standard could define it as 2, 3, etc., to allow for conditional compilation on which version of the Standard a translator conforms to. The C89 Committee felt that this macro would be of use in moving to a conforming implementation.

C++

16.8p1 *Whether __STDC__ is predefined and if so, what its value is, are implementation-defined.*

It is to be expected that a C++ translator will not define the **__STDC__**, the two languages are different, although a conforming C++ translator may often behave in a fashion expected of a conforming C translator. Some C++ translators have a switch that causes them to operate in a C compatibility mode (in this case it is to be expected that this macro will be defined as per the requirements of the C Standard).

Common Implementations

Some implementations define this macro to have the value 0 when operating in non-standards conforming mode and sometimes the value 2 when extensions to the standard are enabled.

Coding Guidelines

The definition of this macro represents two pieces of information— (1) is definition as a macro, and (2) the tokens in its replacement list. Given that many vendors have chosen to always define the __STDC__ macro and use its replacement list to specify the details of the conformance status, it is the value of the replacement list rather than the status of being defined that provides reliable information.

Cg 2009.1

Tests of the conformance status of a translator, in source code, shall use the value of the replacement list of the __STDC__ macro, not its status as a defined macro.

2010 **__STDC_HOSTED__** The integer constant **1** if the implementation is a hosted implementation or the integer constant **0** if it is not.

__STDC_HOSTED macro

Commentary

The ability of an implementation to specify an accurate definition of the __STDC_HOSTED__ macro depends on tight integration between various phases of translation.

C90

Support for the __STDC_HOSTED__ macro is new in C99.

C++

Support for the __STDC_HOSTED__ macro is new in C99 and it is not available in C++.

Common Implementations

While some vendors only sell implementations targeted to purely a hosted or freestanding environment, a few vendors sell into both markets.

Coding Guidelines

Support for the __STDC_HOSTED__ macro is new in C99 and it is too early to tell whether there are any common translation phase dependency mistakes made by developers in its usage.

2011 **__STDC_VERSION__** The integer constant **199901L**.[153)]

__STDC_VERSION macro

Commentary

Because of existing, implementation, practice of giving values other than 1 to the __STDC__ macro, existing code (and implementations) would have been broken had this macro been used to denote the version of the standard supported. The simplest solution was to define a new macro that explicitly indicated the version of the standard supported by an implementation.

The integer constant 199901 has type **int** in some implementations. Specifying a suffix ensures the type of the integer constant denoted by this macro is always the same.

C90

Support for the __STDC_VERSION__ macro was first introduced in Amendment 1 to C90, where it was specified to have the value 199409L. In a C90 implementation (with no support for Amendment 1) occurrences of this macro are likely to be replaced by 0 (because it will not be defined as a macro).

1878 #if identifier replaced by 0

C++

Support for the __STDC_VERSION__ macro is not available in C++.

Other Languages

Perl supports the special variable $PERL_VERSION.

2012 **__TIME__** The time of translation of the preprocessing translation unit: a character string literal of the form **"hh:mm:ss"** as in the time generated by the **asctime** function.

__TIME__ macro

Commentary

There is no guarantee that the value for the __TIME__ macro will be obtained on the same day as the value for the __DATE__ macro. It is possible, for instance, for the value __TIME__ macro to be obtained first (returning "23:59:59") followed by the value of the __DATE__ macro (returning a date on the following day).

__DATE__ macro 2005

The discussion given for the __DATE__ macro is applicable here.

Common Implementations

The extent to which host platforms on which the translators execute maintains an accurately time of day can vary significantly. The realtime clock in many PCs often drifts by several seconds in a day. The internet time protocol, nntp, provides one method of ensuring that the error in the estimated current time does not become too large over long periods.

Coding Guidelines

A common use of the __TIME__ macro is to provide program build configuration management information (e.g., the time at which a source file was translated). As such great accuracy is rarely required. During development there may be many builds and build times becomes important if more than one is performed in a day. Issues such as the values of the macros __TIME__ and __DATE__ being synchronized to refer to the same day is a configuration management issue and is outside the scope of these coding guidelines.

If the time of translation is not available, an implementation-defined valid time shall be supplied. 2013

Commentary

__DATE__ date not available 2006

The discussion given for the __DATE__ macro also applies here.

