CHANGES

Commentary

The phrase *at the time of writing* is sometimes used. For this version of the material this time should be taken to mean no later than December 2008.

```
2x Jan 2008  1.1   Integrated in changes made by TC3, required C sentence renumbering.
                   60+ recent references added + associated commentary.
                   A few Usage figures and tables added.
                   Page layout improvements.  Lots of grammar fixes.
 5 Aug 2005  1.0b  Many hyperlinks added.  pdf searching through page 782 speeded up.
                   Various typos fixed (over 70% reported by Tom Plum).
16 Jun 2005  1.0a  Improvements to character set discussion (thanks to Kent Karlsson), margin
                   references, C99 footnote number typos, and various other typos fixed.
30 May 2005  1.0   Initial release.
```

README

-4 This book probably needs one of these.

Commentary

While it was written sequentially, starting at sentence 1 and ending with sentence 2043, readers are unlikely to read it in this way.

At some point you ought to read all of sentence 0 (the introduction).

The conventions used in this book are discussed on the following pages.

There are several ways in which you might approach the material in this book, including the following:

- You have read one or more sentences from the C Standard and want to learn more about them. In this case simply locate the appropriate C sentence in this book, read the associated commentary, and follow any applicable references.
- You want to learn about a particular topic. This pdf is fully searchable. Ok, the search options are not as flexible as those available in a search engine. The plan is to eventually produce separate html versions of each C sentence and its associated commentary. For the time being only the pdf is available.

For anybody planning to print a (double sided) paper copy. Using 80g/m^2 stock produces a stack of paper that is 9.2cm (3.6inches) deep.

Preface

Commentary

This book contains a detailed analysis of the International Standard for the C language,[-3.1] excluding the library from a number of perspectives. The organization of the material is unusual in that it is based on the actual text of the published C Standard. The unit of discussion is the individual sentences from the C Standard (2043 of them).

Readers are assumed to have more than a passing familiarity with C.

C90

My involvement with C started in 1988 with the implementation of a C to Pascal translator (written in Pascal). In 1991 my company was one of the three companies that were joint first, in the world, in having their C compiler formally validated. My involvement with the world of international standards started in 1988 when I represented the UK at a WG14 meeting in Seattle. I continued to head the UK delegation at WG14 meetings for another six years before taking more of a back seat role.

C++

Having never worked on a C++ compiler or spent a significant amount of time studying C++ my view on this language has to be considered as a C only one. While I am a member of the UK C++ panel I rarely attend meetings and have only been to one ISO C++ Standard meeting.

There is a close association between C and C++ and the aim of this subsection is the same as the C90 one: document the differences.

Other Languages

The choice of *other languages* to discuss has been driven by those languages in common use today (e.g., Java), languages whose behavior for particular constructs is very different from C (e.g., Perl or APL), and languages that might be said to have been an early influence on the design of C (mostly BCPL and Algol 68).

The discussion in these subsections is also likely to have been influenced by my own knowledge and biases. Writing a compiler for a language is the only way to get to know it in depth and while I have used many other languages I can only claim to have expertise in a few of them. Prior to working with C I had worked on compilers and source code analyzers for Algol 60, Coral 66, Snobol 4, CHILL, and Pascal. All of these languages might be labeled as imperative 3GLs. Since starting work with C the only other languages I have been involved in at the professional compiler writer level are Cobol and SQL.

Common Implementations

The perceived needs of customers drive translator and processor vendors to design and produce products. The two perennial needs of performance and compatibility with existing practice often result in vendors making design choices that significantly affect how developers interact with their products. The common implementation subsections discuss some the important interactions, primarily by looking at existing implementations and at times research projects (although it needs to be remembered that many of research ideas never make it into commercial products).

I have written code generators for Intel 8086, Motorola 68000, Versal (very similar to the Zilog Z80), Concurrent 3200, Sun SPARC, Motorola 88000, and a variety of virtual machines. In their day these processors have been incorporated in minicomputers or desktop machines. The main hole in my cv. is a complete lack of experience in generating code for DSPs and vector processors (i.e., the discussion is based purely on book learning in these cases).

[-3.1] The document analysed is actually WG14/N1256 (available for public download from the WG14 web site www.open-std.org/jtc1/sc22/wg14/). This document consists of the 1999 version of the ISO C Standard with the edits from TC1, TC2 and TC3 applied to it (plus a few typos corrected).

Coding Guidelines

Writing coding guidelines is a very common activity. Whether these guidelines provide any benefit other than satisfying the itch that caused their author to write them is debatable. My own itch scratchings are based on having made a living, since 1991, selling tools that provide information to developers about possible problems in C source code.

The prime motivating factor for these coding guidelines subsections is money (other coding guideline documents often use technical considerations to label particular coding constructs or practices as *good* or *bad*). The specific monetary aspect of software of interest to me is reducing the cost of source code ownership. Given that most of this cost is the salary of the people employed to work on it, the performance characteristics of human information processing is the prime consideration.

Software developer interaction with source code occurs over a variety of timescales. My own interests and professional experience primarily deals with interactions whose timescale are measured in seconds. For this reason these coding guidelines discuss issues that are of importance over this timescale. While interactions that occur over longer timescales (e.g., interpersonal interaction) are important, they are not the primary focus of these coding guideline subsections. The study of human information processing, within the timescale of interest, largely falls within the field of cognitive psychology and an attempt has been made to underpin the discussion with the results of studies performed by researchers in this field.

The study of software engineering has yet to outgrow the mathematical roots from which it originated. Belief in the mathematical approach has resulted in a research culture where performing experiments is considered to be unimportant and every attempt is made to remove human characteristics from consideration. Industry's insatiable demand for software developers has helped maintain the academic status quo by attracting talented individuals with the appropriate skills away from academia. The end result is that most of the existing academic software engineering research is of low quality and suffers from the problem of being carried out by people who don't have the ability to be mathematicians or the common sense to be practicing software engineers. For this reason the results of this research have generally been ignored.

Existing models of human cognitive processes provide a general framework against which ideas about the mental processes involved in source code comprehension can be tested. However, these cognitive models are not yet sophisticated enough (and the necessary empirical software engineering data is not available) to enable optimal software strategies to be calculated. The general principles driving the discussion that occurs in these coding guidelines subsections include:

1. the more practice people have performing some activity the better they become at performing it.

> *Our attitude towards what we listen to is determined by our habits. We expect things to be said in the ways in which we are accustomed to talk ourselves: things that are said some other way do not seem the same to all but seem rather incomprehensible. . . . Thus, one needs already to have been educated in the way to approach each subject.*
>
> Aristotle Metaphysics book II

   Many of the activities performed during source code comprehension (e.g., reasoning about sequences of events and reading) not only occur in the everyday life of software developers but are likely to have been performed significantly more often in an everyday context. Using existing practice provides a benefit purely because it is existing practice. For a change to existing practice to be worthwhile the total benefit has to be greater than the total cost (which needs to include relearning costs),

2. when performing a task people make implicitly cost/benefit trade-offs. One reason people make mistakes is because they are not willing to pay a cost to obtain more accurate information than they already have (e.g., relying on information available in their head rather expending effort searching for it in the real world). While it might be possible to motivate people to make them more willing pay a greater cost for less benefit the underlying trade-off behavior remains the same,

3. people's information processing abilities are relatively limited and cannot physically be increased (this is not to say that the cognitive strategies used cannot be improved to make the most efficient use of

these resources). In many ways the economics of software development is the economics of human attention.

Usage

Software engineering is an experimental, not a theoretical discipline, and an attempt has been made to base the analysis of C on what software developers and language translators do in practice.

The source code for many of the tools used to extract the information needed to create these figures and tables is available for download from the book's web site.

Measuring the characteristics of software that change over many releases (software evolution) is a relatively new research topic. Software evolution is discussed in a few sentences and any future major revision ought to cover this important topic in substantially more detail.

Table -3.1: Occurrences of various constructs in this book.

Quantity	Kind of information
2,022	C language sentences
1,600	C library paragraphs
1,450	Citations to published books and papers
228	Tables
208	Figures
1,721	Unique cross-reference entries

Acknowledgments

-2 The New C Standard: An economic and cultural commentary

Commentary

Thanks to Sean Corfield (corfield.org) and later Gavin Halliday for many interesting discussions on implementing C90. Also thanks to Clive Feather, the UK C panel, the members of WG14, and my consulting customers who were the source of many insights.

Clive Feather reviewed most of the material in this book. Fred Tydeman reviewed the floating-point material in all subsections. Frank Griswold provided a detailed review of over half of the C++ material. Stephen Parker reviewed a very early draft of some of the coding guidelines. Ken Odgers converted the C99 troff to xml.

Most of the work on the scripts and style sheets/macros used for the layout was done by Vic Kirk. Thanks to the authors of TeXlive, grap, pic, graphviz, and a variety of 'nix based tools.

Marilyn Rash (rrocean@shore.net) copyedited 75% of the material.

Thanks to the librarians of Reading, Surrey, and Warwick Universities for providing access to their collections of Journals. Thanks to all those people who made their papers available online (found via Altavista and later Google and Citeseer).

Post version 1.0

Thanks to the following people for reporting problems in previous versions: David Bremner, Giacomo A. Catenazzi, Cliff Click, Martin Elwin, Jeffrey Haemer, Chris Johansen, Kent Karlsson, Philipp Klaus Krause, Chris Lattner, Jonathan Leffler, Riesch Nicolas, Casey Peel, Jesse Perry, Tom Plum, David Poirier, Arvin Schnell, Ralph Siemsen, Pavel Vozenilek, and Gregory Warnes.

Conventions

information defined here

This is a sentence from WG14/N1124, the number on the inside margin (it would be in a bound book) is the sentence number and this wording has been ~~deleted~~added from/to the wording in C99 by the response to a defect report. -1

Commentary

another sentence

This is some insightful commentary on the above sentence. We might also say something relating to this issue in another sentence (see sentence number and reference heading in the outside margin—it would be in a bound book).

Terms and phrases, such as *blah*, visually appear as just demonstrated.

Rationale

This is a quote from the Rationale document produced by the C Committee to put a thoughtful spin on the wording in the standard.

Various fonts and font-styles are used to denote source code examples (e.g., `a+b*c`), keywords (e.g., **`else`**), syntax terminals (e.g., *`integer-constant`*), complete or partial file names (e.g., `.obj`), programs (e.g., `make`), program options (e.g., `-xs1234`), C Standard identifiers (e.g., `wchar_t`), library functions (e.g., `malloc`) and macros (e.g., `offsetof`).

The headers that appear indented to the left, displayed in a bold Roman font, appear in the C Standard between the two C sentences that they appear between in this book.

C90

This section deals with the C90 version of the standard. Specifically, how it differs from the C99 version of the above sentence. These sections only appear if there is a semantic difference (in some cases the words may have changed slightly, leaving the meaning unchanged).

DR #987

This is the text of a DR (defect report) submitted to the ISO C Standard committee.

Response

The committee's response to this DR is that this question is worth repeating at this point in the book.

This is where we point out what the difference, if any (note the change bar), and what the developer might do, if anything, about it.

C++

1.1p1

This is a sentence from the C++ standard specifying behavior that is different from the above C99 sentence. The 1.1p1 in the outside margin is the clause and paragraph number of this quote in the C++ Standard.

This is where we point out what the difference is, and what the developer might do, if anything, about it. You believed the hype that the two languages are compatible? Get real!

Other Languages

Developers are unlikely to spend their entire professional life using a single language. This section sometimes gives a brief comparison between the C way of doing things and other languages.

Comment received during balloting

We vote against the adoption of the proposed new COBOL standard because we have lost some of our source code and don't know whether the requirements in the proposed new standard would invalidate this source.

Common Implementations

Discussion of how implementations handle the above sentence. For instance, only processors with 17 bit integers can implement this requirement fully (note the text in the outside column—flush left or flush right to the edge of the page—providing a heading that can be referenced from elsewhere). gcc has extensions to support 16 bit processors in this area (the text in the outside margin is pushed towards the outside of the page, indicating that this is where a particular issue is discussed; the text appearing in a smaller point size is a reference to material appearing elsewhere {the number is the C sentence number}).

processors 17 bit

translated invalid program

This is a quote from the document referenced in the outside sidebar.

The New C Standard

Coding Guidelines

General musings on how developers use constructs associated with the above sentence. Some of these sections recommend that a particular form of the construct described in the above sentence not be used.

Cg -1.1 Do it this way and save money.

Dev -1.1 A possible deviation from the guideline, for a described special case.

Rev -1.2 Something to look out for during a code review. Perhaps a issue that requires a trade off among different issues, or that cannot be automated.

Example

An example, in source code of the above sentence.

The examples in this book are generally intended to illustrate some corner of the language. As a general rule it is considered good practice for authors to give examples that readers should follow. Unless stated otherwise, the examples in this book always break this rule.

```
1  struct {float mem;} main(void)
2  {
3  int blah;  /* The /* form of commenting describes the C behavior   */
4             // The // form of commenting describes the C++ behavior
5  }
```

Usage

A graph or table giving the number of occurrences (usually based on this book's benchmark programs) of the constructs discussed in the above C sentence.

Table of Contents

Introduction

0 With the introduction of new devices and extended character sets, new features may be added to this International Standard. Subclauses in the language and library clauses warn implementors and programmers of usages which, though valid in themselves, may conflict with future additions.

Certain features are *obsolescent*, which means that they may be considered for withdrawal in future revisions of this International Standard. They are retained because of their widespread use, but their use in new implementations (for implementation features) or new programs (for language [6.11] or library features [7.26]) is discouraged.

This International Standard is divided into four major subdivisions:

— preliminary elements (clauses 1–4);
— the characteristics of environments that translate and execute C programs (clause 5);
— the language syntax, constraints, and semantics (clause 6);
— the library facilities (clause 7).

Examples are provided to illustrate possible forms of the constructions described. Footnotes are provided to emphasize consequences of the rules described in that subclause or elsewhere in this International Standard. References are used to refer to other related subclauses. Recommendations are provided to give advice or guidance to implementors. Annexes provide additional information and summarize the information contained in this International Standard. A bibliography lists documents that were referred to during the preparation of the standard.

The language clause (clause 6) is derived from “The C Reference Manual”.

The library clause (clause 7) is based on the 1984 */usr/group Standard*.

Commentary

defect report 0

This book is about the latest version of the C Standard, ISO/IEC 9899:1999 plus TC1, TC2 and TC3 (these contain wording changes derived from WG14's responses to defect reports). It is structured as a detailed, systematic analysis of that entire language standard (clauses 1–6 in detail; clause 7, the library, is only covered briefly). A few higher-level themes run through all this detail, these are elaborated on below. This book is driven by existing developer practices, not ideal developer practices (whatever they might be). How developers use computer languages is not the only important issue; the writing of translators for them and the characteristics of the hosts on which they have to be executed are also a big influence on the language specification.

Every sentence in the C Standard appears in this book (under the section heading C99). Each of these sentences are followed by a Commentary section, and sections dealing with C90, C++, Other Languages, Common Implementations, Coding Guidelines, Example, and Usage as appropriate. A discussion of each of these sections follows.

culture of C 0

Discussions about the C language (indeed all computer languages), by developers, are often strongly influenced by the implementations they happen to use. Other factors include the knowledge, beliefs and biases (commonly known as folklore, or idiom) acquired during whatever formal education or training developers have had and the culture of the group that they current work within. In an attempt to simplify discussions your author has attempted to separate out these various threads.

Your author has found that a common complaint made about his discussion of C is that it centers on what

the standard says, not on how particular groups of developers use the language. No apology is made for this outlook. There can be no widespread discussion about C until all the different groups of developers start using consistent terminology, which might as well be that of the standard. While it is true that your author's involvement in the C Standards' process and association with other like-minded people has resulted in a strong interest in unusual cases that rarely, if ever, occur in practice, he promises to try to limit himself to situations that occur in practice, or at least only use the more obscure cases when they help to illuminate the meaning or intent of the C Standard.

No apologies are given for limiting the discussion of language extensions. If you want to learn the details of specific extensions, read your vendor's manuals.

Always remember the definitive definition is what the words in the C Standard say. In responding to defect reports the C committee have at times used the phrase *the intent of the Committee*. This phrase has been used when the wording in the standard is open to more than one possible interpretation and where committee members can recall discussions (via submitted papers, committee minutes, or committee email) in which the intent was expressed. The Committee has generally resisted suggestions to rewrite existing, unambiguous, wording to reflect intent (when the wording has been found to specify different behavior than originally intended). 0 defect report

As well as creating a standards document the C committee also produced a rationale. This rationale document provides background information on the thinking behind decisions made by the Committee. Rationale

Wording that appears within a sectioned area like this wording is a direct quote from the rationale (the document used was WG14/N937, dated 17 March 2001).

No standard is perfect (even formally defined languages contain mistakes and ambiguities[710]). There is a mechanism for clarifying the wording in ISO standards, defect reports (DRs as they are commonly called). The text of C99 DRs are called out where applicable. 0 defect report

1 Effort invested in producing the C Standard

The ANSI Committee which produced C90, grew from 13 members at the inaugural meeting, in June 1983, to around 200 members just prior to publication of the first Standard. During the early years about 20 people would attend meetings. There was a big increase in numbers once drafts started to be sent out for public review and meeting attendance increased to 50 to 60 people. Meetings occurred four times a year for six years and lasted a week (in the early years meetings did not always last a week). People probably had to put, say, a week's effort into reading papers and preparing their positions before a meeting. So in round numbers let's say:

```
(20 people × 1.3 weeks × 3 meetings × 1 years) +
(20 people × 1.7 weeks × 4 meetings × 2 years) +
(50 people × 2.0 weeks × 4 meetings × 3 years) ⇒ 1,540 person weeks (not quite 30 years)
```

What about the 140 people not included in this calculation— how much time did they invest? If they spent just a week a year keeping up with the major issues, then we have 16 person years of effort. On top of this we have the language users and implementors reviewing drafts that were made available for public review. Not all these sent in comments to the Committee, but it is not hard to imagine at least another 4 person years of effort. This gives the conservative figure of 50 person years of effort to produce C90.

Between the publication of C90 and starting work on the revision of C99, the C committee met twice a year for three days; meeting attendance tended to vary between 10 and 20. There was also a significant rise in the use of email during this period. There tended to be less preparation work that needed to be done before meetings— say 2 person years of effort.

The C99 work was done at the ISO level, with the USA providing most of the active committee membership. The Committee met twice a year for five years. Membership numbers were lower, at about 20 per meeting.

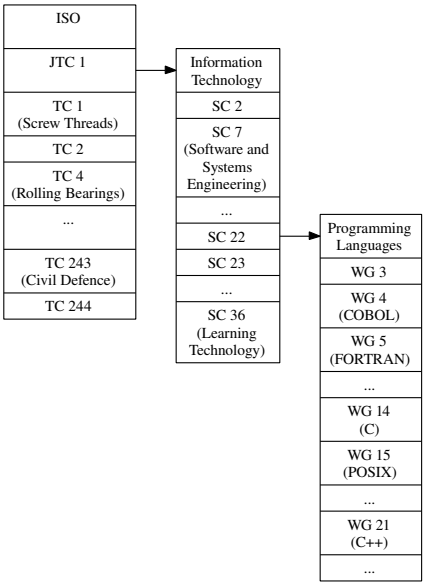

Figure 0.1: The ISO Technical Committee structure— JTC (Joint Technical Committee, with the IEC in this case), TC (Technical Committee), SC (Standards Committee), WG (Working Group).

This gives a figure of 8 person years. During development of C99 there was a significant amount of discussion on the C Standard's email list; just a week per year equates to more than 2 person years (the UK and Japanese national bodies had active working groups, many of whose members did not attend meetings).

Adding these numbers up gives a conservative total of 62 person years of effort that was invested in the C99 document. This calculation does not include the cost of travelling or any support cost (the document duplication bill for one committee mailing was approximately $5,000).

ISO

The C committee structure

The three letters ISO are said to be derived from the Greek *isos*, meaning "the same" (the official English term used is International Organization for Standardization, not a permutation of these words that gives the ordering ISO). Countries pay to be members of ISO (or to be exact, standards organizations in different countries pay). The size of the payment depends on a country's gross domestic product (a measure of economic size) and the number of ISO committees they want to actively participate in. Within each country, standards' bodies (there can be more than one) organize themselves in different ways. In many countries it is possible for their national standards' body(s) to issue a document as a standard in that country. The initial standards work on C was carried out by one such national body — ANSI (American National Standards Institute). The document they published was only a standard in the USA. This document subsequently went
X3J11 0 through the process to become an International Standard. As of January 2003, ISO has 138 national standards bodies as members, a turnover of 150 million Swiss Francs, and has published 13,736 International Standards (by 188 technical committees, 550 subcommittees, and 2,937 working groups)(see Figure 0.1).

The documents published by ISO may be formally labeled as having a particular status. These labels include Standard, Technical Report (Type 1, 2, or 3), and a draft of one of these kinds of documents (there are also various levels of draft). The documents most commonly seen by the public are Standards and Type 2 Technical Reports. A Type 2 Technical Report (usually referred to as simply a TR) is a document that is believed to be worth publishing as an ISO Standard, but the material is not yet sufficiently mature to be published as a standard. It is a kind of standard in waiting.