The following macro names are conditionally defined by the implementation: 2014

Commentary

Specifying that these macro names are conditionally defined simplifies the writing of source that may need to be processed by C90 implementations (which are unlikely to have defined these macro names). The affect on program conformance status of using conditional features is discussed elsewhere.

footnote 96 2

C90

Support for conditionally defined macros is new in C99.

C++

Support for conditionally defined macros is new in C99 and none are defined in the C++ Standard.

Coding Guidelines

__STDC__ macro 2009

Like the __STDC__ macro these conditionally defined macros represent two pieces of information. However, these macros are not required to be defined by an implementation. The extent to which implementations will define these macros to have values other than those specified in the standard are not known. The very infrequent use of these macros (which may be because they are new, or because source that needs to make use of the information they provide are not yet common) a guideline recommendation similar to that given for the __STDC__ macro is not considered cost effective.

__STDC__ check replacement list 2009.1

__STDC_IEC_559__ macro

__STDC_IEC_559__ The integer constant **1**, intended to indicate conformance to the specifications in annex F (IEC 60559 floating-point arithmetic). 2015

Commentary

The C Standard does not specify how conformance to the specification in annex F is to be measured.

C90

Support for the __STDC_IEC_559__ macro is new in C99.

C++

Support for the __STDC_IEC_559__ macro is new in C99 and it is not available in C++.

The C++ Standard defines, in the `std` namespace:

18.2.1.1

```
static const bool is_iec559 = false;
```

false is the default value. In the case where the value is **true** the requirements stated in C99 also occur in the C++ Standard. The member `is_iec559` is part of the numerics template and applies on a per type basis. However, the requirement for the same value representation, of floating types, implies that all floating types are likely to have the same value for this member.

2016 151) See "future language directions" (6.11.9). footnote 151

2017 152) The presumed source file name and line number can be changed by the **#line** directive. footnote 152

Commentary

This footnote clarifies the intent that implementations behave as if there is an association between evaluating a **#line** directive and the expanded form of subsequent occurrences of the __FILE__ __LINE__ macros.

C90

This observation is new in the C99 Standard.

C++

Like C90, the C++ Standard does not make this observation.

2018 153) This macro was not specified in ISO/IEC 9899:1990 and was specified as **199409L** in ISO/IEC 9899/AMD1:1995. footnote 153

Commentary

This is a brief history of the __STDC_VERSION__ macro. 2011 __STDC_VERS macro

---

2019 The intention is that this will remain an integer constant of type **long int** that is increased with each revision of this International Standard.

Commentary

The type **long int** (or its unsigned version) is the only standard integer type supported by the C90 Standard and required to be capable of supporting the necessary range of values. 493 standard integer types

Coding Guidelines

In C99 the C committee made changes to the behavior, required by the C90 Standard, of strictly conforming programs. What behavior future revisions of the C Standard will specify is unknown, although the subsection on future language directions gives some warnings. 1000 operator () Future language directions

This macro is only really of practical use in checking that the translator being used supports a version of the C Standard that is greater than, or equal to, some known version.

2020 **__STDC_IEC_559_COMPLEX__** The integer constant **1**, intended to indicate adherence to the specifications in informative annex G (IEC 60559 compatible complex arithmetic). __STDC__IEC_559 macro

Commentary

The C Standard does not specify how adherence to the specification in annex G is to be measured (or how adherence differs from conformance). 2015 __STDC_IEC_ macro

C90

Support for the __STDC_IEC_559_COMPLEX__ macro is new in C99.

C++

Support for the `__STDC_IEC_559_COMPLEX__` macro is new in C99 and is not available in C++.

__STDC_ISO_10646__ macro

`__STDC_ISO_10646__` An integer constant of the form **`yyyymmL`** (for example, **`199712L`**). 2021

Commentary

ISO 10646 28 The wording was changed by the response to DR #273.

C90

Support for the `__STDC_ISO_10646__` macro is new in C99.

C++

Support for the `__STDC_ISO_10646__` macro is new in C99 and is not available in C++.

Other Languages

ISO 10646 28 The few languages (e.g., Java) that currently support ISO 10646 do not provide access to equivalent version information.