C90

C90 was the first version of the C Standard, known as ISO/IEC 9899:1990(E) (Ritchie[1169] gives a history of prestandard development). It has now been officially superseded by C99. The C90 sections ask the question: What are the differences, if any, between the C90 Standard and the new C99 Standard?
Text such this occurs (with a bar in the margin) when a change of wording can lead to a developer visible change in behavior of a program.

Possible differences include:

- C90 said X was black, C99 says X is white.
- C99 has relaxed a requirement specified in C90.
- C99 has tightened a requirement specified in C90.
- C99 contains a construct that was not supported in C90.

If a construct is new in C99 this fact is only pointed out in the first sentence of any paragraph discussing it. This section is omitted if the wording is identical (word for word, or there are minor word changes that do not change the semantics) to that given in C99. Sometimes sentences have remained the same but have changed their location in the document. Such changes have not been highlighted.

The first C Standard was created by the US ANSI Committee X3J11 (since renamed as NCITS J11). This document is sometimes called C89 after its year of publication as an ANSI standard (The shell and utilities portion of POSIX[636] specifies a c89 command, even although this standard references the ISO C Standard, not the ANSI one.). The published document was known as ANSI X3.159–1989. X3J11

This ANSI standard document was submitted, in 1990, to ISO for ratification as an International Standard. Some minor editorial changes needed to be made to the document to accommodate ISO rules (a sed script was used to make the changes to the troff sources from which the camera-ready copy of the ANSI and ISO standards was created). For instance, the word Standard was replaced by International Standard and some major section numbers were changed. More significantly, the Rationale ceased to be included as part of the document (and the list of names of the committee members was removed). After publication of this ISO standard in 1990, ANSI went through its procedures for withdrawing their original document and adopting the ISO Standard. Subsequent purchasers of the ANSI standard see, for instance, the words International Standard not just Standard.

2 Updates to C90

Part of the responsibility of an ISO Working Group is to provide answers to queries raised against any published standard they are responsible for. During the early 1990s, the appropriate ISO procedure seemed to be the one dealing with defects, and it was decided to create a Defect Report log (entries are commonly known as *DR*s). These procedures were subsequently updated and defect reports were renamed *interpretation requests* by ISO. The C committee continues to use the term *defect* and DR, as well as the new term *interpretation request*. defect report

Standards Committees try to work toward a publication schedule. As the (self-imposed) deadline for publication of the C Standard grew nearer, several issues remained outstanding. Rather than delay the publication date, it was agreed that these issues should be the subject of an Amendment to the Standard. The purpose of this Amendment was to address issues from Denmark (readable trigraphs), Japan (additional support for wide character handling), and the UK (tightening up the specification of some constructs whose wording was considered to be ambiguous). The title of the Amendment was *C Integrity*.

As work on DRs (this is how they continue to be referenced in the official WG14 log) progressed, it became apparent that the issues raised by the UK, to be handled by the Amendment, were best dealt with via these same procedures. It was agreed that the UK work item would be taken out of the Amendment and converted into a series of DRs. The title of the Amendment remained the same even though the material that promoted the choice of title was no longer included within it.

To provide visibility for those cases in which a question had uncovered problems with wording in the published standard the Committee decided to publish collections of DRs. The ISO document containing such corrections is known as a Technical Corrigendum (*TC*) and two were published for C90. A TC is normative and contains edits to the existing standard's wording only, not the original question or any rationale behind the decision reached. An alternative to a TC is a Record of Response (*RR*), a non-normative document.

Wording from the Amendment, the TCs and decisions on defect reports that had not been formally published were integrated into the body of the C99 document.

A determined group of members of X3J11, the ANSI Committee, felt that C could be made more attractive to numerical programmers. To this end it was agreed that this Committee should work toward producing a technical report dealing with numerical issues.

NCEG

The Numerical C Extensions Group (*NCEG*) was formed on May 10, 1989; its official designation was X3J11.1. The group was disbanded on January 4, 1994. The group produced a number of internal, committee reports, but no officially recognized Technical Reports were produced. Topics covered included: compound literals and designation initializers, extended integers via a header, complex arithmetic, restricted pointers, variable length arrays, data parallel C extensions (a considerable amount of time was spent on discussing the merits of different approaches), and floating-point C extensions. Many of these reports were used as the base documents for constructs introduced into C99.

base document

Support for parallel threads of execution was not addressed by NCEG because there was already an ANSI Committee, X3H5, working toward standardizing a parallelism model and Fortran and C language bindings to it.

C++

Many developers view C++ as a superset of C and expect to be able to migrate C code to C++. While this book does not get involved in discussing the major redesigns that are likely to be needed to make effective use of C++, it does do its best to dispel the myth of C being a subset of C++. There may be a language that is common to both, but these sections tend to concentrate on the issues that need to be considered when translating C source using a C++ translator.

What does the C++ Standard, ISO/IEC 14882:1998(E), have to say about constructs that are in C99?

- *Wording is identical.* Say no more.
- *Wording is similar.* Slight English grammar differences, use of terminology differences and other minor issues. These are sometimes pointed out.
- *Wording is different but has the same meaning.* The sequence of words is too different to claim they are the same. But the meaning appears to be the same. These are not pointed out unless they highlight a C++ view of the world that is different from C.
- *Wording is different and has a different meaning.* Here the C++ wording is quoted, along with a discussion of the differences.
- *No C++ sentence can be associated with a C99 sentence.* This often occurs because of a construct that does not appear in the C++ Standard and this has been pointed out in a previous sentence occurring before this derived sentence.

There is a stylized form used to comment source code associated with C— `/* behavior */`— and C++— `// behavior`.

The precursor to C++ was known as C with Classes. While it was being developed C++ existed in an environment where there was extensive C expertise and C source code. Attempts by Stroustrup to introduce incompatibilities were met by complaints from his users.[1310]

The intertwining of C and C++, in developers mind-sets, in vendors shipping a single translator with a language selection option, and in the coexistence of translation units written in either language making up one program means that it is necessary to describe any differences between the two.

The April 1989 meeting of WG14 was asked two questions by ISO: (1) should the C++ language be standardized, and (2) was WG14 the Committee that should do the work? The decision on (1) was very close, some arguing that C++ had not yet matured sufficiently to warrant being standardized, others arguing that working toward a standard would stabilize the language (constant changes to its specification and implementation were causing headaches for developers using it for mission-critical applications). Having agreed that there should be a C++ Standard WG14 was almost unanimous in stating that they were not the Committee that should create the standard. During April 1991 WG21, the ISO C++ Standard's Committee was formed; they met for the first time two months later.

In places additional background information on C++ is provided. Particularly where different concepts, or terminology, are used to describe what is essentially the same behavior.

In a few places constructs available in C++, but not C, are described. The rationale for this is that a C developer, only having a C++ translator to work with, might accidentally use a C++ construct. Many C++ translators offer a C compatibility mode, which often does little more than switch off support for a few C++ constructs. This description may also provide some background about why things are different in C++.

Everybody has a view point, even the creator of C++, Bjarne Stroustrup. But the final say belongs to the standards' body that oversees the development of language standards, SC22. The following was the initial position.

Resolutions Prepared at the Plenary Meeting of

ISO/IEC JTC 1/SC22

Vienna, Austria

September 23–29, 1991

Resolution AK Differences between C and C++

Notwithstanding that C and C++ are separate languages, ISO/IEC JTC1/SC22 directs WG21 to document differences in accordance with ISO/IEC TR 10176.

Resolution AL WG14 (C) and WG21 (C++) Coordination

While recognizing the need to preserve the respective and different goals of C and C++, ISO/IEC JTC1/SC22 directs WG14 and WG21 to ensure, in current and future development of their respective languages, that differences between C and C++ are kept to the minimum. The word "differences" is taken to refer to strictly conforming programs of C which either are invalid programs in C++ or have different semantics in C++.

This position was updated after work on the first C++ Standard had been completed, but too late to have any major impact on the revision of the C Standard.

Resolutions Prepared at the Eleventh Plenary Meeting of

ISO/IEC JTC 1/SC22

Snekkersten, Denmark

August 24–27, 1998

Resolution 98-6: Relationship Between the Work of WG21 and that of WG14

Recognizing that the user communities of the C and C++ languages are becoming increasingly divergent, ISO/IEC JTC 1/SC22 authorizes WG21 to carry out future revisions of ISO/IEC 14882:1998 (Programming Language C++) without necessarily adopting new C language features contained in the current revision to ISO/IEC 9899:1990 (Programming Language C) or any future revisions thereof.

ISO/IEC JTC 1/SC22 encourages WG14 and WG21 to continue their close cooperation in the future.

Other Languages

Why are other languages discussed in this book? Developers are unlikely to spend their entire working life using a single language (perhaps some Cobol and Fortran programmers may soon achieve this).

C is not the only programming language in the world (although some developers act as if it were). Characteristics of other languages can help sharpen a developer's comprehension of the spirit (design, flavor, world-view) of C. Some of C's constructs could have been selected in several alternative ways, others interrelate to each other.

The functionality available in C can affect the way an algorithm is coded (not forgetting individual personal differences[1117, 1118]). Sections of source may only be written that way because that is how things are done in C; they may be written differently, and have different execution time characteristics,[1119] in other languages. Appreciating the effects of C language features in the source they write can be very difficult for developers to do; rather like a fish trying to understand the difference between water and dry land.

Some constructs are almost universal to all programming languages, others are unique to C (and often C++). Some constructs are common to a particular class of languages— algorithmic, functional, imperative, formal, and so on. The way things are done in C is not always the only way of achieving the same result, or the same algorithmic effect. Sometimes C is unique. Sometimes C is similar to what other languages do. Sometimes there are languages that do things very differently from C, either in implementing the same idea, or in having a different view of the world.

It is not the intent to claim that C or any other language is better or worse because it has a particular design philosophy, or contains a particular construct. Neither is this subsection intended as a survey of what other languages do. No attempt is made to discuss any other language in any way apart from how it is similar or different from C. Other languages are looked at from the C point of view.

Developers moving from C to another language will, for a year or so (or longer depending on the time spent using the new language), tend to use that language in a C-like style (much the same as people learning English tend to initially use the grammar and pronunciations of their native language; something that fluent speakers have no trouble hearing).

Your author's experience with many C developers is that they tend to have a *C is the only language worth knowing attitude*. This section is unlikely to change that view and does not seek to. Some knowledge of how other languages do things never hurt.

There are a few languages that have stood the test of time, Cobol and Fortran for example. While Pascal and Ada may have had a strong influence on the thinking about how to write maintainable, robust code, they have come and gone in a relatively short period of time. At the time of this writing there are six implementations of Ada 95. A 1995 survey[590] of language usage found 49.5 million lines of Ada 83 (C89 32.5 million, other languages 66.18 million) in DoD weapon systems. The lack of interest in the Pascal standard is causing people to ask whether it should be withdrawn as a recognized standard (ISO rules require that a standard be reviewed every five years). The Java language is making inroads into the embedded systems market (the promise of it becoming the lingua franca of the Internet does not seem to have occurred). It is also trendy, which keeps it in the public eye. Lisp continues to have a dedicated user base 40 years after its creation. A paper praising its use, over C, has even been written.[411]

The references for the other languages mentioned in this book are: Ada,[645] Algol 68,[1407] APL,[654] BCPL,[1162] CHILL,[656] Cobol,[634] Fortran,[640] Lisp[650] (Scheme[719]), Modula-2,[646] Pascal,[639] Perl,[1438] PL/1,[633] Snobol 4,[521] and SQL.[641]

References for the implementation of languages that have significant differences from C include APL,[178] functional languages,[1082] and ML.[50]

Common Implementations

3 Introduction

This subsection gives an overview of translator implementation issues. The specific details are discussed in the relevant sentence. The following are the main issues.

- *Translation environment.* This environment is defined very broadly here. It not only includes the language specification (dialects and common extensions), but customer expectations, known translation

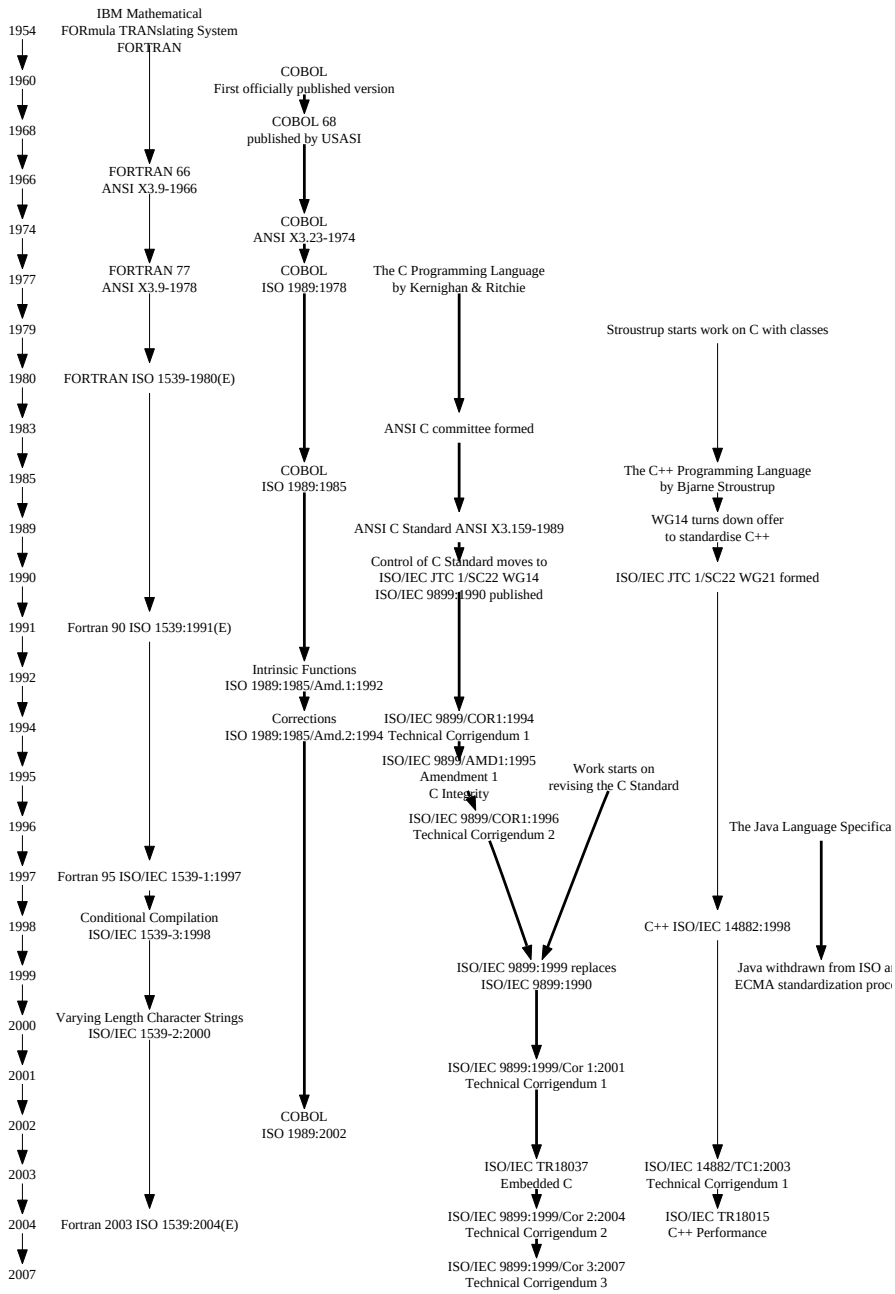

Figure 0.2: Outline history of the C language and a few long-lived languages. (Backus[69] describes the earliest history of Fortran.)

technology and the resources available to develop and maintain translators. Like any other application development project, translators have to be written to a budget and time scale.

- *Execution environment.* This includes the characteristics of the processor that will execute the program image (instruction set, number of registers, memory access characteristics, etc.), and the runtime interface to the host environment (storage allocation, function calling conventions, etc.).
- *Measuring implementations.* Measurements on the internal working of translators is not usually published. However, the execution time characteristics of programs, using particular implementations, is of great interest to developers and extensive measurements are made (many of which have been published).

4 Translation environment

The translation environment is where developers consider their interaction with an implementation to occur. Any requirement that has existed for a long period of time (translators, for a variety of languages, have existed for more than 40 years; C for 25 years) establishes practices for how things should be done, accumulates a set of customer expectations, and offers potential commercial opportunities.

Although the characteristics of the language that need to be translated have not changed significantly, several other important factors have changed. The resources available to a translator have significantly increased and the characteristics of the target processors continue to change. This increase in resources and need to handle new processor characteristics has created an active code optimization research community.

4.1 Developer expectations

developer expectations

Developers have expectations about what language constructs mean and how implementations will process them. At the very least developers expect a translator to accept their existing source code and generate to a program image from it, the execution time behavior being effectively the same as the last implementation they used. Implementation vendors want to meet developer expectations whenever possible; it reduces the support overhead and makes for happier customers. Authors of translators spend a lot of time discussing what their customers expect of their product; however, detailed surveys of customer requirements are rarely carried out. What is available is existing source code. It is this existing code base that is often taken as representing developers expectations (translators should handle it without complaint, creating programs that deliver the expected behavior).

Three commonly encountered expectations are good performance, low code expansion ratio, and no surprising behavior; the following describes these expectations in more detail.

1. *C has a reputation for efficiency.* It is possible to write programs that come close to making optimum usage of processor resources. Writing such code manually relies on knowledge of the processor and how the translator used maps constructs to machine code. Very few developers know enough about these subjects to be able to consistently write very efficient programs. Your author sometimes has trouble predicting the machine code that would be generated when using the compilers he had written. As a general rule, your author finds it safe to say that any ideas developers have about the most efficient construct to use, at the statement level, are wrong. A cost effective solution is to not worry about statement level efficiency issues and let the translator look after things.
2. *C has a reputation for compactness.* The ratio of machine code instructions per C statement is often a small number compared to other languages. It could be said that C is a WYSIWYG language, the mapping from C statement to machine code being simple and obvious (leaving aside what an optimizer might subsequently do). This expectation was used by some members of WG14 as an argument against allowing the equality operator to have operands with structure type; a single operator potentially causing a large amount of code, a comparison for each member, to be generated. The introduction of the **inline** function-specifier has undermined this expectation to some degree (depending on whether **inline** is thought of as a replacement for function-like macros, or the inlining of functions that would not have been implemented as macros).

function specifier 1522
syntax
macro 1933
function-like

3. *C has a reputation for being a consistent language.* Developers can usually predict the behavior of the code they write. There are few dark corners whose accidental usage can cause constructs to behave in unexpected ways. While the C committee can never guarantee that there would never be any surprising behaviors, it did invest effort in trying to ensure that the least-surprising behaviors occurred.

4.2 The language specification

common implementations language specification

The C Standard does not specify everything that an implementation of it has to do. Neither does it prevent vendors from adding their own extensions. C is not a registered trademark that is policed to ensure implementations follow its requirements; unlike Ada, which until recently was a registered trademark, owned by the US Department of Defense, which required that an implementation pass a formal validation procedure before allowing it to be called Ada. The C language also has a history— it existed for 13 years before a formally recognized standard was ratified.

The commercial environments in which C was originally used have had some influence on its specification. The C language started life on comparatively small platforms and the source code of a translator (`pcc`, the portable C compiler[673]) was available for less than the cost of writing a new one. Smaller hardware vendors without an established customer base, were keen to promote portability of applications to their platform. Thus, there were very few widely accepted extensions to the base language. In this environment vendors tended to compete more in the area of available library functions. For this reason, significant developer communities, using different dialects of C, were not created. Established hardware vendors are not averse to adding language extensions specific to their platforms, which resulted in several widely used dialects of both Cobol and Fortran.

Implementation vendors have found that they can provide a product that simply follows the requirements contained in the C Standard. While some vendors have supplied options to support for some prestandard language features, the number of these features is small.

Although old source code is rarely rewritten, it still needs a host to run on. The replacement of old hosts by newer ones means that either existing source has to be ported, or new software acquired. In both cases it is likely that the use of prestandard C constructs will diminish. Many of the programs making use of C language dialects, so common in the 1980s, are now usually only seen executing on very old hosts. The few exceptions are discussed in the relevant sentences.

4.3 Implementation products

Translators are software products that have customers like any other application. The companies that produce them have shareholders to satisfy and, if they are to stay in business, need to take commercial issues into account. It has always been difficult to make money selling translators and the continuing improvement in the quality of Open Source C translators makes it even harder. Vendors who are still making most of their income by selling translators, as opposed to those who have to supply one as part of a larger sale, need to be very focused and tend to operate within specific markets.[1480] For instance, some choose to concentrate on the development process (speed of translation, integrated development environment, and sophisticated debugging tools), others on the performance of the generated machine code (Kuck & Associates, purchased by Intel, for parallelizing scientific and engineering applications, Code Play for games developers targeting the Intel x86 processor family). There are even specialists within niches. For instance, within the embedded systems market Byte Craft concentrates on translators for 8-bit processors. Vendors who are still making most of their income from selling other products (e.g., hardware or operating systems) sometimes include a translator as a loss leader. Given its size there is relatively little profit for Microsoft in selling a C/C++ translator; having a translator gives the company greater control over its significantly more profitable products (written in those languages) and, more importantly, mind-share of developers producing products for its operating systems.

It is possible to purchase a license for a C translator front-end from several companies. While writing one from scratch is not a significant undertaking (a few person years), writing anything other than a straightforward code generator can require a large investment. By their very nature, many optimization techniques deal with special cases, looking to fine-tune the use of processor resources. Ensuring that correct code is

generated, for all the myriad different combinations of events that can occur, is very time-consuming and expensive.

The performance of generated machine code is rarely the primary factor in developer selection of which translator to purchase, if more than one is available to choose from. Factors such as implicit Vendor preference (it is said that nobody is sacked for buying Microsoft), preference for the development environment provided, possessing existing code that is known to work well with a particular vendor's product, and many other possible issues. For this reason optimization techniques often take many years to find their way from published papers to commercial products, if at all.[1175]

Companies whose primary business is the sale of translators do not seem to grow beyond a certain point. The largest tend to have a turnover in the tens of millions of dollars. The importance of translators to companies in other lines of business has often led to these companies acquiring translator vendors, both for the expertise of their staff and for their products. Several database companies have acquired translator vendors to use their expertise and technology in improving the performance of the database products (the translators subsequently being dropped as stand-alone products).

Overall application performance is often an issue in the workstation market. Here vendors, such as HP, SGI, and IBM, have found it worthwhile investing in translator technology that improves the quality of generated code for their processors. Potential customers evaluating platforms using benchmarks will be looking at numbers that are affected by both processor and translator performance— the money to be made from multiple hardware sales being significantly greater than that from licensing a translator to relatively few developers. These companies consider it worthwhile to have an in-house translator development group.

GCC

GCC, the GNU C compiler[1278] (now renamed the GNU Compiler Collection; the term *gcc* will be used here to refer to the C compiler), was distributed in source code form long before Linux and the rise of the Open Source movement. Its development has been checkered, but it continues to grow from strength to strength. This translator was designed to be easily retargeted to a variety of different processors. Several processor vendors have provided, or funded ports of the back end to their products. Over time the optimizations performed by GCC have grown more sophisticated. This has a lot to do with researchers using GCC as the translator on which to implement and test their optimization ideas. On those platforms where its generated machine code does not rank first in performance, it usually ranks second.

The source code to several other C translators has also been released under some form of public use license. These include: `lcc`[448] along with `vpo` (very portable optimizer[113]), the SGIPRO C compiler[1237] (which performs many significant optimizations), the TenDRA C/C++ project,[44] Watcom,[1446] Extensible Interactive C (an interpreter),[156] and the Trimaran compiler system.[46]

The lesson to be drawn from these commercial realities is that developers should not expect a highly competitive market in language translators.[1480] Investing large amounts of money in translator development is unlikely to be recouped purely from sales of translators (some vendors make the investment to boost the sales of their processors). Developers need to work with what they are given.

4.4 Translation technology

translation technology

Translators for C exist within a community of researchers (interested in translation techniques) and also translators for other languages. Some techniques have become generally accepted as the way some construct is best implemented; some are dictated by trends that come and go. This book does not aim to document every implementation technique, but it may discuss the following.

- How implementations commonly map constructs for execution by processors.
- Unusual processor characteristics, which affect implementations.
- Common extensions in this area.
- Possible trade-offs involved in implementing a construct.
- The impact of common processor architectures on the C language.

In the early days of translation technology vendors had to invest a lot of effort simply to get them to run within the memory constraints of the available development environments. Many existed as a collection of separate programs, each writing output to be read by the succeeding phase, the last phase being assembler code that needed to be processed by an assembler.

Ever since the first Fortran translator[69] the quality of machine code produced has been compared to handwritten assembler. Initially translators were only asked to not produce code that was significantly worse than handwritten assembler; the advantages of not having to retrain developers (in new assembly languages) and rewrite applications outweigh the penalties of less performance. The fact that processors changed frequently, but software did not, was a constant reminder of the advantages of using a machine-independent language. Whether most developers stopped making the comparison against handwritten assembler because fewer of them knew any assembler, or because translators simply got better is an open issue. In some application domains the quality of code produced by translators is nowhere near that of handwritten assembler[1254] and many developers still need to write in machine code to be able to create usable applications.

Much of the early work on translators was primarily concerned with different language constructs and parsing them. A lot of research was done on various techniques for parsing grammars and tools for compressing their associated data tables. The work done at Carnegie Mellon on the PQCC project[847] introduced many of the ideas commonly used today. By the time C came along there were some generally accepted principles about how a translator should be structured.

A C translator usually operates in several phases. The first phase (called the *front-end* by compiler writers and often the parser by developers) performs syntax and semantic analysis of the source code and builds a tree representation (usually based on the abstract syntax); it may also map operations to an intermediate form (some translators have multiple intermediate forms, which get progressively lower as constructs proceed through the translation process) that has a lower-level representation than the source code but a higher-level than machine code. The last phase (often called the *back-end* by compiler writers or the *code generator* by developers) takes what is often a high-level abstract machine code (an intermediate code) and maps it to machine code (it may generate assembler or go directly to object code). Operations, such as storage layout and optimizations on the intermediate code, could be part of one of these phases, or be a separate phase (sometimes called the *middle-end* by compiler writers).

120 footnote 5

1354 storage layout

The advantage of generating machine code from intermediate code is a reduction in the cost of retargeting the translator to a new processor; the front-end remains virtually the same and it is often possible to reuse substantial parts of later passes. It becomes cost effective for a vendor to offer a translator that can generate machine code for different processors from the same source code. Many translators have a single intermediate code. GCC currently has one, called RTL (register transfer language), but may soon have more (a high-level, machine-independent, RTL, which is then mapped to a more machine specific form of RTL). Automatically deriving code generators from processor descriptions[209] sounds very attractive. However, until recently new processors were not introduced sufficiently often to make it cost effective to remove the human compiler written from the process. The cost of creating new processors, with special purpose instruction sets, is being reduced to the point where custom processors are likely to become very common and automatic derivation of code generators is essential to keep these costs down.[810, 843]

The other advantage of breaking the translator into several components is that it offers a solution to the problem caused by a common host limitation. Many early processors limited the amount of memory available to a program (64 K was a common restriction). Splitting a translator into independent components (the preprocessor was usually split off from the syntax and semantics processing as a separate program) enabled each of them to occupy this limited memory in turn. Today most translators have many megabytes of storage available to them; however, many continue to have internal structures designed when storage limitations were an important issue.

There are often many different ways of translating C source into machine code. Developers invariably want their programs to execute as quickly as possible and have been sold on the idea of translators that

perform code optimization. There is no commonly agreed on specification for exactly what a translator needs to do to be classified as optimizing, although claims made in a suitably glossy brochure is often sufficient for many developers.

4.4.1 Translator optimizations

translator optimizations

Traditionally optimizations have been aimed at reducing the time needed to execute a program (this is what the term *increasing program performance* is usually intended to mean) or reducing the size of the program image (this usually means the amount of storage occupied during program execution— consisting of machine code instructions, some literal values, and object storage). Many optimizations have the effect of increasing performance and reducing size. However, there are some optimizations that involve making a trade-off between performance and size.

The growth in mobile phones and other hand-held devices containing some form of processor have created a new optimization requirement— power minimization. Software developers want to minimize the amount of electrical power required to execute a program. This optimization requirement is likely to be new to readers; for this reason a little more detail is given at the end of this subsection.

Some of the issues associated with generating optimal machine code for various constructs are discussed within the sentences for those constructs. In some cases transformations are performed on a relatively high-level representation and are relatively processor-independent (see Bacon, Graham, and Sharp[70] for a review). Once the high-level representation is mapped to something closer to machine code, the optimizations can become very dependent on the characteristics of the target processor (Bonk and Rüde[136] look at number crunchers). The general techniques used to perform optimizations at different levels of representation can be found in various books.[9, 448, 524, 976]

The problems associated with simply getting a translator written became tractable during the 1970s. Since then the issues associated with translators have been the engineering problem of being able to process existing source code and the technical problem of generating high-quality machine code. The focus of code optimization research continues to evolve. It started out concentrating on expressions, then basic blocks, then complete functions and now complete programs. Hardware characteristics have not stood still either. Generating optimized machine code can now require knowledge of code and data cache behaviors, speculative execution, dependencies between instructions and their operands. There is also the issue of processor vendors introducing a range of products, all supporting the same instruction set but at different price levels and different internal performance enhancements; optimal instruction selection can now vary significantly across a single processor family.

Sometimes all the information about some of the components used by a program will not be known until it is installed on the particular host that executes it; for instance, any additional instructions supported over those provided in the base instruction set for that processor, the relative timings of instructions for that processor model, and the version of any dynamic linked libraries. These can also change because of other systems software updates. Also spending a lot of time during application installation generating an optimal executable program is not always acceptable to end users. One solution is to perform optimizations on the program while it is executing. Because most of the execution time usually occurs within a small percentage of a program's machine code, an optimizer only needs to concentrate on these areas. Experimental systems are starting to deliver interesting results.[742]

Thorup[1352] has shown that a linear (in the number of nodes and vertices in the control flow graph) algorithm for register allocation exists that is within a factor of seven (six if no short-circuit evaluation is used) of the optimal solution for any C program that does not contain `gotos`.

One way of finding optimal instruction sequences is to generate all possible sequences and to select the optimal one that provides the desired input to output transformation. Massalin[901] built a *superoptimizer* to do just that; it worked off-line and was not intended to be used to generate instruction sequences during translation. Bansal and Aiken[91] built a superoptimizer that is intended to be used within a translator to find optimal instruction sequences. The tools used various strategies to reduce the search space, e.g., pruning instruction sequences known to be nonoptimal and maintaining a database of previously generated optimal

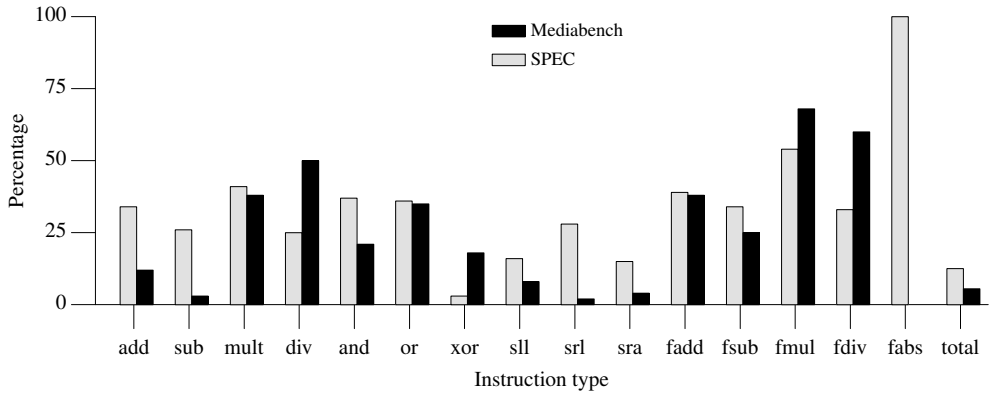

Figure 0.3: Dynamic frequency, percentage calculated over shown instructions (last column gives percentage of these instruction relative to all instructions executed) during execution of the SPEC and MediaBench benchmarks of some computational oriented instructions. Adapted from Yi and Lilja.[1492]

sequences.

Code optimization is a, translation time, resource-hungry process. To reduce the quantity of analysis that needs to be performed, optimizers have started to use information on a program's runtime characteristics. This profile information enables optimizers to concentrate resources on frequently executed sections of code (it also provides information on the most frequent control flow path in conditional statements, enabling the surrounding code to be tuned to this most likely case).[527, 1490] However, the use of profile information does not always guarantee better performance.[807]

The stability of execution profiles, that is the likelihood that a particular data set will always highlight the same sections of a program as being frequently executed is an important issue. A study by Chilimbi[227] found that data reference profiles, important for storage optimization, were stable, while some other researchers have found that programs exhibit different behaviors during different parts of their execution.[1227]

Optimizers are not always able to detect all possible savings. A study by Yi and Lilja[1492] traced the values of instruction operands during program execution. They found that a significant number of operations could have been optimized (see Figure 0.3) had one of their operand values been known at translation time (e.g., adding/subtracting zero, multiplying by 1, subtracting/dividing two equal values, or dividing by a power of 2).

Power consumption

optimize power consumption

The following discussion is based one that can be found in Hsu, Kremer and Hsiao.[602] The dominant source of power consumption in digital CMOS circuits (the fabrication technology used in mass-produced processors) is the dynamic power dissipation, P, which is based on three factors:

$$P \propto CV^2F \tag{0.1}$$

where C is the effective switching capacitance, V the supply voltage, and F the clock speed. A number of technical issues prevent the voltage from being arbitrarily reduced, but there are no restrictions on reducing the clock speed (although some chips have problems running at too low a rate).

For cpu bound programs simply reducing the clock speed does not usually lead to any significant saving in total power consumption. A reduction in clock speed often leads to a decrease in performance and the program takes longer to execute. The product of dynamic power consumption and time taken to execute remains almost unchanged (because of the linear relationship between dynamic power consumption and clock speed). However, random access memory is clocked at a rate that can be an order of magnitude less than the processor clock rate.

For memory-intensive applications a processor can be spending most of its time doing nothing but waiting for the results of load instructions to appear in registers. In these cases a reduction in processor clock rate will have little impact on the performance of a program. Program execution time, T, can be written as:

$$T = T_{cpu\_busy} + T_{memory\_busy} + T_{cpu\_and\_mem\_busy} \tag{0.2}$$

An analysis (using a processor simulation) of the characteristics of the following code:

```
1  for (j = 0; j < n; j++)
2     for (i = 0; i < n; i++)
3        accu += A[i][j];
```

found that (without any optimization) the percentage of time spent in the various subsystems was: *cpu_busy=0.01%*, *memory_busy=93.99%*, *cpu_and_mem_busy=6.00%*.

Given these performance characteristics, a factor of 10 reduction in the clock rate and a voltage reduction from 1.65 to 0.90 would reduce power consumption by a factor of 3, while only slowing the program down by 1% (these values are based on the Crusoe TM5400 processor).

Performing optimizations changes the memory access characteristics of the loop, as well as potentially reducing the amount of time a program takes to execute. Some optimizations and their effect on the performance of the preceding code fragment include the following:

loop control 1774
variable array 994
row-major storage order

- Reversing the order of the loop control variables (arrays in C are stored in row-major order) creates spatial locality, and values are more likely to have been preloaded into the cache: *cpu_busy=18.93%, memory_busy=73.66%, cpu_and_mem_busy=7.41%*

loop unrolling 1774
basic block 1710

- Loop unrolling increases the amount of work done per loop iteration (decreasing loop housekeeping overhead and potentially increasing the number of instructions in a basic block): *cpu_busy=0.67%, memory_busy=65.60%, cpu_and_mem_busy=33.73%*
- Prefetching data can also be a worthwhile optimization:[1408] *cpu_busy=0.67%, memory_busy=74.04%, cpu_and_mem_busy=25.29%*

These ideas are still at the research stage[601] and have yet to appear in commercially available translators (support, in the form of an instruction to change frequency/voltage, also needs to be provided by processor vendors).

At the lowest level processors are built from transistors, which are grouped together to form logic gates. In CMOS circuits power is dissipated in a gate when its output changes (i.e., it goes from 0 to 1, or from 1 to 0). Vendors interested in low power consumption try to minimize the number of gate transitions made during the operation of a processor. Translators can also help here. Machine code instructions consist of sequences of zeros and ones. Differences in bit patterns between adjacent instructions, encountered during program execution, cause gate transitions. The Hamming distance between two binary values (instructions) is the number of places at which their bit settings differ. Ordering instructions to minimize the total Hamming distance over the entire sequence will reduce power consumption in the instruction decoding area of a processor. Simulations based on such a reordering have shown savings of 13% to 20%.[824]

5 Execution environment

environment 104
execution

Two kinds of execution environment are specified in the C Standard, hosted and freestanding. These tend to affect implementations in terms of the quantity of resources provided (functionality to support library requirements— e.g., I/O, memory capacity, etc.).

There are classes of applications that tend to occur in only one of these environments, which can make it difficult to classify an issue as being application- or environment-based.

For hosted environments C programs may need to coexist with programs written in a variety of languages. Vendors often define a set of conventions that programs need to follow; for instance, how parameters are passed. The popularity of C for systems development means that such conventions are often expressed in C terms and the implementations of other languages have to adapt to the C view of how things work.

Existing environments have affected the requirements in the C Standard library. Unlike some languages the C language has tried to take the likely availability of functionality in different environments into account. For instance, the inability of some hosts to support signals has meant that there is no requirement that any signal handling (other than function stubs) be provided by an implementation. Minimizing the dependency on constructs being supported by a host environment enables C to be implemented on a wide variety of platforms. This wide implementability comes at the cost of some variability in supported constructs.

5.1 Host processor characteristics

host processors introduction

It is often recommended that developers ignore the details of host processor characteristics. However, the C language was, and continues to be, designed for efficient mapping to commonly available processors. Many of the benchmarks by which processor performance is measured are written in C. A detailed analysis of C needs to include a discussion of processor characteristics.

0 SPEC benchmarks

Many developers continue to show a strong interest in having their programs execute as quickly as possible, and write code that they think will achieve this goal. Developer interest in processor characteristics is often driven by this interest in performance and efficiency. Developer interest in performance could be considered to be part of the culture of programming. It does not seem to be C specific, although this language's reputation for efficiency seems to exacerbate it. There is sometimes a customer-driven requirement for programs to execute within resource constraints (execution time and memory being the most common constrained resources). In these cases detailed knowledge of processor characteristics may help developers tune an application (although algorithmic tuning invariably yields higher returns on investment). However, the information given in this book is at the level of a general overview. Developers will need to read processor vendor's manuals, very carefully, before they can hope to take advantage of processor-specific characteristics by changing how they write source code.

The following are the investment issues, from the software development point of view, associated with processor characteristics:

- Making effective use of processor characteristics usually requires a great deal of effort (for an in-depth tutorial on getting the best out of a particular processor see,[1343] for an example of performance forecasting aimed at future processors see Armstrong and Eigenmann[57]). The return on investment of this effort is often small (if not zero). Experience shows that few developers invest the time needed to systematically learn about individual processor characteristics. Preferring, instead, to rely on what they already know, articles in magazines, and discussions with other developers. A small amount of misguided investment is no more cost effective than overly excessive knowledgeable investment.
- Processors change more frequently than existing code. Although there are some application domains where it appears that the processor architecture is relatively fixed (e.g., the Intel x86 and IBM 360/370/3080/3090/etc.), the performance characteristics of different members of the same family can still vary dramatically. Within the other domains new processor architectures are still being regularly introduced. The likelihood of a change of processor remains an important issue.
- The commercial availability of translators capable of producing machine code, the performance of which is comparable to that of handwritten assembler (this is not true in some domains;[1254] one study[1395] found that in many cases translator generated machine code was a factor of 5–8 times slower than hand crafted assembler) means that any additional return on developer resource investment is likely to be low.

translator performance vs. assembler

Commercial and application considerations have caused hardware vendors to produce processors aimed at several different markets. It can be said that there are often family characteristics of processors within a

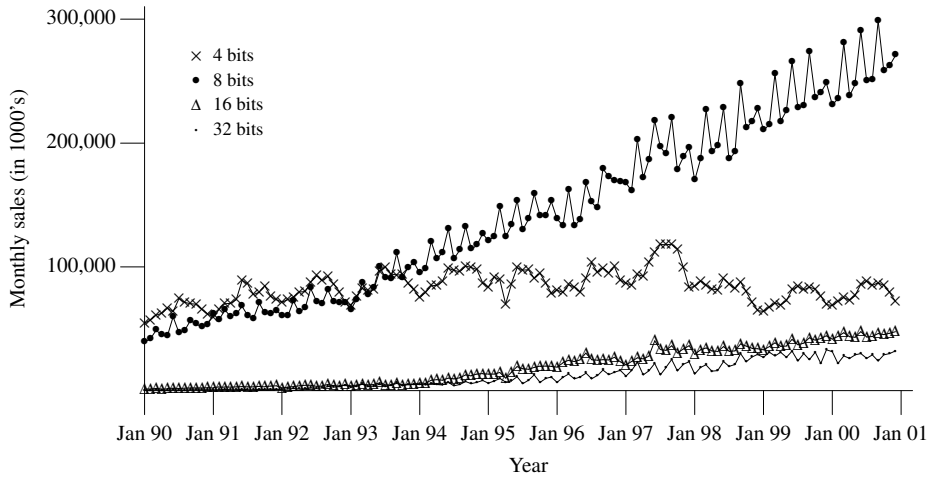

Figure 0.4: Monthly unit sales of microprocessors having a given bus width. Adapted from Turley[1369] (using data supplied by Turley).

given market, although the boundaries are blurred at times. It is not just the applications that are executed on certain kinds of processors. Often translator vendors target their products at specific kinds of processors. For instance, a translator vendor may establish itself within the embedded systems market. The processor architectures can have a dramatic effect on the kinds of problems that machine code generators and optimizers need to concern themselves with. Sometimes the relative performance of programs written in C, compared to handwritten assembler, can be low enough to question the use of C at all.