Common Implementations

The implementation shipped with RedHat Linux version 9 has the value 200009L.

If this symbol is defined, then every character in the Unicode required set, when stored in an object of type **`wchar_t`**, has the same value as the short identifier of that character. 2022

Commentary

This is a requirement on an implementation that defines the `__STDC_ISO_10646__` macro. A short identifier short identifier 818 is representable in eight hexadecimal digits (i.e., values in the range `0..4294967295`). For instance:

```
1  L'\u00A3' == L'\x00A3'            if __STDC_ISO_10646__ defined
2  L'\u00A3' == L'£'                 always true
3  L'\x00A3' == (wchar_t) 0x00A3     always true
4  L'\x00A3' == L'£'                 if __STDC_ISO_10646__ defined
5  L'£' == (wchar_t) 0x00A3          if __STDC_ISO_10646__ defined
```

The term *Unicode required set* is defined in the following C sentence.

This wording was changed by the response to DR #273.

C90

This form of encoding was not mentioned in the C90 Standard.

C++

This form of encoding is not mentioned in the C++ Standard.

Unicode required set

The *Unicoderequiredset* consists of all the characters that are ~~intended to indicate that values of type **`wchar_t`** are the coded representations of the characters~~ defined by ISO/IEC 10646, along with all amendments and technical corrigenda, as of the specified year and month. 2023

Commentary

This gives permission for implementations to support amendments and technical corrigenda to ISO/IEC ISO 10646 28 10646 that are published after the C99 Standard. However, all documents published on or before the specified month must be supported.

The wording was changed by the response to DR #273.

Coding Guidelines

Program dependencies on the version of ISO/IEC 10646 is a configuration management issue that is outside the scope of these guidelines.

2024 **__STDC_MB_MIGHT_NEQ_WC__** The integer constant **1**, intended to indicate that, in the encoding for **wchar_t**, a member of the basic character set need not have a code value equal to its value when used as the lone character in an integer character constant.

Commentary

Until the publication of TC2, implementations were required to support the equality `'x' == L'x'`, where x is any member of the basic character set. This requirement restricted an implementation's choice of encoding for the type `wchar_t`. The response to DR #279 removed this restriction, but did not provide a mechanism for developers to write code that checked the behavior of their implementation (a large body of existing code relies on pre-TC2 guaranteed behavior).

L'x' == 'x'
215 basic character set
62 wide character

The expression `L'\xhh' == '\xhh'` is always true (as long as 0xhh is less than UCHAR_MAX). Developers would be very confused if this equality was true for escape sequences, but was not true when the escape sequences were replaced by members of the basic execution character set having the same numeric value (in a particular character set, for instance Ascii).

This sentence was added by the response to DR #333 and provides a specification for the pre-defined macro name introduced by the response to DR #321 (and supported by the Austin Group).

2025 The values of the predefined macros (except for **__FILE__** and **__LINE__**) remain constant throughout the translation unit.

predefined macros constant values during translation

Commentary

This is a requirement on the implementation. The standard places no requirements on exactly when the implementation assigns a value to the `__DATE__` and `__TIME__` macros.

The predefined macros `__DATE__` and `__TIME__` are intended to provide configuration management information about when the source was translated. Having to deal with time differences caused by the finite time needed to translate a source file would be an unnecessary complication for developers.

Given a sufficiently high-performance processor and fast translation, or a translation environment where no date and time information is available, it is possible that the values of the `__DATE__` and `__TIME__` macros will be the same during translations of different source files.

Common Implementations

Many implementations allow more than one source file to be specified, for translation, at the same time. The standard is silent about the values of these predefined macros, across multiple sources files, during a single invocation of a translator.

10 program transformation mechanism
120 footnote 5

Many implementations use several programs to translate a source file, preprocessing being handled by one of these programs. The details of invoking these separate programs is handled by a controlling program that provides the user interface, including breaking the translation of multiple source files into a sequence of translations of individual source files. Given this implementation strategy it is very likely that the preprocessor will be invoked separately for every source file being processed (with the value of the predefined macros being set during the startup of this preprocessor program) and can be different between different invocations.