- *General purpose processors.* These are intended to be capable of running a wide range of applications. The processor is a significant, but not dominant, cost in the complete computing platform. The growing importance of multimedia applications has led many vendors to extend existing architectures to include instructions that would have previously only been found in DSP processors.[1254] The market size can vary from tens of millions (e.g., Intel x86[1335]) to hundreds of millions (e.g., ARM[1335]).
- *Embedded processors.* These are used in situations where the cost of the processor and its supporting chip set needs to be minimized. Processor costs can be reduced by reducing chip pin-out (which reduces the width of the data bus) and by reducing the number of transistors used to build the processor. The consequences of these cost savings are that instructions are often implemented using slower techniques and there may not be any performance enhancers such as branch prediction or caches (or even multiple and divide instructions, which have to be emulated in software). Some vendors offer a range of different processors, others a range of options within a single family, using the same instruction set (i.e., the price of an Intel i960 can vary by an order of magnitude, along with significant differentiation in its performance, packaging, and level of integration). The total market size is measured in billions of processors per year (see Figure 0.4).

DSP processors

- *Digital Signal Processors (DSP).* As the name suggests, these processors are designed for manipulating digital signals— for instance, decoding MPEG data streams, sending/receiving data via phone lines, and digital filtering types of applications. These processors are specialized to perform this particular kind of application very well; it is not intended that nondigital signal-processing applications ever execute on them. Traditionally DSPs have been used in applications where dataflow is the dominating factor;[120] making the provision of handcrafted library routines crucial. Recently new markets, such as telecoms and the automobile industry have started to use DSPs in a big way, and their applications have tended to be dominated by control flow, reducing the importance of libraries. Araújo[331] contains an up-to-date discussion on generating machine code for DSPs. The total worldwide market in 1999 was 0.6 billion processors;[1335] individual vendors expect to sell hundreds of millions of units.

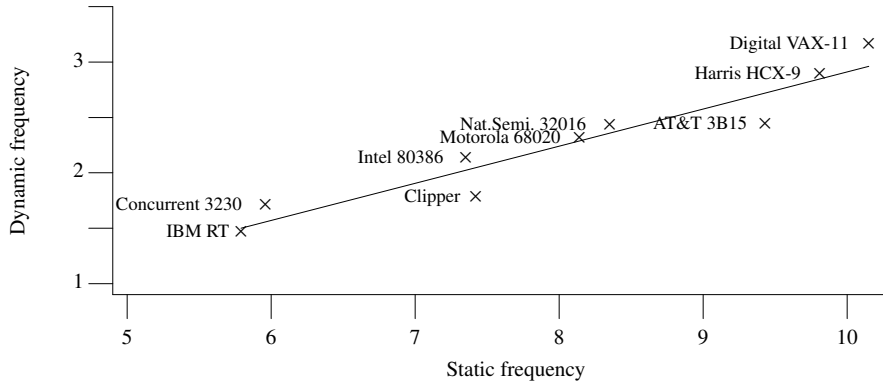

Figure 0.5: Dynamic/static frequency of *call* instructions. Adapted from Davidson.[325]

- *Application Specific Instruction-set Processors (ASIP).* Note that the acronym ASIC is often heard, this refers to an Application Specific Integrated Circuit— a chip that may or may not contain an instruction-set processor. These processors are designed to execute a specific program. The general architecture of the processor is fixed, but the systems developer gets to make some of the performance/resource usage (transistors) trade-off decisions. These decisions can involve selecting the word length, number of registers, and selecting between various possible instructions.[488] The cost of retargeting a translator to such program-specific ASIPs has to be very low to make it worthwhile. Processor description driven code generators are starting to appear,[844] which take the description used to specify the processor characteristics and build a translator for it. While the market for ASICs exceeds $10 billion a year, the ASIP market is relatively small (but growing).
- *Number crunchers.* The quest for ever-more performance has led to a variety of designs that attempt to spread the load over more than one processor. Technical problems associated with finding sufficient work, in existing source code (which tends to have a serial rather than parallel form) to spread over more than one processor has limited the commercial viability of such designs. They have only proven cost effective in certain, application-specific domains where the computations have a natural mapping to multiple processors. The cost of the processor is often a significant percentage of the complete computing device. The market is small and the customers are likely to be individually known to the vendor.[45] The use of clusters of low-price processors, as used in Beowulf, could see the demise of processors specifically designed for this market.[109]

There are differences in processor characteristics within the domains just described. Processor design evolves over time and different vendors make different choices about the best way to use available resources (on chip transistors). For a detailed analysis of the issues involved for the Sun UltraSPARC processor, see.[1498]

instruction profile for different processors

The profile of the kinds of instructions generated for different processors can differ in both their static and their dynamic characteristics, even within the same domain. This was shown quite dramatically by Davidson, Rabung, and Whalley[325] who measured static and dynamic instruction frequencies for nine different processors using the same translator (generating code for the different processors) on the same source files (see Figure 0.5). For a comparison of RISC processor instruction counts, based on the SPEC benchmarks, see McMahan and Lee.[921]

The following are the lessons to be learned from the later discussions on processor details:

- Source code that makes the best use of one particular processor is unlikely to make the best use of any other processor.
- Making the best use of a particular processor requires knowledge of how it works and measurements of the program running on it. Without the feedback provided by the measurement of dynamic program

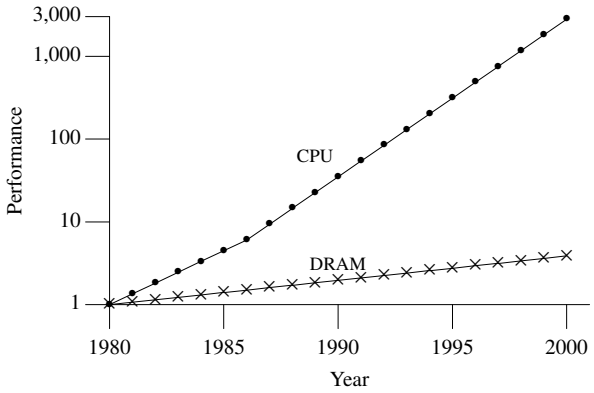

Figure 0.6: Relative performance of CPU against storage (DRAM), 1980==1. Adapted from Hennessy.[560]

behavior, it is almost impossible to tune a program to any host.

5.1.1 Overcoming performance bottlenecks

There continues to be a market for processors that execute programs more quickly than those currently available. There is a commercial incentive to build higher-performance processors. Processor design has reached the stage where simply increasing the processor clock rate does not increase rate of program execution.[1178] A processor contains a variety of units, any one of which could be the bottleneck that prevents other units from delivering full performance. Some of these bottlenecks, and their solutions, can have implications at the source code level (less than perfect branch predictions[695]) and others don't (the possibility of there being insufficient pins to support the data bandwidth required; pin count has only been increasing at 16% per year[181]).

Data and instructions have to be delivered to the processor, from storage, to keep up with the rate it handles them. Using faster memory chips to keep up with the faster processors is not usually cost effective. Figure 0.6 shows how processor performance has outstripped that of DRAM (the most common kind of storage used). See Dietz and Mattox[355] for measurements of access times to elements of arrays of various sizes, for 13 different Intel x86 compatible processors whose clock rates ranged from 100 MHz to 1700 MHz.

A detailed analysis by Agarwal, Hrishikesh, Keckler, and Burger[5] found that delays caused by the time taken for signals to travel through on-chip wires (12–32 cycles to travel the length of a chip using 35nm CMOS technology, clocked at 10GHz), rather than transistor switching speed, was likely to be a major performance factor in future processors. Various methods have been proposed[990] to get around this problem, but until such processor designs become available in commercially significant quantities they are not considered further here.

cache

Cache

A commonly used solution to the significant performance difference between a processor and its storage is to place a small amount of faster storage, a *cache*, between them. Caching works because of locality of reference. Having accessed storage location X, a program is very likely to access a location close to X in the very near future. Research has shown[560] that even with a relatively small cache (i.e., a few thousand bytes) it is possible to obtain significant reductions in accesses to main storage.

Modern, performance-based processors have two or more caches. A level 1 cache (called the *L1 cache*), which can respond within a few clock cycles (two on the Pentium 4, four on the UltraSPARC III), but is relatively small (8 K on the Pentium 4, 64 K on the UltraSPARC III), and a level 2 cache (called the *L2 cache*) which is larger but not as quick (256 K/7 clocks on the Pentium 4). Only a few processors have further levels of cache. Main storage is significantly larger, but its contents are likely to be more than 250 clock cycles away.

Developer optimization of memory access performance is simplest when targeting processors that contain a cache, because the hardware handles most of the details. However, there are still cases where developers may need to manually tune memory access performance (e.g., application domains where large, sophisticated hardware caches are too expensive, or where customers are willing to pay for their applications to execute as fast as possible on their existing equipment). Cache behavior when a processor is executing more than one program at the same time can be quite complex.[219, 1358]

The locality of reference used by a cache applies to both instructions and data. To maximize locality of reference, translators need to organize instructions in the order that an executing program is most likely to need them and allocate object storage so that accesses to them always fill the cache with values that will be needed next. Knowing which machine code sequences are most frequently executed requires execution profiling information on a program. Obtaining this information requires effort by the developer. It is necessary to instrument and execute a program on a representative set of data. This data, along with the original source is used by some translators to create a program image having a better locality of reference. It is also possible to be translator-independent by profiling and reorganizing the basic blocks contained in executable programs. Tomiyama and Yasuura[1354] used linear programming to optimize the layout of basic blocks in storage and significantly increased the instruction cache hit rate. Running as a separate pass after translation also reduces the need for interactive response times; the analysis took more than 10 hours on a 85 MHz microSPARC-II.

Is the use of a cache by the host processor something that developers need to take into account? Although every effort has been made by processor vendors to maximize cache performance and translator vendors are starting to provide the option to automatically tune the generated code based on profiling information,[547] sometimes manual changes to the source (by developers) can make a significant difference. It is important to remember that any changes made to the source may only make any significant changes for one particular processor implementation. Other implementations within a processor family may share the same instruction set but they could have different cache behaviors. Cache-related performance issues are even starting to make it into the undergraduate teaching curriculum.[816]

A comparison by Bahar, Calder, and Grunwald[79] showed that code placement by a translator could improve performance more than a hardware-only solution; the two combined can do even better. In some cases the optimizations performed by a translator can affect cache behavior, for instance loop unrolling. Translators that perform such optimizations are starting to become commercially available.[252] The importance of techniques for tuning specific kinds of applications are starting to be recognized (transaction processing as in Figure 0.8,[11] numerical computations[1367]).

1774 loop unrolling

Specific cases of how optimizers attempt to maximize the benefits provided by a processor's cache are discussed in the relevant C sentences. In practice these tend to be reorganizations of the sequence of instructions executed, not reorganizations of the data structures used. Intel[628] provides an example of how reorganization of a data structure can improve performance on the Pentium 4:

```
1  struct {
2          float x, y, z,   r, g, b;
3          } a_screen_3D[1000];
4  struct {
5          float x[1000], y[1000], z[1000];
6          float r[1000], g[1000], b[1000];
7          } b_screen_3D;
8  struct {
9          float x[4], y[4], z[4];
10         float r[4], g[4], b[4];
11         } c_screen_3D[250];
```

The structure declaration used for `a_screen_3D` might seem the obvious choice. However, it is likely that operations will involve either the tuple `x`, `y`, and `z`, or the tuple `r`, `g`, and `b`. A cache line on the Pentium 4 is 64 bytes wide, so a fetch of one of the `x` elements will cause the corresponding `r`, `g`, and `b` elements to be loaded. This is a waste of resource usage if they are not accessed. It is likely that all elements of the

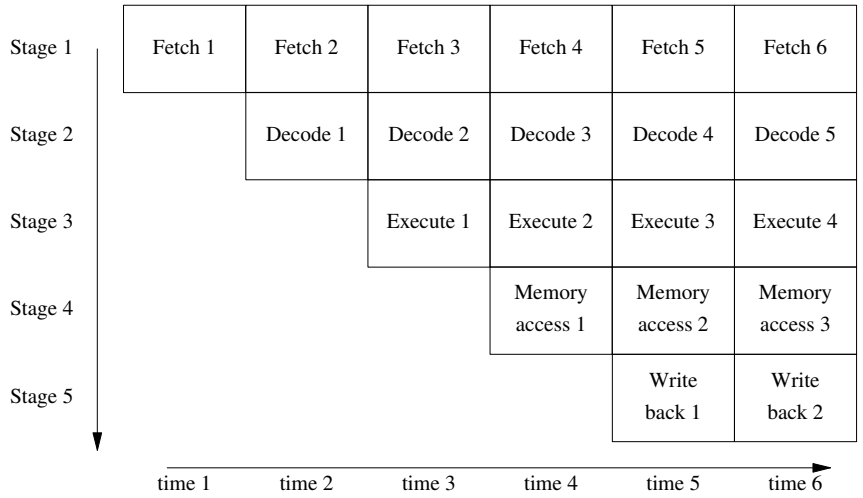

Figure 0.7: Simplified diagram of some typical stages in a processor instruction pipeline: Instruction fetch, decode, execute, memory access, and write back.

array will be accessed in sequence and the structure declaration used for `b_screen_3D` makes use of this algorithmic information. An access to an element of `x` will cause subsequent elements to be loaded into the cache line, ready for the next iteration. The structure declaration, suggested by Intel, for `c_screen_3D` makes use of a Pentium 4 specific characteristic; reading/writing 16 bytes from/to 16-byte aligned storage is the most efficient way to use the storage pipeline. Intel points to a possible 10% to 20% performance improvement through modifications that optimize cache usage; a sufficiently large improvement to warrant using the nonobvious, possibly more complex, data structures in some competitive markets.

storage dividing up

Dividing up storage

Many host operating systems provide the ability for programs to make use of more storage than the host has physical memory (so-called *virtual memory*). This virtual memory is divided up into units called *pages*, which can be *swapped* out of memory to disk when it is not needed.[560] There is a severe performance penalty on accesses to data that has been swapped out to disk (i.e., some other page needs to be swapped out and the page holding the required data items swapped back into memory from disk). Developers can organize data accesses to try to minimize this penalty. Having translators do this automatically, or even having them insert code into the program image to perform the swapping at points that are known to be not time-critical is a simpler solution.[973]

Speeding up instruction execution

processor pipeline

A variety of techniques are used to increase the number of instructions executed per second. Most processors are capable of executing more than one instruction at the same time. The most common technique, and one that can affect program behavior, is instruction *pipelining*. Pipelining breaks instruction execution down into a series of stages (see Figure 0.7). Having a different instruction processed by each stage at the same time does not change the execution time of a single instruction. But it does increase the overall rate of instruction execution because an instruction can complete at the end of every processor cycle. Many processors break down the stages shown in Figure 0.7 even further. For instance, the Intel Pentium 4 has a 20-stage pipeline.

signal interrupt 191
abstract machine processing

The presence of a pipeline can affect program execution, depending on processor behavior when an exception is raised during instruction execution. A discussion on this issue is given elsewhere.

Other techniques for increasing the number of instructions executed per second include: *VLIW* (Very Long Instruction Word) in which multiple operations are encoded in one long instruction, and parallel execution in which a processor contains multiple instruction execution units.[1342] These techniques have no more direct

impact on program behavior than instruction pipelining. In practice translators have had difficulty finding long sequences of instructions that can be executed in some concurrent fashion. Some help (e.g., source code annotations) from the developer is still needed for these processors to approach peak performance.

5.2 Runtime library

An implementation's runtime library handles those parts of a program that are not directly translated to machine code. Calls to the functions contained in this library may occur in the source or be generated by a translator (i.e., to some internal routine to handle arithmetic operations on values of type **`long long`**). The runtime library may be able to perform the operation completely (e.g., the trigonometric functions) or may need to call other functions provided by the host environment (e.g., O/S function, not C implementation functions).

6 Measuring implementations

Measuring implementations

Although any number of different properties of an implementation might be measured, the most commonly measured is execution time performance of the generated program image. In an attempt to limit the number of factors influencing the results, various organizations have created sets of test programs— *benchmarks*— that are generally accepted within their domain. Some of these test programs are discussed below (SPEC, the Transaction Processing council, Embedded systems, Linpack, and DSPSTONE). In some application areas the size of the program image can be important, but there are no generally accepted benchmarks for comparing size of program image. The growth in sales of mobile phones and other hand-held devices has significantly increased the importance of minimizing the electrical energy consumed by a program (the energy consumption needs of different programs performing the same function are starting to be compared[103]).

141 program image

A good benchmark will both mimic the characteristics of the applications it is intended to be representative of, and be large enough so that vendors cannot tune their products to perform well on it without also performing well on the real applications. The extent to which the existing benchmarks reflect realistic application usage is open to debate. Not only can different benchmarks give different results, but the same benchmark can exhibit different behavior with different input.[378] Whatever their shortcomings may be the existing benchmarks are considered to be the best available (they are used in almost all published research).

It has long been an accepted truism that programs spend most of their time within loops and in particular a small number of such loops. Traditionally most processor-intensive applications, that were commercially important, have been scientific or engineering based. A third kind of application domain has now become commercially more important (in terms of hardware vendors making sales)— data-oriented applications such as transaction processing and data mining.

1763 iteration statement syntax

Some data-oriented applications share a characteristic with scientific and engineering applications in that a large proportion of their time is spent executing a small percentage of the code. However, it has been found that for Online Transaction Processing (OLTP), specifically the TPC-B benchmarks, the situation is more complicated.[1143] Recent measurements of four commercial databases running on an Intel Pentium processor showed that the processor spends 60% of its time stalled[11] (see Figure 0.8).

0 TPC-B

A distinction needs to be made between characteristics that are perceived, by developers, to make a difference and those that actually do make a difference to the behavior of a program. Discussion within these Common Implementation sections is concerned with constructs that have been shown, by measurement, to make a difference to the execution time behavior of a program. Characteristics that relate to perceived differences fall within the realm of discussions that occur in the Coding guideline sections.

The measurements given in the Common Implementation sections tend to be derived from the characteristics of a program while it is being executed— dynamic measurements. The measurements given in the Usage sections tend to be based on what appears in the source code— static measurements.

6.1 SPEC benchmarks

SPEC benchmarks

Processor performance based on the SPEC (Standard Performance Evaluation Corporation, `http://www.spec.org`) benchmarks are frequently quoted by processor and implementation vendors. Academic research on optimizers often base their performance evaluations on the programs in the SPEC suite. SPEC benchmarks

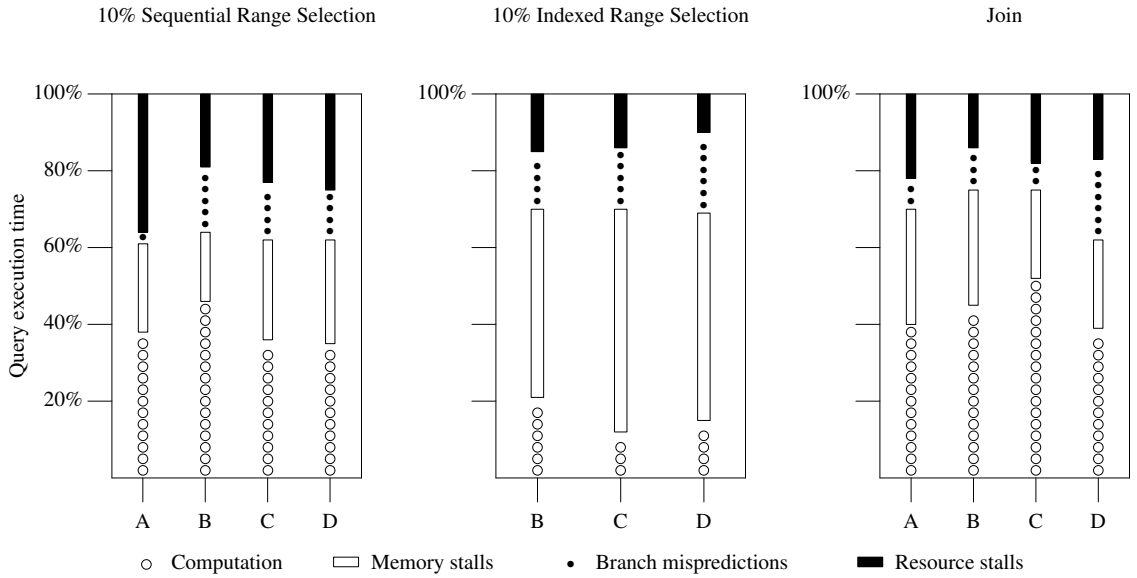

Figure 0.8: Execution time breakdown, by four processor components (bottom of graphs) for three different application queries (top of graphs). Adapted from Ailamaki.[11]

cover a wide range of performance evaluations: graphics, NFS, mailservers, and CPU.[365] The CPU benchmarks are the ones frequently used for processor and translator measurements.

The SPEC CPU benchmarks are broken down into two groups, the integer and the floating-point programs; these benchmarks have been revised over the years, the major releases being in 1989, 1992, 1995, and 2000. A particular set of programs is usually denoted by combining the names of these components. For instance, SPECint95 is the 1995 integer SPEC benchmark and SPECfp2000 is the 2000 floating-point benchmark.