2026 None of these macro names, nor the identifier **defined**, shall be the subject of a **#define** or a **#undef** preprocessing directive.

predefined macros not #defined

Commentary

This wording covers some of the possible source code constructs where **defined** can occur, but not all. For instance:

```
1  #define f(defined) defined
2
3  x = f(1);
4
```

```
5  #if f(1)
6  /* ... */
7  #endif
8
9  #if defined(defined)
10 /* ... */
11 #endif
```

Rationale If the identifier **defined** were to be defined as a macro, `defined(X)` would mean the macro expansion in C text proper and the operator expression in a preprocessing directive (or else that the operator would no longer be available). To avoid this problem, such a definition is not permitted (§6.10.8).

C++

The C++ Standard uses different wording that has the same meaning.

16.8p3 *If any of the pre-defined macro names in this subclause, or the identifier* ***defined****, is the subject of a* ***#define*** *or a* ***#undef*** *preprocessing directive, the behavior is undefined.*

Common Implementations

Some, but not all, implementations allow predefined macros to be **#undef**ed and for the identifier **defined** to be defined as a macro name.

Coding Guidelines

The usage described is very rare and for this reason a guideline recommendation is not considered cost effective.

---

macro name predefined reserved

Any other predefined macro names shall begin with a leading underscore followed by an uppercase letter or a second underscore. 2027

Commentary

This is a requirement on the implementation. It also acts as a warning to developers that macro names beginning with these sequences of characters may be reserved by an implementation. A predefined macro is generally considered to be one that is defined by a translator prior to the start of translation, i.e., it is not necessary for the source file to **#include** a particular header for it to be defined.

C++

The C++ Standard does not reserve names for any other predefined macros.

Common Implementations

The definition of some predefined macros may be affected by command line options passed to the translator. For instance, specifying the version of a particular processor architecture to generate machine code for. Such version specific architecture macro definitions might then affect which conditional inclusion directives are processed, within implementation supplied headers.

Although the standard reserves identifiers having these spellings for use by implementations, most implementations also use identifiers having spellings outside of this set, for their own internal use.

__cplusplus

The implementation shall not predefine the macro **__cplusplus**, nor shall it define it in any standard header. 2028

Commentary

This is a requirement on the implementation. It has become established practice to use this macro name to distinguish those parts of a header that are specific to C++ only and should be ignored by a C translator.

C90

This requirement was not specified in the C90 Standard. Given the prevalence of C++ translators, vendors were aware of the issues involved in predefining such a macro name (i.e., they did not do it).

C++

The name __cplusplus is defined to the value 199711L when compiling a C++ translation unit.[143)] 16.8p1

Other Languages

This macro name is unique to C in the sense that this language is sufficiently similar to the C++ language for implementors to be able to share headers in implementations of both languages.

2029 **Forward references:** the **asctime** function (7.23.3.1), standard headers (7.1.2).

6.10.9 Pragma operator

Semantics

2030 A unary operator expression of the form: _Pragma operator

```
_Pragma ( string-literal )
```

is processed as follows: The string literal is *destringized* by deleting the **L** prefix, if present, deleting the leading and trailing double-quotes, replacing each escape sequence \" by a double-quote, and replacing each escape sequence \\ by a single backslash.

Commentary

This defines the term *destringized*. This operation the inverse of the operation performed by the stringize operator. 1954 # escape sequence handling

As an alternative syntax for a **#pragma** directive, the **_Pragma** operator has the advantage that it can be used in a macro replacement list. If a translator is directed to produce a preprocessed version of the source file, then expressions involving the unary **_Pragma** operator and **#pragma** directives should be treated consistently in whether they are preserved and in whether macro invocations within them are expanded. Rationale

The prior art on which this directive was based comes from the Cray Standard C compiler (see WG14/N449).

C90

Support for the **_Pragma** unary operator is new in C99.

C++

Support for the **_Pragma** unary operator is new in C99 and it is not available in C++.

Coding Guidelines

Support for the **_Pragma** operator is new in C99 and at the time of this writing there is insufficient experience available in its use to know whether any guideline recommendation is worthwhile.

Example

The **_Pragma** operator can be used to reduce the visual clutter in source code. For instance, rather than duplicating a sequence of conditional inclusion directives, controlling a **pragma** directive, in the various source files or function definitions that require them, they can be encapsulated in a single macro definition.

```
#if defined(Machine_A)
   #define IZATION_HINT _Pragma("ivdep")       /* Ignore vector dependencies. */
#elif defined(Machine_B)
   #define IZATION_HINT _Pragma("independent") /* Iterations are independent. */
#endif

void N449_a(int n, double * a, double * b)
{
#if defined(Machine_A)
   #pragma ivdep            /* Vectorization hint (ignore vector dependencies).   */
#elif defined(Machine_B)
   #pragma independent      /* Parallelization hint (iterations are independent). */
#endif
while (n-- > 0)
   {
   *a++ += *b++;
   }
}

void N449_b(int n, double * a, double * b)
{
IZATION_HINT
while (n-- > 0)
   {
   *a++ += *b++;
   }
}
```

The resulting sequence of characters is processed through translation phase 3 to produce preprocessing tokens that are executed as if they were the *pp-tokens* in a pragma directive. 2031

Commentary

The string literal, or any macro invocations used to create it, will have already been processed by translation phases 1–3. Consequently the resulting sequence of characters will not include any new-line characters (because a string literal cannot them) or trigraph sequences (they will have been replaced in translation phase 1 and the escape sequence processing that might create new trigraph sequences does not occur until translation phase 5).

string literal 895 syntax
trigraph sequences 117 phase 1
translation phase 133 5

The original four preprocessing tokens in the unary operator expression are removed. 2032

Commentary

Exactly when this removal occurs, within translation phase 4 (other preprocessing tokens are deleted at the end of translation phase 4), is not specified. Because defining **_Pragma** as a macro name (e.g., `#define _Pragma func_call`) results in undefined behavior it is not possible for the timing of the removal to affect the output of a strictly conforming program.

preprocessing directives 132 deleted

EXAMPLE A directive of the form: 2033

EXAMPLE _Pragma

```
#pragma listing on "..\listing.dir"
```

can also be expressed as:

```
_Pragma ( "listing on \"..\\listing.dir\"" )
```

The latter form is processed in the same way whether it appears literally as shown, or results from macro replacement, as in:

```
#define LISTING(x) PRAGMA(listing on #x)
#define PRAGMA(x)  _Pragma(#x)

LISTING ( ..\listing.dir )
```

Commentary

The macro expansion sequence is:

```
1  LISTING ( ..\listing.dir )
2  PRAGMA(listing on "..\listing.h")
3  _Pragma("listing on \"..\\listing.h\"")
```

with the character `.` being treated as a "each non-white-space character that cannot be one of the above". 770 preprocessing token syntax

6.11 Future language directions

Commentary

Future language directions

This subclause includes specific mention of the future direction in which the Committee intends to extend and/or restrict the language. The contents of this subclause should be considered as quite likely to become a part of the next version of the Standard. Implementors are advised that failure to take heed of the points mentioned herein is considered undesirable for a conforming implementation. Users are advised that failure to take heed of the points mentioned herein is considered undesirable for a conforming program. Rationale

6.11.1 Floating types

2034 Future standardization may include additional floating-point types, including those with greater range, precision, or both than **`long double`**.

floating types future language directions

Commentary

Unlike the integer types, the standard does not specify any mechanism for implementations to provide additional floating-point types. 482 extended signed integer types

C90

This future direction is new in C99.

C++

The C++ Standard specifies (Annex D) deprecated features. With one exception these all relate to constructs specific to C++.

Each C header, whose name has the form `name.h`*, behaves as if each name placed in the Standard library namespace by the corresponding* `cname` *header is also placed within the namespace scope of the namespace* `std` *and is followed by an explicit* `using-declaration` *(7.3.3)* D.5p2

Common Implementations

While some processors support floating types having 128 bits value bits,[571] support for 256 bits (known as *quad-double*) is currently only available in software.[572]

Coding Guidelines

Some existing programs were broken by the introduction, in C99, of an integer type that was *bigger* than **`long`**. This situation occurred because of an assumption made by developers (and at times the C committee). The introduction of a floating-point type with greater range and precision than **`long double`** may cause existing programs to break for the same reason. However, it is not possible to estimate the costs and benefits of taking account of this possibility, when writing or modifying code, in guideline recommendations aimed at a wide audience. Developers are left to make their own cost/benefit analysis.