The SPEC CPU benchmarks are based on publicly available source code (written in C for the integer benchmarks and, predominantly, Fortran and C for the floating-point). The names of the programs are known and versions of the source code are available on the Internet. The actual source code used by SPEC may differ slightly because of the need to be able to build and execute identical programs on a wide range of platforms (any changes needed to a program's source to enable it to be built are agreed to by the SPEC membership).

A study by Saavedra and Smith[1190] investigated correlations between constructs appearing in the source code and execution time performance of benchmarks that included SPEC.

6.2 Other benchmarks

benchmarks

The SPEC CPU benchmarks had their origins in the Unix market. As such they were and continue to be aimed at desktop and workstation platforms. Other benchmarks that are often encountered, and the rationale used in their design, include the following:

- DSPSTONE[1395] is a DSP-oriented set of benchmarks,
- The characteristics of programs written for embedded applications are very different.[390] The EDN Embedded Microprocessor Benchmarking Consortium (EEMBC, pronounced Embassy — http://www.eembc.org), was formed in 1997 to develop standard performance benchmarks for the embedded market (e.g., telecommunications, automotive, networking, consumer, and office equipment). They currently have over 40 members and their benchmark results are starting to become known.
- MediaBench[818] is a set of benchmarks targeted at a particular kind of embedded application—multimedia and communications. It includes programs that process data in various formats, including JPEG, MPEG, GSM, and postscript.

- The Olden benchmark[198] attempts to measure the performance of architectures based on a distributed memory. Olden benchmark
- The Stanford ParalleL Applications for SHared memory (SPLASH, now in its second release as SPLASH-2[14481]), is a suite of parallel applications intended to facilitate the study of centralized and distributed shared-address-space multiprocessors.
- The TPC-B benchmark from the Transaction Processing Performance Council (TPC). TPC-B

> *TPC-B models a banking database system that keeps track of customers' account balances, as well as balances per branch and teller. Each transaction updates a randomly chosen account balance, which includes updating the balance of the branch the customer belongs to and the teller from which the transaction is submitted. It also adds an entry to the history table which keeps a record of all submitted transactions.* Ranganathan[1143]

6.3 Processor measurements

Processor vendors also measure the characteristics of executing programs. Their reason is to gain insights that will enable them to build better products, either faster versions of existing processors or new processors. What are these measurements based on? The instructions executed by a processor are generated by translators, which may or may not be doing their best with the source they are presented with. Translator vendors may, or may not, have tuned their output to target processors with known characteristics. Fortunately this book does not need to concern itself further with this problem.

Processor measurements have been used to compare different processors,[248] predict how many instructions a processor might be able to issue at the same time,[1259] and tune arithmetic operations.[885] Processor vendors are not limited to using benchmarks or having access to source code to obtain useful information; Lee[820] measured the instruction characteristics of several well-known Windows NT applications.

Coding Guidelines

7 Introduction

The intent of these coding guidelines is to help management minimize the cost of ownership of the source code they are responsible for. The guidelines take the form of prepackaged recommendations of which source constructs to use, or not use, when more than one option is available. These coding guidelines sit at the bottom layer of what is potentially a complex, integrated software development environment. coding guidelines introduction

Adhering to a coding guideline is an immediate cost. The discussion in these coding guidelines' sections is intended to help ensure that this cost payment is a wise investment yielding savings later.

The discussion in this section provides the background material for what appears in other coding guideline sections. It is also the longest section of the book and considers the following:

- The financial aspects of software development and getting the most out of any investment in adhering to coding guidelines.
- Selecting, adhering to, and deviating from guidelines.
- Applications and their influence on the source that needs to be written.
- Developers; bounding the limits, biases, and idiosyncrasies of their performance.

There are other Coding guideline subsections containing lengthy discussions. Whenever possible such discussions have been integrated into the C sentence-based structure of this book (i.e., they occur in the relevant C sentences).

The term used in this book to describe people whose jobs involve writing source code is *software developer*. The term *programmer* tends to be associated with somebody whose only job function is to write software. A

typist might spend almost 100% of the day typing. People do not spend all their time directly working on source code (in most studies, the time measured on this activity rarely rises above 25%), therefore the term programmer is not appropriate. The term software developer, usually shortened to *developer*, was chosen because it is relatively neutral, but is suggestive of somebody whose primary job function involves working with source code.

Developers often object to following coding guidelines, which are often viewed as restricting creative freedom, or forcing them to write code in some unnatural way. Creative freedom is not something that should be required at the source code implementation level. While particular ways of doing things may appeal to individual developers, such usage can be counter-productive. The cost to the original developer may be small, but the cost to subsequent developers (through requiring more effort by them to work with code written that way) may not be so small.

8 Source code cost drivers

coding guidelines cost drivers

Having source code occupy disk space rarely costs very much. The cost of ownership for source code is incurred when it is used. Possible uses of source code include:

- modifications to accommodate customer requests which can include fixing faults;
- major updates to create new versions of a product; and
- ports to new platforms, which can include new versions of platforms already supported.

These coding guideline subsections are applicable during initial implementation and subsequent modifications at the source code level. They do not get involved in software design issues, to the extent that these are programming language-independent. The following are the underlying factors behind these cost drivers:

- *Developer characteristics (human factors).* Developers fail to deduce the behavior of source code constructs, either through ignorance of C or because of the limits in human information processing (e.g., poor memory of previously read code, perception problems leading to identifiers being misread, or information overload in short-term memory) causing faults to be introduced. These issues are dealt with here in the Coding guideline subsections.
- *Translator characteristics.* A change of translator can result in a change of behavior. Changes can include using a later version of the translator originally used, or a translator from a different vendor. Standards are rarely set in stone and the C Standard is certainly not. Variations in implementation behavior permitted by the standard means that the same source code can produce different results. Even the same translator can have its behavior altered by setting different options, or by a newer release. Differences in translator behavior are discussed in Commentary and Common Implementations subsections. Portability to C++ and C90 translators is dealt with in their respective sections.
- *Host characteristics.* Just like translator behavior this can vary between releases (updates to system libraries) and host vendors. The differences usually impact the behavior of library calls, not the language. These issues are dealt with in Common Implementation sections.
- *Application characteristics.* Programs vary in the extent to which they need to concern themselves with the host on which they execute— for instance, accessing memory ports. They can also place different demands on language constructs— for instance, floating-point or dynamic memory allocation. These issues are dealt with under Usage, indirectly under Common Implementations and here in Coding Guideline sections.

Usage 0 1

- *Product testing.* The complexity of source code can influence the number of test cases that need to be written and executed. This complexity can be affected by design, algorithmic and source code construct selection issues. The latter can be the subject of coding guidelines.

coding 0 guidelines testability

Covering all possible source code issues is impossible. Frequency of occurrence is used to provide a cutoff filter. The main purpose of the information in the Usage sections is to help provide evidence for what filtering to apply.

Usage 0 1

8.1 Guideline cost/benefit

When a guideline is first encountered it is educational. It teaches developers about a specific problem that others have encountered and that they are likely to encounter. This is a one-time learning cost (that developers are likely to have to pay at some time in their careers). People do forget, so there may be a relearning cost. (These oversights are the sort of thing picked up by an automated guideline enforcement tool, jogging the developer's memory in the process.)

coding guidelines importance

Adhering to guidelines requires an investment in the form of developer's time. Like all investments it needs to be made on the basis that a later benefit will provide an adequate return. It is important to bear in mind that failure to recoup the original investment is not the worst that can happen. The value of lost opportunity through being late to market with a product can equal the entire development budget. It is management's responsibility to select those coding guidelines that have a return on investment applicable to a particular project.

0 NPV

A set of guidelines can be viewed as a list of recommended coding practices, the economic cost/benefit of which has been precalculated and found to be acceptable. This precalculation, ideally, removes the need for developers to invest in performing their own calculations. (Even in many situations where they are not worthwhile, the cost of performing the analysis is greater than the cost of following the guideline.)

Researchers[90, 1321] are only just starting to attempt to formally investigate the trade-off involved between the cost of creating maintainable software and the cost of maintaining software.

A study by Visaggio[1423] performed a retrospective analysis of a reengineering process that had been applied to a legacy system containing 1.5 M lines. The following is his stated aim:

Visaggio[1423]

1. Guidelines are provided for calculating the quality and economic scores for each component; These can be reused in other projects, although they can and must also be continually refined with use;

2. A model for determining the thresholds on each axis is defined; the model depends on the quality and economics policy adopted by the organization intending to renew the legacy system;

3. A decision process is included, that helps to establish which renewal process should be carried out for each component; this process may differ for components belonging to the same quadrant and depends on the targets the organization intends to attain with the renewal process.

8.1.1 What is the cost?

Guidelines may be more or less costly to follow (in terms of modifying, or not using, constructs once their lack of conformance to a guideline is known). Estimating any cost change caused by having to use constructs not prohibited by a guideline will vary from case to case. It is recognized that the costs of following a guideline recommendation can be very high in some cases. One solution is the deviation mechanism, which is discussed elsewhere.

coding guidelines the cost

0 deviations coding guidelines

Guidelines may be more or less easy to flag reliably from a static analysis tool point of view. The quality of static analysis tools is something that developers need to evaluate when making a purchase decision. These coding guidelines recognize the difficulties in automating some checks by indicating that some should be performed as part of code reviews.

0 code reviews

All guidelines are given equal weight in terms of the likelihood of not adhering to them causing a fault. Without data correlating a guideline not being followed to the probability of the containing code causing a fault, no other meaningful options are available.

8.1.2 What is the benefit?

What is the nature of the benefit obtained from an investment in adhering to coding guidelines? These coding guidelines assume that the intended final benefit is always financial. However, the investment proposal may not list financial benefits as the immediate reason for making it. Possible other reasons include:

coding guidelines the benefit

- mandated by some body (e.g., regulatory authority, customer Q/A department);

- legal reasons— companies want to show that they have used industry best practices, whatever they are, in the event of legal action being taken against them;
- a mechanism for controlling source code: The purpose of this control may be to reduce the dependency on a particular vendor's implementation (portability issues), or it may be an attempt to overcome inadequacies in developer training.

Preventing a fault from occurring is a benefit. How big is this benefit (i.e., what would the cost of the fault have been? How is the cost of a fault measured?) Is it in terms of the cost of the impact on the end user of experiencing the fault in the program, or is it the cost to the vendor of having to deal with it being uncovered by their customers (which may include fixing it)? Measuring the cost to the end user is very difficult to do, and it may involve questions that vendors would rather have left unasked. To simplify matters these guidelines are written from the point of view of the vendor of the product containing software. The cost we consider is the cost to fix the fault multiplied by the probability of the fault needing to be fixed (fault is found and customer requirements demand a fix).

8.1.3 Safer software?

coding guidelines
safer software

Coding guidelines, such as those given in this book, are often promoted as part of the package of measures to be used during the development of safety-critical software.

The fact that adherence to guideline recommendations may reduce the number of faults introduced into the source by developers is primarily an economic issue. The only difference between safety critical software and other kinds of software is the level of confidence required that a program will behave as intended. Achieving a higher level of confidence often involves a higher level of cost. While adherence to guideline recommendations may reduce costs and enable more confidence level boosting tasks to be performed, for the same total cost, management may instead choose to reduce costs and not perform any additional tasks.

Claiming that adhering to coding guidelines makes programs safer suggests that the acceptance criteria being used are not sufficient to achieve the desired level of confidence on their own (i.e., reliance is being placed on adherence to guideline recommendations reducing the probability of faults occurring in sections of code that have not been fully tested).

An often-heard argument is that some language constructs are the root cause of many faults in programs and that banning the use of these constructs leads to fewer faults. While banning the use of these constructs may prevent them from being the root cause of faults, there is rarely any proof that the alternative constructs used will not introduce as many faults, if not more, than the constructs they replace.

This book does not treat *safety-critical* as being a benefit of adherence to guideline recommendations in its own right.

8.2 Code development's place in the universe

development context

Coding guidelines need to take account of the environment in which they will be applied. There are a variety of reasons for creating programs. Making a profit is a common rationale and the only one considered by these coding guidelines. Writing programs for enjoyment, by individuals, involves reasons of a personal nature, which are not considered in this book.

A program is created by developers who will have a multitude of reasons for doing what they do. Training and motivating these developers to align there interests with that of the organization that employs them is outside the scope of this book, although staffing issues are discussed.

coding 0 guidelines staffing

Programs do not exist in isolation. While all applications will want fault-free software, the importance assigned to faults can depend on the relative importance of the software component of the total package. This relative importance will also influence the percentage of resources assigned to software development and the ability of the software manager to influence project time scales.

The kind of customers an organization sells to, can influence the software development process. There are situations where effectively there is a single customer. For instance, a large organization paying for the development of a bespoke application will invariably go through a formal requirements analysis, specification,

design, code, test, and handover procedure. Much of the research on software development practices has been funded by and for such development projects. Another example is software that is invisible to the end user, but is part of a larger product. Companies and projects differ as to whether software controls the hardware or vice versa (the hardware group then being the customer).

Most *Open Source* software development has a single customer, the author of the software.[483, 1010] In this case the procedures followed are likely to be completely different from those followed by paying customers. In a few cases Open Source projects involving many developers have flourished. Several studies[951] have investigated some of the group dynamics of such cooperative development (where the customer seems to be the members of a core team of developers working on the project). While the impact of this form of production on traditional economic structures is widely thought to be significant,[114] these guidelines still treat it as a form of production, which has different cost/benefit cost drivers; whether the motivating factors for individual developers are really any different is not discussed here.

When there are many customers, costs are recouped over many customers, who usually pay less than the development cost of the software. In a few cases premium prices can be charged by market leaders, or by offering substantial customer support. The process used for development is not normally visible to the customer. Development tends to be led by marketing and is rarely structured in any meaningful formal way; in fact too formal a process could actively get in the way of releasing new products in a timely fashion.

Research by Carmel[201] of 12 firms (five selling into the mass market, seven making narrow/direct sales) involved in packaged software development showed that the average firm has been in business for three years, employed 20 people, and had revenues of $1 million (1995 figures).

As pointed out by Carmel and others, time to market in a competitive environment can be crucial. Being first to market is often a significant advantage. A vendor that is first, even with a very poorly architected, internally, application often gets to prosper. While there may be costs to pay later, at least the company is still in business. A later market entrant may have a wonderfully architected product that has scope for future expansion and minimizes future maintenance costs, but without customers it has no future.

A fundamental problem facing software process improvement is how best to allocate limited resources, to obtain optimal results. Large-scale systems undergo continuous enhancement and subcontractors may be called in for periods of time. There are often relatively short release intervals and a fixed amount of resources. These characteristics prohibit revolutionary changes to a system. Improvements have to be made in an evolutionary fashion.

Coding guidelines need to be adaptable to these different development environments. Recognizing that guideline recommendations will be adapted, it is important that information on the interrelationship between them is made available to the manager. These interrelationships need to be taken into account when tailoring a set of guideline recommendations.

8.3 Staffing

The culture of information technology appears to be one of high staff turnover[961] (with reported annual turnover rates of 25% to 35% in Fortune 500 companies). coding guidelines staffing

If developers cannot be retained on a project new ones need to be recruited. There are generally more vacancies than there are qualified developers to fill them. Hiring staff who are less qualified, either in application-domain knowledge or programming skill, often occurs (either through a conscious decision process or because the developer's actual qualifications were not appreciated). The likely competence of future development staff may need to be factored into the acceptable complexity of source code.

A regular turnover of staff creates the need for software that does not require a large investment in upfront training costs. While developers do need to be familiar with the source they are to work on, companies want to minimize familiarization costs for new staff while maximizing their productivity. Source code level guideline recommendations can help reduce familiarization costs in several ways:

- Not using constructs whose behavior varies across translator implementations means that recruitment does not have to target developers with specific implementation experience, or to factor in the cost of

retraining— it will occur, usually through on-the-job learning.

- Minimizing source complexity helps reduce the cognitive effort required from developers trying to comprehend it.
- Increased source code memorability can reduce the number of times developers need to reread the same source.
- Visible source code that follows a consistent set of idioms can take advantage of people's natural ability to categorize and make deductions based on these categorizes.

Implementing a new project is seen, by developers, as being much more interesting and rewarding that maintaining existing software. It is common for the members of the original software to move on to other projects once the one they are working is initially completed. Studies by Couger and Colter[291] investigated various approaches to motivating developers working on maintenance activities. They identified the following two factors:

1. *The motivating potential of the job*, based on skill variety required, the degree to which the job requires completion as a whole (task identity), the impact of the job on others (task significance), degree of freedom in scheduling and performing the job, and feedback from the job (used to calculate a *Motivating Potential Score*, MPS).
2. *What they called an individual's growth need strength (GNS)*, based on a person's need for personal accomplishment, to be stimulated and challenged.

The research provided support for the claim that MPS and GNS could be measured and that jobs could be tailored, to some degree, to people. Management's role was to organize the work that needed to be done so as to balance the MPS of jobs against the GNS of the staff available.

It is your author's experience that very few companies use any formally verified method for measuring developer characteristics, or fitting their skills to the work that needs to be done. Project staffing is often based on nothing more than staff availability and a date by which the tasks must be completed.

8.3.1 Training new staff

developer training

Developers new to a project often need to spend a significant amount of time (often months) building up their knowledge base of a program's source code.[1239] One solution is a training program, complete with well-documented introductions, road maps of programs, and how they map to the application domain, all taught by well-trained teachers. While this investment is cost effective if large numbers of people are involved, most source code is worked on by a relatively small number of people. Also most applications evolve over time. Keeping the material up-to-date could be difficult and costly, if not completely impractical. In short, the cost exceeds the benefit.

In practice new staff have to learn directly from the source code. This may be supplemented by documentation, provided it is reasonably up-to-date. Other experienced developers who have worked on the source may also be available for consultation.

8.4 Return on investment

ROI

The risk of investing in the production of software is undertaken in the expectation of receiving a return that is larger than the investment. Economists have produced various models that provide an answer for the question: "What return should I expect from investing so much money at such and such risk over a period of time?"

Obtaining reliable estimates of the risk factors, the size of the financial investment, and the time required is known to be very difficult. Thankfully, they are outside the scope of this book. However, given the prevailing situation within most development groups, where nobody has had any systematic cost/benefit analysis training, an appreciation of the factors involved can provide some useful background.

Minimizing the total cost of a software product (e.g., balancing the initial development costs against subsequent maintenance costs) requires that its useful life be known. The risk factors introduced by third parties (e.g., competitive products may remove the need for continued development, customers may not purchase the product) mean that there is the possibility that any investment made during development will never be realized during maintenance because further work on the product never occurs.

The physical process of writing source code is considered to be so sufficiently unimportant that doubling the effort involved is likely to have a minor impact on development costs. This is the opposite case to how most developers view the writing process. It is not uncommon for developers to go to great lengths to reduce the effort needed during the writing process, paying little attention to subsequent effects of their actions; reports have even been published on the subject.[1125]

8.4.1 Some economics background

Before going on to discuss some of the economic aspects of coding guidelines, we need to cover some of the basic ideas used in economics calculations. The primary quantity that is used in this book is Net Present Value (NPV). NPV

8.4.1.1 Discounting for time

A dollar today is worth more than a dollar tomorrow. This is because today's dollar can be invested and start earning interest immediately. By tomorrow it will have increased in value. The present value (PV) of a future payoff, C, can be calculated from:

$$PV = discount\ factor \times C \tag{0.3}$$

where the $discountfactor$ is less than one. It is usually represented by:

$$discount\ factor = \frac{1}{1+r} \tag{0.4}$$

where r is known as the rate of return; representing the amount of reward demanded by investors for accepting a delayed payment. The rate of return is often called the *discount rate* or the *opportunity cost* of capital. It is often quoted over a period of a year, and the calculation for PV over n years becomes:

$$PV = \frac{C}{(1+r)^{\mathrm{n}}} \tag{0.5}$$

By expressing all future payoffs in terms of present value, it is possible to compare them on an equal footing.

Example (from Raffo[1136]). A manager has the choice of spending $250,000 on the purchase of a test tool, or the same amount of money on hiring testers. It is expected that the tool will make an immediate cost saving of $500,000 (by automating various test procedures). Hiring the testers will result in a saving of $750,000 in two years time. Which is the better investment (assuming a 10% discount rate)?

$$PV_{tool} = \frac{\$500,000}{(1+0.10)^0} = \$500,000 \tag{0.6}$$

$$PV_{testers} = \frac{\$750,000}{(1+0.10)^2} = \$619,835 \tag{0.7}$$

Based on these calculations, hiring the testers is the better option (has the greatest present value).

8.4.1.2 Taking risk into account

The previous example did not take risk into account. What if the tool did not perform as expected, what if some of the testers were not as productive as hoped? A more realistic calculation of present value needs to take the risk of future payoffs not occurring as expected into account.

A risky future payoff is not worth as much as a certain future payoff. The risk is factored into the discount rate to create an *effective discount rate*: $k = r + \theta$ (where r is the risk-free rate and θ a premium that depends on the amount of risk). The formulae for present value becomes:

$$PV = \frac{C}{1 + k^{\mathrm{n}}} \tag{0.8}$$

Recognizing that both r and θ can vary over time we get:

$$PV = \sum_{i=1}^{t} \frac{return_i}{1 + k_i} \tag{0.9}$$

where $return_i$ is the return during period i.

Example. Repeating the preceding example, but assuming a 15% risk premium for the testers option.

$$PV_{tool} = \frac{\$500,000}{(1 + 0.10)^0} = \$500,000 \tag{0.10}$$

$$PV_{testers} = \frac{\$750,000}{(1 + 0.10 + 0.15)^2} = \$480,000 \tag{0.11}$$

Taking this risk into account shows that buying the test tool is the better option.

8.4.1.3 Net Present Value

Future payoffs do not just occur, an investment needs to be made. A quantity called the *Net Present Value* (NPV) is generally considered to lead to the better investment decisions.[154] It is calculated as:

$$NPV = PV - investment\ cost \tag{0.12}$$

Example (from Raffo[1136]). A coding reading initiative is expected to cost $50,000 to implement. The expected payoff, in two years time, is $100,000. Assuming a discount rate of 10%, we get:

$$NPV = \frac{\$100,000}{1 \times 10^2} - \$50,000 = \$32,645 \tag{0.13}$$

Several alternatives to NPV, their advantages and disadvantages, are described in Chapter five of Brealey[154] and by Raffo.[1136] One commonly seen rule within rapidly changing environments is the payback rule. This requires that the investment costs of a project be recovered within a specified period. The payback period is the amount of time needed to recover investment costs. A shorter payback period being preferred to a longer one.

8.4.1.4 Estimating discount rate and risk

The formulae for calculating value are of no use unless reliable figures for the discount rate and the impact of risk are available. The discount rate represents the risk-free element and the closest thing to a risk-free investment is government bonds and securities. Information on these rates are freely available. Governments face something of a circularity problem in how they calculate the discount rate for their own investments. The US government discusses these issues in its *Guidelines and Discount Rates for Benefit-Cost Analysis of Federal Programs*[1456] and specifies a rate of 7%.

Analyzing risk is a much harder problem. Information on previous projects carried out within the company can offer some guidance on the likelihood of developers meeting productivity targets. In a broader context the market conditions also need to be taken into account, for instance: how likely is it that other companies will bring out competing products? Will demand for the application still be there once development is complete?

One way of handling these software development risks is for companies to treat these activities in the same way that options are used to control the risk in a portfolio of stocks. Some very sophisticated models and formula for balancing the risks involved in holding a range of assets (e.g., stocks) have been developed. The match is not perfect in that these methods rely on a liquid market, something that is difficult to achieve using people (moving them to a new project requires time for them to become productive). A number of researchers[412, 1313, 1478] have started to analyze some of the ways these methods might be applied to creating and using options within the software development process.

8.5 Reusing software

It is rare for a single program to handle all the requirements of a complete application. An application is often made up of multiple programs and generally there is a high degree of similarity in many of the requirements for these programs. In other cases there may be variations in a hardware/software product. Writing code tailored to each program or product combination is expensive. Reusing versions of the same code in multiple programs sounds attractive.

In practice code reuse is a complex issue. How to identify the components that might be reusable, how much effort should be invested in writing the original source to make it easy to reuse, how costs and benefits should be apportioned are a few of the questions.

A survey of the economic issues involved in software reuse is provided by Wiles.[1464] These coding guidelines indirectly address code reuse in that they recommend against the use of constructs that can vary between translator implementations.

8.6 Using another language

A solution that is sometimes proposed to get around problems in C that are seen as the root cause of many faults is to use another language. Commonly proposed languages include Pascal, Ada, and recently Java. These languages are claimed to have characteristics, such as strong typing, that help catch faults early and reduce maintenance costs.

Ada using

In 1987 the US Department of Defense mandated Ada (DoD Directive 3405.1) as the language in which bespoke applications, written for it, had to be written. The aim was to make major cost savings over the full lifetime of a project (implementation and maintenance, throughout its operational life); the higher costs of using Ada during implementation[1155] being recovered through reduced maintenance costs over its working lifetime.[1504] However, a crucial consideration had been overlooked in the original cost analysis. Many projects are canceled before they become operational.[404, 1281] If the costs of all projects, canceled or operational, are taken into account, Ada is not the most cost-effective option. The additional cost incurred during development of projects that are canceled exceeds the savings made on projects that become operational. The directive mandating the use of Ada was canceled in 1997.[1394]

Proposals to use other languages sometimes have more obvious flaws in their arguments. An analysis of why Lisp should be used[411] is based on how that language overcomes some of the C-inherent problems, while overlooking its own more substantial weaknesses (rather like proposing that people hop on one leg as a solution to wearing out two shoes by walking on two).

The inability to think through a reasoned argument, where choice of programming language is concerned, is not limited to academic papers[994] (5.3.11 Safe Subsets of Programming languages).

The use of software in applications where there is the possibility of loss of life, or serious injury, is sometimes covered by regulations. These regulations often tend to be about process— making sure that various checks are carried out. But sometimes subsets of the C language have been defined (sometimes called by the name safe subsets). The associated coding guideline is that constructs outside this subset not be used. Proof for claiming that use of these subsets result in safer programs is nonexistent. The benefit of following coding guidelines is discussed elsewhere.

coding 0 guidelines the benefit

8.7 Testability

coding guidelines testability

This subsection is to provide some background on testing programs. The purpose of testing is to achieve a measurable degree of confidence that a program will behave as expected. Beizer[107] provides a practical introduction to testing.

Testing is often written about as if its purpose were to find faults in applications. Many authors quote figures for the cost of finding a fault, looking for cost-effective ways of finding them. This outlook can lead to an incorrectly structured development process. For instance, a perfect application will have an infinite cost per fault found, while a very badly written application will have a very low cost per fault found. Other figures often quoted involve the cost of finding faults in different phases of the development process. In particular, the fact that the cost per fault is higher, the later in the process it is discovered. This observation about relative costs often occurs purely because of how development costs are accounted for. On a significant development effort equipment and overhead costs tend to be fixed, and there is often a preassigned number of people working on a particular development phase. These costs are not likely to vary by much, whether there is a single fault found or 100 faults. However, it is likely that there will be significantly fewer faults found in later phases because most of them will have been located in earlier phases. Given the fixed costs that cannot be decreased, and the smaller number of faults, it is inevitable that the cost per fault will be higher in later phases.

Many of the faults that exist in source code are never encountered by users of an application. Examples of such faults are provided in a study by Chou, Yang, Chelf, Hallem, and Engler[232] who investigated the history of faults in the Linux kernel (found using a variety of static analysis tools). The source of different releases of the Linux kernel is publicly available (for this analysis 21 snapshots of the source over a seven year period were used). The results showed how faults remained in successive releases of code that was used for production work in thousands (if not hundreds of thousands) of computers. The average fault lifetime, before being fixed, or the code containing it ceasing to exist was 1.8 years.

The following three events need to occur for a fault to become an application failure:

1. A program needs to execute the statement containing the fault.
2. The result of that execution needs to infect the subsequent data values, another part of the program.
3. The infected data values must propagate to the output.

The probability of a particular fault affecting the output of an application for a given input can be found by multiplying together the probability of the preceding three events occurring for that set of input values. The following example is taken from Voas:[1427]

```
1  #include <math.h>
2  #include <stdio.h>
3
4  void quadratic_root(int a, int b, int c)
5  /*
6   * If one exists print one integral solution of:
7   *  ax^2 + bx + c = 0
8   */
9  {
```

```
10  int d,
11      x;
12
13  if (a != 0)
14     {
15     d = (b * b) - (5 * a * c); /* Fault, should multiply by 4. */
16     if (d < 0)
17        x = 0;
18     else
19        x = (sqrt(d) / (2 * a)) - b;
20     }
21  else
22     x = -(c / b);
23
24  if ((a * x * x + b * x + c) == 0)
25     printf("%d is an integral solution\n", x);
26  else
27     printf("There is no integral solution\n");
28  }
```

Execution of the function `quadratic_root` has four possibilities:

1. The fault is not executed (e.g., `quadratic_root(0, 3, 6)`).
2. The fault is executed but does not infect any of the data (e.g., `quadratic_root(3, 2, 0)`).
3. The fault is executed and the data is infected, but it does not affect the output (e.g., `quadratic_root(1, -1, -12)`).
4. The fault is executed and the infected data causes the output to be incorrect (e.g., `quadratic_root(10, 0, 10)`).

This program illustrates the often-seen situations of a program behaving as expected because the input values used were not sufficient to turn a fault in the source code into an application failure during program execution.

Testing by execution examines the source code in a different way than is addressed by these coding guidelines. One looks at only those parts of the program (in translated form) through which flow of control passes and applies specific values, the other examines source code in symbolic form.

A study by Adams[3] looked at faults found in applications over time. The results showed (see Table 0.1) that approximately one third of all detected faults occurred on average every 5,000 years of execution time. Only around 2% of faults occurred every five years of execution time.

Table 0.1: Percentage of reported problems having a given mean time to first problem occurrence (in months, summed over all installations of a product) for various products (numbered 1 to 9), e.g., 28.8% of the reported faults in product 1 were, on average, first reported after 19,000 months of program execution time (another 34.2% of problems were first reported after 60,000 months). From Adams.[3]

8.8 Software metrics

metrics introduction

In a variety of engineering disciplines, it is possible to predict, to within a degree of uncertainty, various behaviors and properties of components by measuring certain parameters and matching these measurements against known behaviors of previous components having similar measurements. A number of software metrics (software measurements does not sound as scientific) are based on the number of lines of source code. Comments are usually excluded from this count. What constitutes a line is at times fiercely debated.[1054] The most commonly used count is based on a simple line count, ignoring issues such as multiple statements on one line or statements spanning more than one line.

The results from measurements of software are an essential basis for any theoretical analysis.[419] However, some of the questions people are trying to answer with measurements of source code have serious flaws in their justification. Two commonly asked questions are the effort needed to implement a program (before it is implemented) and the number of faults in a program (before it is shipped to customers). Fenton attempted to introduce a degree of rigour into the use of metrics.[417,418]

COCOMO

The COCOMO project (COnstructive COst Model, the latest release is known as COCOMO II) is a research effort attempting to produce an Open Source, public domain, software cost, effort, and schedule for developing new software development. Off-the-shelf, untuned models have been up to 600% inaccurate in their estimates. After Bayesian tuning models that are within 30% of the actual figures 71% of the time have been built.[235] Effort estimation is not the subject of this book and is not discussed further.

These attempts to find meaningful measures all have a common goal — the desire to predict. However, most existing metrics are based on regression analysis models, they are not causal models. To build these models, a number of factors believed to affect the final result are selected, and a regression analysis is performed to calculate a correlation between them and the final results. Models built in this way will depend on the data from which they were built and the factors chosen to correlate against. Unlike a causal model (which predicts results based on "telling the story",[417]) there is no underlying theory that explains how these factors interact. For a detailed critique of existing attempts at program defect prediction based on measures of source code and fault history, see Fenton.[417]

The one factor that existing fault-prediction models ignore is the human brain/mind. The discussion in subsequent sections should convince the reader that source code complexity only exists in the mind of the reader. Without taking into account the properties in the reader's mind, it is not possible to calculate a complexity value. For instance, one frequently referenced metric is Halstead's software science metric, which uses the idea of the *volume* of a function. This *volume* is calculated by counting the operators and operands appearing in that function. There is no attempt to differentiate functions containing a few complex expressions from functions containing many simple expressions; provided the total and unique operand/operator count is the same, they will be assigned the same complexity.

9 Background to these coding guidelines

coding guidelines background to

These coding guidelines are conventional, if a little longer than most, in the sense that they contain the usual exhortation not to use a construct, to do things a particular way, or to watch out for certain problems. They are unconventional because of the following:

- An attempt has been made to consider the impact of a prohibition— do the alternatives have worse cost/benefit?
- Deviations are suggested— experience has shown that requiring a yes/no decision on following a guideline recommendation can result in that recommendation being ignored completely. Suggesting deviations can lead to an increase in guideline recommendations being followed by providing a safety valve for the awkward cases.
- Economics is the only consideration— it is sometimes claimed that following guideline recommendations imbues software with properties such as being better or safer. Your author does not know of any way of measuring betterness in software. The case for increased safety is discussed elsewhere.

coding guidelines the benefit 0

- An attempt has been made to base those guideline recommendations that relate to human factors on the experimental results and theories of cognitive psychology.

0 cognitive psychology

The wording used in these guideline recommendations is short and to the point (and hopefully unambiguous). It does assume some degree of technical knowledge. There are several ISO standards[635, 649] dealing with the wording used in the specification of a computer language. The principles of designing and documenting procedures to be carried out by others are thoroughly covered by Degani and Wiener.[336]

It is all very well giving guideline recommendations for developers to follow. But, how do they do their job. How were they selected? When do they apply? These are the issues discussed in the following sections.

9.1 Culture, knowledge, and behavior

culture of C

Every language has a culture associated with its use. A culture entails thinking about and doing certain things in a certain way.[1015] How and why these choices originally came about may provide some interesting historical context and might be discussed in other sections of this book, but they are generally not relevant to Coding guideline sections.

Culture is perhaps too grand a word for the common existing practices of C developers. Developers are overconfident and insular enough already without providing additional blankets to wrap themselves in. The term *existing practice* is both functional and reduces the possibility of aggrandizement.

Existing practices could be thought of as a set of assumptions and expectations about how things are done (in C). The term *C style* is sometimes used to describe these assumptions and expectations. However, this term has so many different meanings, for different developers, in different contexts, that its use is very prone to misunderstanding and argument. Therefore every effort will be made to stay away from the concept of style in this book.

0 coding guidelines
coding style

In many ways existing practice is a *meme machine*.[125] Developers read existing code, learn about the ideas it contains, and potentially use those ideas to write new code. Particular ways of writing code need not be useful to the program that contains them. They only need to appear to be useful to the developer who writes the code, or fit in with a developer's preferred way of doing things. In some cases developers do not thoroughly analyze what code to write, they follow the lead of others. Software development has its fads and fashions, just like any other information-driven endeavor.[124]

Before looking at the effect of existing practice on coding guidelines we ought to ask what constitutes existing practice. As far as the guideline recommendations in this book are concerned, what constitutes existing practice is documented in the Usage subsections. Developers are unlikely to approach this issue in such a scientific way. They will have worked in one or more application domains, been exposed to a variety of source code, and discussed C with a variety of other developers. While some companies might choose to tune their guidelines to the practices that apply to specific application domains and working environments, the guideline recommendations in this book attempt to be generally applicable.

0 measure-ments
5ESS

Existing practices are not always documented and, in some cases, developers cannot even state what they are. Experienced developers sometimes use expressions such as *the C way of doing things*, or *I feel*. When asked what is meant by these expressions, they are unable to provide a coherent answer. This kind of human behavior (knowing something without being able to state what it is) has been duplicated in the laboratory.

implicit learning

- A study by Lewicki, Hill and Bizot[849] demonstrated the effect of implicit learning on subjects expectations, even when performing a task that contained no overt learning component. In this study, while subjects watched a computer screen a letter was presented in one of four possible locations. Subjects had to press the button corresponding to the location of the letter as quickly as possible. The sequence of locations used followed a consistent, but complex, pattern. The results showed subjects' response times continually improving as they gained experience. The presentation was divided into 17 segments of 240 trials (a total of 4,080 letters), each segment was separated by a 10-second break. The pattern used to select the sequence of locations was changed after the 15th segment (subjects were not told about the existence of any patterns of behavior). When the pattern changed, the response times

immediately got worse. After completing the presentation subjects were interviewed to find out if they had been aware of any patterns in the presentation; they had not.

letter patterns
implicit learning

- A study by Reber and Kassin[1150] compared implicit and explicit pattern detection. Subjects were asked to memorize sets of words containing the letters *P*, *S*, *T*, *V*, or *X*. Most of these words had been generated using a finite state grammar. However, some of the sets contained words that had not been generated according to the rules of this grammar. One group of subjects thought they were taking part in a purely memory-based experiment; the other group was also told to memorize the words but was also told of the existence of a pattern to the letter sequences and that it would help them in the task if they could deduce this pattern. The performance of the group that had not been told about the presence of a pattern almost exactly mirrored that of the group who had been told on all sets of words (pattern words only, pattern plus non-pattern words, non-pattern words only). Without being told to do so, subjects had used patterns in the words to help perform the memorization task.
- A study carried out by Berry and Broadbent[117] asked subjects to perform a task requiring decision making using numerical quantities. In these experiments subjects were told that they were in charge of a sugar production factory. They had to control the rate of sugar production to ensure it kept at the target rate of 9,000 tons. The only method of control available to them was changing the size of the workforce. Subjects were not told anything about the relationship between the current production rate, the number of workers and previous production rates. The starting point was 600 workers and an output rate of 6,000 tons. Subjects had to specify the number of workers they wished to employ and were then told the new rate of production (interaction was via a terminal connected to a computer). At the end of the experiment, subjects had to answer a questionnaire about the task they had just performed. The results showed that although subjects had quickly learned to keep the rate of sugar production close to the desired level, they were unable to verbalize how they achieved this goal.

The studies performed by these and other researchers demonstrate that it is possible for people to perform quite complex tasks using knowledge that they are not consciously aware of having. By working with other C developers and reading existing C source code, developers obtain the nonverbalized knowledge that is part of the unwritten culture of C. This knowledge is expressed by developers having expectations and making assumptions about software development in C.

Another consequence of being immersed within existing practice is that developers use the characteristics of different entities to form categories. This categorization provides a mechanism for people to make generalizations based on relatively small data sets. A developer working with C source code which has been written by other people will slowly build up a set of assumptions and expectations of the general characteristics of this code.

A study by Nisbett, Krantz, Jepson and Kunda[1014] illustrates peoples propensity to generalize, based on past experience. Subjects were given the following scenario. (Some were told that three samples of each object was encountered, while other subjects were told that 20 samples of each object was encountered.)

> Imagine that you are an explorer who has landed on a little-known island in the Southeastern Pacific. You encounter several new animals, people, and objects. You observe the properties of your "samples" and you need to make guesses about how common these properties would be in other animals, people, or objects of the same type:
>
> 1. suppose you encounter a new bird, the shreeble. It is blue in color. What percent of all shreebles on the island do you expect to be blue?
> 2. suppose the shreeble you encounter is found to nest in a eucalyptus tree, a type of tree that is fairly common on this island. What percentage of all shreebles on the island do you expect to nest in a eucalyptus tree?

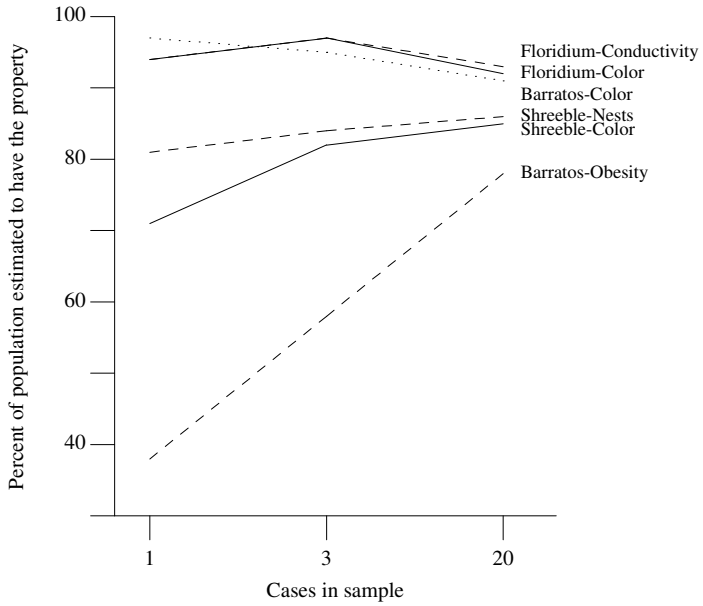

Figure 0.9: Percentage of population estimated to have the sample property against the number of cases in the sample. Adapted from Nisbett.[1014]

3. suppose you encounter a native, who is a member of a tribe called the Barratos. He is obese. What percentage of the male Barratos do you expect to be obese?
4. suppose the Barratos man is brown in color. What percentage of male Barratos do you expect be brown (as opposed to red, yellow, black, or white)?
5. suppose you encounter what the physicist on your expedition describes as an extremely rare element called floridium. Upon being heated to a very high temperature, it burns with a green flame. What percentage of all samples of floridium found on the island do you expect to burn with a green flame?
6. suppose the samples of floridium, when drawn into a filament, is found to conduct electricity. What percentage of all samples of floridium found on the island do you expect to conduct electricity?

The results show that subjects used their knowledge of the variability of properties in estimating the probability that an object would have that property. For instance, different samples of the same element are not expected to exhibit different properties, so the number of cases in a sample did not influence estimated probabilities. However, people are known to vary in their obesity, so the estimated probabilities were much lower for the single sample than the 20 case sample.

The lesson to be learned here is a general one concerning the functionality of objects and functions that are considered to form a category. Individual members of a category (e.g., a source file or structure type created by a developer) should have properties that would not be surprising to somebody who was only familiar with a subset of the members (see Figure 0.9).