6.11.2 Linkages of identifiers

identifier linkage
future language directions

Declaring an identifier with internal linkage at file scope without the **static** storage-class specifier is an obsolescent feature. 2035

Commentary

static 425
internal linkage

Declaring an identifier at file scope using the **static** storage-class specifier gives it internal linkage. Although, in C99, subsequent declarations of the same identifier may omit the storage-class specifier (it either has internal linkage, or the behavior is undefined), future revisions of the standard may not support this usage.

function 430
no storage-class
object 431
file scope no storage-class

C90

This future direction is new in C99.

Usage

The translated form of this book's benchmark programs contained 12 declarations of an identifier with internal linkage at file scope without the **static** storage-class specifier.

6.11.3 External names

significant characters
future language directions

Restriction of the significance of an external name to fewer than 255 characters (considering each universal character name or extended source character as a single character) is an obsolescent feature that is a concession to existing implementations. 2036

Commentary

internal 282
identifier
significant characters

The issues surrounding this restriction are discussed elsewhere.

C90

Part of the future language direction specified in C90 was implemented in C99.

Restriction of the significance of an external name to fewer than 31 characters or to only one case is an obsolescent feature that is a concession to existing implementations.

6.11.4 Character escape sequences

escape sequences
future language directions

Lowercase letters as escape sequences are reserved for future standardization. 2037

Commentary

escape sequence 866
syntax

This position has not changed since publication of C90. The Committee received requests to support additional escape sequences in C99, but with one exception (i.e., \u) turned them down.

Other characters may be used in extensions. 2038

Commentary

The Committee chose to support \U in C99.

6.11.5 Storage-class specifiers

storage-class specifiers
future language directions

The placement of a storage-class specifier other than at the beginning of the declaration specifiers in a declaration is an obsolescent feature. 2039

Commentary

This position has not changed since publication of C90.

Rationale

The practice of placing the storage class specifier other than first in a declaration was branded obsolescent. The Committee felt it desirable to rule out such constructs as

```
enum { aaa, aab,
    /* etc. */
zzy, zzz } typedef a2z;
```

in some future standard.

This issue is also discussed elsewhere.

1357 declaration specifiers

Other Languages

This restriction is required by the syntax of many programming languages.

6.11.6 Function declarators

2040 The use of function declarators with empty parentheses (not prototype-format parameter type declarators) is an obsolescent feature.

function declarators future language directions

Commentary

This position has not changed since the publication of the C90 Standard.

Rationale

It was obviously out of the question to remove syntax used in the overwhelming majority of extant C code, so the Standard specifies two ways of writing function declarations and function definitions. Characterizing the old style as obsolescent is meant to discourage its use and to serve as a strong endorsement by the Committee of the new style. It confidently expects that approval and adoption of the prototype style will make it feasible for some future C Standard to remove the old style syntax.

Removing support for this form of declaration could also impact its definition.

2041 function definitions future language directions

Coding Guidelines

If the guideline recommendation specifying the use of function prototypes is followed then any future change will not be an issue.

1810.1 function declaration use prototype

6.11.7 Function definitions

2041 The use of function definitions with separate parameter identifier and declaration lists (not prototype-format parameter type and identifier declarators) is an obsolescent feature.

function definitions future language directions

Commentary

This position has not changed since the publication of the C90 Standard. The issues are the same as for function declarators.

2040 function declarators future language directions

6.11.8 Pragma directives

2042 Pragmas whose first preprocessing token is `STDC` are reserved for future standardization.

Pragma directives future language directions

Commentary

The Committee is claiming a very limited subset of possible **`pragma`** directives for their own future use. However, this does not mean that any future standard **`pragma`** directives will have `STDC` as the third preprocessing token.

C90

Support for this form of **`pragma`** directive is new in C99.

6.11.9 Predefined macro names

Predefined macro names future language directions

Macro names beginning with `__STDC_` are reserved for future standardization. 2043

Commentary

The C90 Standard reserved identifiers that began with two underscores in the library. This specification appears in a language clause and would imply that this set of spellings is reserved for use by the preprocessor (perhaps for predefined macro names).

C90

The specification of this reserved set of macro name spellings is new in C99.