Having expectations and making assumptions (or more technically, using inductive reasoning) can be useful in a slowly changing world (such as the one inhabited by our ancestors). They provide a framework from which small amounts of information can be used to infer, seemingly unconnected (to an outsider), conclusions. Is there a place for implicit expectations and assumptions in software development? A strong

case can be made for saying that any thought process that is not based on explicit knowledge (which can be stated) should not be used when writing software. In practice use of such knowledge, and inductive reasoning based on it, appears to play an integral role in human thought processes. A guideline recommendation that developers not use such thought processes may be difficult, if not impossible, to adhere to.

These coding guidelines don't seek to change what appears to be innate developer (human) behavior. The approach taken by these guidelines is to take account of the thought processes that developers use, and to work within them. If developers have expectations and make assumptions, then the way to deal with them is to find out what they are and to ensure that, where possible, source code follows them (or at least does not exhibit behavior that differs significantly from that expected). This approach means that these recommendations are tuned to the human way of comprehending C source code.

The issue of implicit knowledge occurs in several coding guidelines.

9.1.1 Aims and motivation

developer motivations

What are developers trying to do when they read and write source code? They are attempting to satisfy a variety of goals. These goals can be explicit or implicit. One contribution cognitive psychology can make is to uncover the implicit goals, and perhaps to provide a way of understanding their effects (with the aim of creating guideline recommendations that minimize any undesirable consequences). Possible developer aims and motives include (roughly from higher level to lower level) the following:

- Performing their role in a development project (with an eye on promotion, for the pleasure of doing a good job, or doing a job that pays for other interests).
- Carrying out a program-modification task.
- Extracting information from the source by explicitly choosing what to pay attention to.

cogni-0
tive effort

- Minimizing cognitive effort; for instance, using heuristics rather than acquiring all the necessary information and using deductive logic.
- Maximizing the pleasure they get out of what they are doing.

belief main-0
tenance

- Belief maintenance: studies have found that people interpret evidence in ways that will maintain their existing beliefs.

The act of reading and writing software has an immediate personal cost. It is the cognitive load on a developer's brain (physical effort is assumed to be small enough that it has no significant cost, noticeable to the developer). Various studies have shown that people try to minimize cognitive effort when performing tasks.[458] A possible consequence of minimizing this effort is that people's actions are not always those that would be predicted on the basis of correct completion of the task at hand. In other words, people make mistakes because they do not invest sufficient effort to carry out a task correctly.

cost/accuracy trade-off

When attempting to solve a problem, a person's cognitive system is assumed to make cost/accuracy trade-offs. The details of how it forms an estimate of the value, cost, and risk associated with an action, and carries out the trade-off analysis is not known. A study by Fu and Gray[458] provides a good example of the effects of these trade-offs on the decisions made by people when performing a task. Subjects were given the task of copying a pattern of colored blocks (on a computer-generated display). To carry out the task subjects had to remember the color of the block to be copied and its position in the target pattern, a memory effort. A perceptual-motor effort was introduced by graying out the various areas of the display where the colored blocks were visible. These grayed out areas could be made temporarily visible using various combinations of keystrokes and mouse movements. When performing the task, subjects had the choice of expending memory effort (learning the locations of different colored blocks) or perceptual-motor effort (using keystrokes and mouse movements to uncover different areas of the display). A subject's total effort was equal to the sum of the perceptual motor effort and the memory storage and recall effort. The extremes of possible effort combinations are: (1) minimize the memory effort by remembering the color and position of a single block, which requires the perceptual-motor effort of uncovering the grayed out area for every block, or (2) minimize

perceptual effort by remembering information on as many blocks as possible (this requires uncovering fewer grayed areas).

The subjects were split into three groups. The experiment was arranged such that one group had to expend a low effort to uncover the grayed out areas, the second acted as a control, and the third had to expend a high effort to uncover the grayed out areas. The results showed that the subjects who had to expend a high perceptual-motor effort, uncovered grayed out area fewer times than the other two groups. These subjects also spent longer looking at the areas uncovered, and moved more colored blocks between uncoverings. The subjects faced with a high perceptual-motor effort reduced their total effort by investing in memory effort. Another consequence of this switch of effort investment, to use of memory, was an increase in errors made.

When reading source code, developers may be faced with the same kind of decision. Having looked at and invested effort in memorizing information about a section of source code, should they invest perceptual-motor effort when looking at a different section of source that is affected by the previously read source to verify the correctness of the information in their memory? A commonly encountered question is the C language type of an object. A developer has to decide between searching for the declaration or relying on information in memory.

A study by Schunn, Reder, Nhouyvanisvong, Richards, and Stroffolino[1206] found that a subject's degree of familiarity with a problem was a better predictor, than retrievability of an answer, of whether subjects would attempt to retrieve or calculate the answer to a problem.

The issue of cognitive effort vs. accuracy in decision making is also discussed elsewhere.

0 effort vs. accuracy decision making

Experience shows that many developers believe that code *efficiency* is an important attribute of code quality. This belief is not unique to the culture of C and has a long history.[772] While efficiency remains an issue in some application domains, these coding guidelines often treat efficiency as a cause of undesirable developer behavior that needs to be considered (with a view handling the possible consequences).

Experience has shown that some developers equate visual compactness of source code with runtime efficiency of the translated program. While there are some languages where such a correlation exists (e.g., some implementations of Basic, mostly interpreter based and seen in early hobbyist computers, perform just in time translation of the source code), it does not exist for C. This is an issue that needs to be covered during developer education.

visually compact code efficiency belief

Experience has also shown that when presented with a choice developer decisions are affected by their own estimates of the amount of typing they will need to perform. Typing minimization behavior can include choosing abbreviated identifier names, using cut-and-paste to copy sections of code, using keyboard short-cuts, and creating editor macros (which can sometimes require significantly more effort than they save).

typing minimization

9.2 Selecting guideline recommendations

No attempt has been made to keep the number of guideline recommendations within a prescribed limit. It is not expected that developers should memorize them. Managers are expected to select guidelines based on their cost effectiveness for particular projects.

guideline recommendations selecting

Leaving the number of guideline recommendations open-ended does not mean that any worthwhile sounding idea has been written up as a guideline. Although the number of different coding problems that could be encountered is infinite, an endless list of guidelines would be of little practical use. Worthwhile recommendations are those that minimize both the likelihood of faults being introduced by a developer or the effort needed by subsequent developers to comprehend the source code. Guideline recommendations covering situations that rarely occur in practice are wasted effort (not for the developers who rarely get to see them, but for the guideline author and tool vendors implementing checks for them).

These coding guidelines are not intended to recommend against the use of constructs that are obviously faults (i.e., developers have done something by mistake and would want to modify the code if the usage was pointed out to them). For instance, a guideline recommending against the use of uninitialized objects is equivalent to a guideline recommending against faults (i.e., pointless). Developers do not need to be given recommendations not to use these constructs. Guidelines either recommend against the use of constructs that are intentionally used (i.e., a developer did not use them by mistake) in a conforming program (any constructs

guidelines not faults

diagnostic 146 shall produce

that would cause a conforming translator to issue a diagnostic are not included), or they recommend that a particular implementation technique be used.

These guidelines deal with the use of C language constructs, not the design decisions behind their selection. It is not the intent to discuss how developers choose to solve the higher-level design and algorithmic issues associated with software development. These guidelines deal with instances of particular constructs at the source code level.

Source code faults are nearly always clichés; that is, developers tend to repeat the mistakes of others and their own previous mistakes. Not every instance of a specific construct recommended against by a guideline (e.g., an assignment operator in a conditional expression, `if (x = y)`) need result in a fault. However, because a sufficient number of instances have caused faults to occur in the past, it is considered to be worthwhile recommending against all usage of a construct.

Guidelines covering a particular construct cannot be considered in isolation from the rest of the language. The question has to be asked, of each guideline: "if developers are not allowed do this, what are they going to do instead?" A guideline that effectively forces developers into using an even more dangerous construct is a lot more than simply a waste of time. For instance, your authors experience is that placing too many restrictions on how enumerated constants are defined leads to developers using macro names instead— a counterproductive outcome.

Selecting guideline recommendations based on the preceding criteria requires both a detailed inventory of software faults for the C language (no distinction is made between faults that are detected in the source and faults that are detected as incorrect output from a program) and some measure of developer comprehension effort. Developer comprehension is discussed elsewhere. There have been relatively few reliable studies of software faults (Knuth's[753] log of faults in TEX is one such; see Fredericks[451] for a survey). Some of those that have been published have looked at faults that occur during initial development,[1344] and faults that occur during the evolution of an application, its maintenance period.[549, 1080]

developer 0 program comprehension

Guidelines that look worthy but lack empirical evidence for their cost effectiveness should be regarded with suspicion. The field of software engineering has a poor track record for experimental research. Studies[874, 1505] have found that most published papers in software related disciplines do not include any experimental validation. Whenever possible this book quotes results based on empirical studies (for the measurements by the author, either the raw data or the source code of the programs that generated the data are available from the author[1516]). Sometimes results from theoretical derivations are used. As a last resort, common practices and experience are sometimes quoted. Those studies that have investigated issues relating to coding practices have often used very inexperienced subjects (students studying at a university). The results of these inexperienced subject-based studies have been ignored.

experimental 0 studies

Table 0.2: Fault categories ordered by frequency of occurrence. The last column is the rank position after the fault fix weighting factor is taken into account. Based on Perry.[1080]

Rank	Fault Description	% Total Faults	Fix Rank	Rank	Fault Description	% Total Faults	Fix Rank
1	internal functionality	25.0	13	12	error handling	3.3	6
2	interface complexity	11.4	10	13	primitive's misuse	2.4	11
3	unexpected dependencies	8.0	4	14	dynamic data use	2.1	15
4	low-level logic	7.9	17	15	resource allocation	1.5	2
5	design/code complexity	7.7	3	16	static data design	1.0	19
6	other	5.8	12	17	performance	0.9	1
7	change coordinates	4.9	14	18	unknown interactions	0.7	5
8	concurrent work	4.4	9	19	primitives unsupported	0.6	19
9	race conditions	4.3	7	20	IPC rule violated	0.4	16
10	external functionality	3.6	8	21	change management complexity	0.3	21
11	language pitfalls i.e., use of = when == intended	3.5	18	22	dynamic data design	0.3	21

- A study by Thayer, Lipow, and Nelson[1344] looked at several Jovial (a Fortran-like language) projects during their testing phase. It was advanced for its time, using tools to analyze the source and being rigorous in the methodology of its detailed measurements. The study broke new ground: "Based on error histories seen in the data, define sets of error categories, both causative and symptomatic, to be applied in the analysis of software problem reports and their closure." Unfortunately, the quality of this work was not followed up by others and the level of detail provided is not sufficient for our needs here.
- Hatton[549] provides an extensive list of faults in C source code found by a static analysis tool. The tool used was an earlier version of one of the tools used to gather the usage information for this book. 0 Usage 1
- Perry[1080] looked at the modification requests for a 1 MLOC system that contained approximately 15% to 20% new code for each release. As well as counting the number of occurrences of each fault category, a weight was given to the effort required to fix them.

Table 0.3: Underlying cause of faults. The *none given* category occurs because sometimes both the fault and the underlying cause are the same. For instance, *language pitfalls*, or *low-level logic*. Based on Perry.[1080]

Rank	Cause Description	% Total Causes	Fix Rank
1	Incomplete/omitted design	25.2	3
2	None given	20.5	10
3	Lack of knowledge	17.8	8
4	Ambiguous design	9.8	9
5	Earlier incorrect fix	7.3	7
6	Submitted under duress	6.8	6
7	Incomplete/omitted requirements	5.4	2
8	Other	4.1	4
9	Ambiguous requirements	2.0	1
10	Incorrect modifications	1.1	5

Looking at the results (shown in Table 0.2) we see that although performance is ranked 17th in terms of number of occurrences, it moves up to first when effort to fix is taken into account. Resource allocation also moves up the rankings. The application measured has to operate in realtime, so performance and resource usage will be very important. The extent to which the rankings used in this case apply to other application domains is likely to depend on the application domain. Perry also measured the underlying causes (see Table 0.3) and the means of fault prevention (see Table 0.4).

Table 0.4: Means of fault prevention. The last column is the rank position after the fault fix weighting factor is taken into account. Based on Perry.[1080]

Rank	Means Description	% Observed	Fix Rank
1	Application walk-through	24.5	8
2	Provide expert/clearer documentation	15.7	3
3	Guideline enforcement	13.3	10
4	Requirements/design templates	10.0	5
5	Better test planning	9.9	9
6	Formal requirements	8.8	2
7	Formal interface specifications	7.2	4
8	Other	6.9	6
9	Training	2.2	1
10	Keep document/code in sync	1.5	7

- A study by Glass[496] looked at what he called *persistent software errors*. Glass appears to make an implicit assumption that faults appearing late in development or during operational use are somehow

different from those found during development. The data came from analyzing *software problem reports* from two large projects. There was no analysis of faults found in these projects during development.

Your author knows of no study comparing differences in faults found during early development, different phases of testing and operational use. Until proven otherwise, these Coding guideline subsections treat the faults found during different phases of development as having the same characteristics.

Usage 0 1

More detailed information on the usage of particular C constructs is given in the Usage sections of this book. While this information provides an estimate of the frequency-of-occurrence of these constructs, it does not provide any information on their correlation to occurrences of faults. These frequency of occurrence measurements were used in the decision process for deciding when particular constructs might warrant a guideline (the extent to which frequency of occurrence might affect developer performance. Note that power law of learning is not considered here.

power law 0 of learning

The selection of these guidelines was also influenced by the intended audience of developers, the types of programs they work on, and the priorities of the environment in which these developers work as follows:

- Developers are assumed to have imperfect memory, work in a fashion that minimizes their cognitive load, are not experts in C language and are liable to have incorrect knowledge about what they think C constructs mean; and have an incomplete knowledge base of the sources they are working on. Although there may be developers who are experts in C language and the source code they are working on, it is assumed here that such people are sufficiently rare that they are not statistically significant; in general these Coding guideline subsections ignore them. A more detailed discussion is given elsewhere.

coding 0 guidelines developers

- Applications are assumed to be large (over 50 KLOC) and actively worked on by more than one developer.

coding 0 guidelines applications

- Getting the software right is only one of the priorities in any commercial development group. Costs and time scales need to be considered. Following coding guidelines is sometimes a small component of what can also be a small component in a big project.

coding 0 guidelines cost drivers

9.2.1 Guideline recommendations must be enforceable

guideline recommendation enforceable

A guideline recommendation that cannot be enforced is unlikely to be of any use. Enforcement introduces several practical issues that constrain the recommendations made by guidelines, including the following:

- *Detecting violations.* It needs to be possible to deduce (by analyzing source code) whether a guideline is, or is not, being adhered to. The answer should always be the same no matter who is asking the question (i.e., the guidelines should be unambiguous).
- *Removing violations.* There needs to be a way of rewriting the source so that no guideline is violated. Creating a situation where it is not possible to write a program without violating one or other guidelines debases the importance of adhering to guidelines and creates a work environment that encourages the use of deviations.

guideline recommendation adherence has a reasonable cost

- *Testing modified programs.* Testing can be a very expensive process. The method chosen, by developers, to implement changes to the source may be based on minimizing the possible impact on other parts of a program, the idea being to reduce the amount of testing that needs to be done (or at least that appears to be needed to be done). Adhering to a guideline should involve an amount of effort that is proportional to the effort used to make changes to the source. Guidelines that could require a major source restructuring effort, after a small change to the source, are unlikely to be adhered to.

The procedures that might be followed in checking conformance to guidelines are not discussed in this book. A number of standards have been published dealing with this issue.[637, 638, 653]

A project that uses more than a handful of guidelines will find it uneconomical and impractical to enforce them without some form of automated assistance. Manually checking the source code against all guidelines is likely to be expensive and error prone (it could take a developer a working week simply to learn the guidelines, assuming 100 rules and 20 minutes study of each rule). Recognizing that some form of automated tool will be used, the wording for guidelines needs to be algorithmic in style.

There are situations where adhering to a guideline can get in the way of doing what needs to be done. Adhering to coding guidelines rarely has the highest priority in a commercial environment. Experience has shown that these situations can lead either to complete guideline recommendations being ignored, or be the thin end of the wedge that eventually leads to the abandonment of adherence to any coding guideline. The solution is to accept that guidelines do need to be broken at times. This fact should not be swept under the carpet, but codified into a deviation mechanism.

9.2.1.1 Uses of adherence to guidelines

While reducing the cost of ownership may be the aim of these guideline recommendations, others may see them as having other uses. For instance, from time to time there are calls for formal certification of source code to some coding guideline document or other. Such certification has an obvious commercial benefit to the certification body and any associated tools vendors. Whether such certification provides a worthwhile benefit to purchasers of software is debatable.[1439]

Goodhart's law[0.1] deals with the impact of external, human pressure on measurement and is applicable here. One of its forms is: "When a measure becomes a target, it ceases to be a good measure." Strathern[1307] describes how the use of a rating system changed the nature of university research and teaching.

Whether there is a greater economic benefit, to a company, in simply doing what is necessary to gain some kind of external recognition of conformance to a coding guideline document (i.e., giving little weight to the internal cost/benefit analysis at the source code level), or in considering adherence to guideline recommendations as a purely internal cost/benefit issue is outside the scope of this book.

9.2.1.2 Deviations

A list of possible deviations should be an integral part of any coding guideline. This list is a continuation of the experience and calculation that forms part of every guideline.

deviations
coding guidelines

The arguments made by the advocates of Total Quality Management[851] appear to be hard to argue against. The relentless pursuit of quality is to be commended for some applications, such as airborne systems and medical instruments. Even in other, less life-threatening, applications, quality is often promoted as a significant factor in enhancing customer satisfaction. Who doesn't want fault-free software? However, in these quality discussions, the most important factor is often overlooked— financial and competitive performance— (getting a product to market early, even if it contains known faults, is often much more important than getting a fault-free product to market later). Delivering a fault-free product to market late can result in financial ruin, just as delivering a fault prone product early to market. These coding guidelines aim of reducing the cost of software ownership needs to be weighed against the broader aim of creating value in a timely fashion. For instance, the cost of following a particular guideline may be much greater than normal, or an alternative technique may not be available. In these situations a strong case can be made for not adhering to an applicable guideline.

There is another practical reason for listing deviations. Experience shows that once a particular guideline has not been adhered to in one situation, developers find it easier not to adhere to it in other situations. Management rarely has access to anybody with sufficient expertise to frame a modified guideline (deviation) appropriate to the situation, even if that route is contemplated. Experience shows that developers rarely create a subset of an individual guideline to ignore; the entire guideline tends to be ignored. A deviation can stop adherence to a particular guideline being an all-or-nothing decision, helping to prevent the leakage of

[0.1] Professor Charles Goodhart, FBA, was chief adviser to the Bank of England and his "law" was originally aimed at financial measures (i.e., "As soon as the government attempts to regulate any particular set of financial assets, these become unreliable as indicators of economic trends.").

nonadherence. Deviations can provide an incremental sequence (increasing in cost and benefit) of decision points.

Who should decide when a deviation can be used? Both the authors of the source code and their immediate managers may have a potential conflict of interest with the longer-term goals of those paying for the development as follows:

- They may be under pressure to deliver a release and see use of a deviation as a short-cut.
- They may not be the direct beneficiaries of the investment being made in adhering to coding guidelines. Redirecting their resources to other areas of the project may seem attractive.
- They may not have the skill or resources needed to follow a guideline in a particular case. Admitting one's own limitations is always hard to do.

The processes that customers (which may be other departments within the same company) put in place to ensure that project managers and developers follow agreed-on practices are outside the scope of this book. Methods for processing deviation requests include:

developer 0 expertise

- referring all requests to an expert. This raises the question of how qualified a *C expert* must be to make technical decisions on deviations.
- making deviation decisions during code review.
- allowing the Q/A department to have the final say about which deviations are acceptable.

However, permission for the use of a deviation is obtained, all uses need to be documented. That is, each source construct that does not adhere to the full guideline, but a deviation of that guideline, needs to be documented. This documentation may simply be a reference to one location where the rationale for that deviation is given. Creating this documentation offers several benefits:

- It ensures that a minimum amount of thought has been given to the reasons for use of a deviation.
- It may provide useful information to subsequent developers. For instance, it can provide an indication of the number of issues that may need to be looked at when porting to a new translator, and the rationale given with a deviation can provide background information on coding decisions.
- It provides feedback to management on the practical implications of the guidelines in force. For instance, is more developer training required and/or should particular guidelines be reviewed (and perhaps reworded)?

Information given in the documentation for a deviation may need to include the following:

- The cost/benefit of following the deviation rather than the full guideline, including cost estimates.
- The risks associated with using the deviation rather than the full guideline recommendation.
- The alternative source code constructs and guidelines considered before selecting the deviation.

9.2.2 Code reviews

code reviews

Some coding guidelines are not readily amenable to automatic enforcement. This can occur either because they involve trade-offs among choices, or because commercial tool technology is not yet sufficiently advanced. The solution adopted here is to structure those guidelines that are not amenable to automatic enforcement so that they can be integrated into a code review process.

It is expected that those guideline recommendation capable of being automatically checked will have been enforced before the code is reviewed. Looking at the output of static analysis tools during code review is

usually an inefficient use of human resources. It makes sense for the developers writing the source code to use the analysis tools regularly, not just prior to reviews.

These coding guidelines are not intended to cover all the issues that should be covered during reviews. Problems with the specification, choice of algorithms, trade-offs in using constructs, agreement with the specification, are among the other issues that should be considered.

The impact of code reviews goes beyond the immediate consequences of having developers read and comment on each other's code. Knowing that their code is to be reviewed by others can affect developer's decision— making strategy. Even hypothetical questions raised during a code review can change subsequent decision making.[428]

0 justifying decisions

Code reviews are subject to the same commercial influences as other development activities; they require an investment of resources (a cost) to deliver benefits. Code reviews are widely seen as a good idea and are performed by many development groups. A very common rationale given for having code reviews is that they are a cost effective means of detecting faults. A recent review[1105] questioned this assumption, based on the lack of experimental evidence showing it to be true. Another reason for performing code reviews is the opportunity it provides for junior developers learn the culture of a development group.

Organizations that have a formal review procedure often follow a three-stage process of preparation, collection, and repair. During preparation, members of the review team read the source looking for as many defects as possible. During review the team as a whole looks for additional defects and collates a list of agreed-on defects. Repair is the resolution of these defects by the author of the source.

Studies by Porter, Siy, Mockuss, and Votta[1106–1108] to determine the best form for code reviews found that: inspection interval and effectiveness of defect detection were not significantly affected by team size (large vs. small), inspection interval and effectiveness of defect detection were not significantly affected by the number of sessions (single vs. multiple), and the effectiveness of defect detection was not improved by performing repairs between sessions of two-session inspections (however, inspection interval was significantly increased). They concluded that single-session inspections by small teams were the most efficient because their defect-detection rate was as good as other formats, and inspection interval was the same or less.

9.3 Relationship among guidelines

Individual guideline recommendations do not exist in isolation. They are collected together to form a set of coding guidelines. Several properties are important in a set of guideline recommendations, including:

coding guidelines relationship among

- It must be possible to implement the algorithmic functionality required by one guideline without violating any of the guidelines in a set.
- Consistency among guidelines within a set is a worthwhile aim.
- Being able to use the same process to enforce all requirements within a set of guidelines is a worthwhile aim.

As a complete set, the guideline recommendations in this book do not meet all of these requirements, but it is possible to create a number of sets that do meet them. It is management's responsibility to select the subset of guidelines applicable to their development situation.

9.4 How do guideline recommendations work?

How can adhering to these coding guidelines help reduce the cost of software ownership? The following are possible mechanisms:

guideline recommendations how they work

- Reduce the number of faults introduced into source code by recommending against the use of constructs known to have often been the cause of faults in the past. For instance, by recommending against the use of an assignment operator in a conditional expression, `if (x = y)`.
- Developers have different skills and backgrounds. Adhering to guidelines does not make developers write good code, but these recommendations can help prevent them from writing code that will be more costly than necessary to maintain.

- Developers' programming experience is often limited, so they do not always appreciate all the implications of using constructs. Guideline recommendations provide a prebuilt knowledge net. For instance, they highlight constructs whose behavior is not as immutable as developers might have assumed. The most common response your author hears from developers is "Oh, I didn't know that".

The primary purpose of coding guidelines is not usually about helping the original author of the code (although as a user of that code they can be of benefit to that person). Significantly more time and effort are spent maintaining existing programs than in writing new ones. For code maintenance, being able to easily extract information from source code, in order to predict the behavior of a program (sometimes called *program comprehension*), is an important issue.

Does reducing the cognitive effort needed to comprehend source code increase the rate at which developers comprehend it and/or reduce the number of faults they introduce into it? While there is no direct evidence proving that it does, these coding guideline subsections assume that it does.

9.5 Developer differences

developer differences

To what extent do individual developer differences affect the selection and wording of coding guidelines? To answer this question some of the things we would need to know include the following:

- the attributes that vary between developers,
- the number of developers (ideally the statistical distribution) having these different attributes and to what extent they possess them, and
- the affect these attribute differences have on developers' performance when working with source code.

Psychologists have been studying and measuring various human attributes for many years. These studies are slowly leading to a general understanding of how human cognitive processes operate. Unfortunately, there is no experimentally verified theory about the cognitive processes involved in software development. So while a lot of information on the extent of the variation in human attributes may be known, how these differences affect developers' performance when working with source code is unknown.

The overview of various cognitive psychology studies, appearing later in this introduction, is not primarily intended to deal with differences between developers. It is intended to provide a general description of the characteristics of the mental processing capabilities of the human mind. Strengths, weaknesses, and biases in these capabilities need to be addressed by guidelines. Sometimes the extent of individuals' capabilities do vary significantly in some areas. Should guidelines address the lowest common denominator (anybody could be hired), or should they assume a minimum level of capability (job applicants need to be tested to ensure they are above this level)?

What are the costs involved in recommending that the capabilities required to comprehend source code not exceed some maximum value? Do these costs exceed the likely benefits? At the moment these questions are somewhat hypothetical. There are no reliable means of measuring developers' different capabilities, as they relate to software development, and the impact of these capabilities on the economics of software development is very poorly understood. Although the guideline recommendations do take account of the capability limitations of developers, they are frustratingly nonspecific in setting boundaries.

developer 0 expertise

These guidelines assume some minimum level of knowledge and programming competence on the part of developers. They do not require any degree of expertise (the issue of expertise is discussed elsewhere).

- A study by Monaghan[956, 957] looked at measures for discriminating *ability* and *style* that are relevant to representational and strategy differences in people's problem solving.
- A study by Oberlander, Cox, Monaghan, Stenning, and Tobin[1023] investigated student responses to multimodal (more than one method of expression, graphical and sentences here) logic teaching. They found that students' preexisting cognitive styles affected both the teaching outcome and the structure of their logical discourse.

- A study by MacLeod, Hunt and Mathews[883] looked at sentence–picture comprehension. They found one group of subjects used a comprehension strategy that fit a linguistic model, while another group used a strategy that fit a pictorial–spatial model. A psychometric test of subjects showed a high correlation between the model a subject used and their spatial ability (but not their verbal ability). Sentence–picture comprehension is discussed in more detail elsewhere. In most cases C source visually appears, to readers, in a single mode, linear text. Although some tools are capable of displaying alternative representations of the source, they are not in widespread use. The extent to which a developer's primary mode of thinking may affect source code comprehension in this form is unknown.

934 sentence-picture relationships

The effect of different developer personalities is discussed elsewhere, as are working memory, reading span, rate of information processing, the affects of age, and cultural differences. Although most developers are male,[320] gender differences are not discussed.

0 developer personality
0 memory developer
1707 reading span
0 developer computational power
792 identifier information extraction
0 memory ageing
0 reasoning ability age-related
0 categorization cultural differences

9.6 What do these guidelines apply to?

A program (at least those addressed by these Coding guidelines) is likely to be built from many source files. Each source file is passed through eight phases of translation. Do all guidelines apply to every source file during every phase of translation? No, they do not. Guideline recommendations are created for a variety of different reasons and the rationale for the recommendation may only be applicable in certain cases; for instance:

coding guidelines what applied to?
108 source files
115 translation phases of
1866 preprocessing

- Reduce the cognitive effort needed to comprehend a program usually apply to the visible source code. That is, the source code as viewed by a reader, for example, in an editor. The result of preprocessing may be a more complicated expression, or sequence of nested constructs than specified by a guideline recommendation. But, because developers are not expected to have to read the output of the preprocessor, any complexity here may not be relevant,
- Common developer mistakes may apply during any phase of translation. The contexts should be apparent from the wording of the guideline and the construct addressed.
- Possible changes in implementation behavior can apply during any phase of translation. The contexts should be apparent from the wording of the guideline and the construct addressed.
- During preprocessing, the sequence of tokens output by the preprocessor can be significantly different from the sequence of tokens (effectively the visible source) input into it. Some guideline recommendations apply to the visible source, some apply to the sequence of tokens processed during syntax and semantic analysis, and some apply during other phases of translation.
- Different source files may be the responsibility of different development groups. As such, they may be subject to different commercial requirements, which can affect management's choice of guidelines applied to them.
- The contents of system headers are considered to be opaque and outside the jurisdiction of these guideline recommendations. They are provided as part of the implementation and the standard gives implementations the freedom to put more or less what they like into them (they could even contain some form of precompiled tokens, not source code). Developers are not expected to modify system headers.

121 header precompiled

- Macros defined by an implementation (e.g., specified by the standard). The sequence of tokens these macros expand to is considered to be opaque and outside the jurisdiction of these coding guidelines. These macros could be defined in system headers (discussed previously) or internally within the translator. They are provided by the implementation and could expand to all manner of implementation-defined extensions, unspecified, or undefined behaviors. Because they are provided by an implementation, the intended actual behavior is known, and the implementation supports it. Developers can use these macros at the level of functionality specified by the standard and not concern themselves with implementation details.

Applying these reasons in the analysis of source code is something that both automated guideline enforcement tools and code reviewers need to concern themselves with.

It is possible that different sets of guideline recommendations will need to be applied to different source files. The reasons for this include the following:

- The cost effectiveness of particular recommendations may change during the code's lifetime. During initial development, the potential savings may be large. Nearer the end of the application's useful life, the savings achieved from implementing some recommendations may no longer be cost effective.
- The cost effectiveness of particular coding guidelines may vary between source files. Source containing functions used by many different programs (e.g., application library functions) may need to have a higher degree of portability, or source interfacing to hardware may need to make use of representation information.
- The source may have been written before the introduction of these coding guidelines. It may not be cost effective to modify the existing source to adhere to all the guidelines that apply to newly written code.

It is management's responsibility to make decisions regarding the cost effectiveness of applying the different guidelines under differing circumstances.

Some applications contain automatically generated source code. Should these coding guidelines apply to this kind of source code? The answer depends on how the generated source is subsequently used. If it is treated as an invisible implementation detail (i.e., the fact that C is generated is irrelevant), then C guideline recommendations do not apply (any more than assembler guidelines apply to C translators that chose to generate assembler as an intermediate step on the way to object code). If the generated source is to be worked on by developers, just like human-written code, then the same guidelines should be applied to it as to human written code.

9.7 When to enforce the guidelines

coding guidelines when to enforce

Enforcing guideline recommendations as soon as possible (i.e., while developers are writing the code) has several advantages, including:

- Providing rapid feedback has been shown[582] to play an essential role in effective learning. Having developers check their own source provides a mechanism for them to obtain this kind of rapid feedback.
- Once code-related decisions have been made, the cost of changing them increases as time goes by and other developers start to make use of them.
- Developers' acceptance is increased if their mistakes are not made public (i.e., they perform the checking on their own code as it is written).

It is developers' responsibility to decide whether to check any modified source before using the compiler, or only after a large number of modifications, or at some other decision point. Checking in source to a version-control system is the point at which its adherence to guidelines stops being a private affair.

To be cost effective, the process of checking source code adherence to guideline recommendations needs to be automated. However, the state of the art in static analysis tools has yet to reach the level of sophistication of an experienced developer. Code reviews are the suggested mechanism for checking adherence to some recommendations. An attempt has been made to separate out those recommendations that are probably best checked during code review. This is not to say that these guideline recommendations should not be automated, only that your author does not think it is practical with current, and near future, static analysis technology.

The extent to which guidelines are automatically enforceable, using a tool, depends on the sophistication of the analysis performed; for instance, in the following (use of uninitialized objects is not listed as a guideline recommendation, but it makes for a simple example):

```
1  extern int glob;
2  extern int g(void);
3
4  void f(void)
5  {
6  int loc;
7
8  if (glob == 3)
9     loc = 4;
10 if (glob == 3)
11    loc++;         /* Does loc have a defined value here? */
12 if (glob == 4)
13    loc--;         /* Does loc have a defined value here? */
14 if (g() == 2)
15    loc = 9;
16 if (g() == glob)
17    ++loc;
18 }
```

The existing value of loc is modified when certain conditions are true. Knowing that it has a defined value requires analysis of the conditions under which the operations are performed. A static analysis tool might: (1) mark objects having been assigned to and have no knowledge of the conditions involved; (2) mark objects as assigned to when particular conditions hold, based on information available within the function that contains their definition; (3) the same as (2) but based on information available from the complete program.

9.8 Other coding guidelines documents

coding guidelines other documents

The writing of coding guideline documents is a remarkably common activity. Publicly available documents discussing C include,[440, 549, 595, 661, 724, 757, 912, 941, 942, 1096, 1097, 1131, 1135, 1142, 1274, 1305] and there are significantly more documents internally available within companies. Such guideline documents are seen as being a *good thing* to have. Unfortunately, few organizations invest the effort needed to write technically meaningful or cost-effective guidelines, they then fail to make any investment in enforcing them.[0.2]

The following are some of the creators of coding guideline include:

- *Software development companies.*[1234] Your author's experience with guideline documents written by development companies is that at best they contain well-meaning platitudes and at worse consist of a hodge-podge of narrow observations based on their authors' experiences with another language.
- *Organizations, user groups and consortia that are users of software.*[1109, 1479] Here the aim is usually to reduce costs for the organization, not software development companies. Coding guidelines are rarely covered in any significant detail and the material usually forms a chapter of a much larger document. Herrmann[568] provides a good review of the approaches to software safety and reliability promoted by the transportation, aerospace, defense, nuclear power, and biomedical industries through their published guidelines.
- *National and international standards.*[655] Perceived authority is an important attribute of any guidelines document. Several user groups and consortia are actively involved in trying to have their documents adopted by national, if not international, standards bodies. The effort and very broad spectrum of consensus needed for publication as an International Standard means that documents are likely to be first adopted as National Standards.

The authors of some coding guideline documents see them as a way of making developers write good programs (whatever they are). Your author takes the view that adherence to guidelines can only help prevent mistakes being made and reduce subsequent costs.

[0.2] If your author is told about the existence of coding guidelines while visiting a company's site, he always asks to see a copy; the difficulty his hosts usually have in tracking down a copy is testament to the degree to which they are followed.

Most guideline recommendations specify subsets, not supersets, of the language they apply to. The term *safe subset* is sometimes used. Perhaps this approach is motivated by the idea that a language already has all the constructs it needs, the desire not to invent another language, or simply an unwillingness to invest in the tools that would be needed to handle additional constructs (e.g., adding strong typing to a weakly typed language). The guidelines in this book have been written as part of a commentary on the C Standard. As such, they restrict themselves to constructs in that document and do not discuss recommendations that involve extensions.

Experience with more strongly typed languages suggests that strong typing does detect some kinds of faults before program execution. Although experimental tool support for stronger type checking of C source is starting to appear,[866, 1004, 1219] little experience in its use is available for study. This book does not specify any guideline recommendations that require stronger type checking than that supported by the C Standard.

Quite a few coding guideline documents have been written for C++.[279, 561, 798, 928–930, 943, 1051, 1098, 1318] It is interesting to note that these coding guideline documents concentrate almost exclusively on the object-oriented features of C++ (i.e., primarily those constructs not available in C). It is almost as if their authors believe that developers using C++ will not make any of the mistakes that C developers make, despite one language almost being a superset of the other.

Coding guideline documents for other languages include those for Ada,[270, 655] Cobol,[1013] Fortran,[772] PERL,[271] Prolog,[293] and SQL.[420]

9.8.1 Those that stand out from the crowd

The aims and methods used to produce coding guidelines documents vary. Many early guideline documents concentrated on giving advice to developers about how to write efficient code.[772] The availability of powerful processors, coupled with large quantities of source code, has changed the modern (since the 1980s) emphasis to one of maintainability rather than efficiency. When efficiency is an issue, the differences between processors and compilers makes it difficult to give general recommendations. Vendors' reference manuals sometimes provide useful background advice.[26, 628] The Object Defect Classification[228] covers a wide variety of cases and has been shown to give repeatable results when used by different people.[388]

9.8.1.1 Bell Laboratories and the 5ESS

measurements 5ESS

Bell Laboratories undertook a root-cause analysis of faults in the software for their 5ESS Switching System.[1497] The following were found to be the top three causes of faults, and their top two subcomponents:

1. Execution/oversight— 38%, which in turn was broken down into inadequate attention to details (75%) and inadequate consideration to all relevant issues (11%).
2. Resource/planning— 19%, which in turn was broken down into not enough engineer time (76%) and not enough internal support (4%).
3. Education/training— 15%, which in turn was broken down into area of technical responsibility (68%) and programming language usage (15%).

In an attempt to reduce the number of faults, a set of "Code Fault Prevention Guidelines" and a "Coding Fault Inspection Checklist" were written and hundreds of engineers were trained in their use. These guideline recommendations were derived from more than 600 faults found in a particular product. As such, they could be said to be tuned to that product (nothing was said about how different root causes might evolve over time).

Based on measurements of previous releases of the 5ESS software and engineering cost per house to implement the guidelines (plus other bug inject countermeasures), it was estimated that for an investment of US$100 K, a saving of US$7 M was made in product rework and testing.

One of the interesting aspects of programs is that they can contain errors in logic and yet continue to perform their designated function; that is, faults in the source do not always show up as a perceived fault by the user of a program. Static analysis of code provides an estimate of the number of potential faults, but not all of these will result in reported faults.

Why did the number of faults reported in the 5ESS software drop after the introduction of these guideline recommendations? Was it because previous root causes were a good measure of future root-cause faults?

The guideline recommendations created do not involve complex constructs that required a deep knowledge of C. They are essentially a list of mistakes made by developers who had incomplete knowledge of C. The recommendations could be looked on as C language knowledge tuned to the reduction of faults in a particular application program. The coding guideline authors took the approach that it is better to avoid a problem area than expect developers to have detailed knowledge of the C language (and know how to deal with problem areas).

In several places in the guideline document, it is pointed out that particular faults had costly consequences. Although evidence that adherence to a particular set of coding guidelines would have prevented a costly fault provides effective motivation for the use of those recommendations, this form of motivation (often seen in coding guideline documents) is counter-productive when applied to individual guideline recommendations. There is rarely any evidence to show that the reason for a particular coding error being more expensive that another one is anything other than random chance.

9.8.1.2 MISRA

MISRA (Motor Industry Software Reliability Association, http://www.misra.org.uk) published a set of *Guidelines for the use of the C language in vehicle based software*.[941, 942] These guideline recommendations were produced by a committee of interested volunteers and have become popular in several domains outside the automobile industry. For the most part, they are based on the implementation-defined, undefined, and unspecified constructs listed in Annex G of the C90 Standard. The guidelines relating to issues outside this annex are not as well thought through (the technicalities of what is intended and the impact of following a guideline recommendation). MISRA

There are now 15 or more vendors who offer products that claim to enforce compliance to the MISRA guidelines. At the time of this writing these tools are not always consistent in their interpretation of the wording of the guidelines. Being based on volunteer effort, MISRA does not have the resources to produce a test suite or provide timely responses to questions concerning the interpretation of particular guidelines.

9.8.2 Ada

Although the original purpose of the Ada language was to reduce total software ownership costs, its rigorous type checking and handling of runtime errors subsequently made it, for many, the language of choice for development of high-integrity systems. An ISO Technical Report[655] (a TR does not have the status of a standard) was produced to address this market. 0 Ada using

The rationale given in many of the *Guidance* clauses of this TR is that of making it possible to perform static analysis by recommending against the use of constructs that make such analysis difficult or impossible to perform. Human factors are not explicitly mentioned, although this could be said to be the major issue in some of the constructs discussed. Various methods are described as not being cost effective. The TR gives the impression that what it proposes is cost effective, although no such claim is made explicitly.

> *. . . , it can be seen that there are four different reasons for needing or rejecting particular language features within this context:* ISO/IEC TR 15942:2000
>
> 1. *Language rules to achieve predictability,*
> 2. *Language rules to allow modelling,*
> 3. *Language rules to facilitate testing,*
> 4. *Pragmatic considerations.*

This TR also deals with the broader issues of verification techniques, code reviews, different forms of static analysis, testing, and compiler validation. It recognizes that developers have different experience levels and sometimes (e.g., clause 5.10.3) recommends that some constructs only be used by experienced developers (nothing is said about how experience might be measured).

9.9 Software inspections

software inspections introduction

Software inspections, technical reviews, program walk-throughs (whatever the name used), all involve people looking at source code with a view to improving it. Some of the guidelines in this book are specified for enforcement during code reviews, primarily because automated tools have not yet achieved the sophistication needed to handle the constructs described.

Software inspections are often touted as a cost-effective method of reducing the number of defects in programs. However, their cost effectiveness, compared to other methods, is starting to be questioned. For a survey of current methods and measurements, see;[793] for a detailed handbook on the subject, see.[452]

Reading inspection
Reading 770
eye movement

During inspections a significant amount of time is spent reading — reading requirements, design documents, and source code. The cost of, and likely mistakes made during, code reading are factors addressed by some guideline recommendations. The following are different ways of reading source code, as it might be applied during code reviews:

- *Ad hoc reading techniques.* This is a catch-all term for those cases, very common in commercial environments, where the software is simply given to developers. No support tools or guidance is given on how they should carry out the inspection, or what they should look for. This lack of support means that the results are dependent on the skill, knowledge, and experience of the people at the meeting.
- *Checklist reading.* As its name implies this reading technique compares source code constructs against a list of issues. These issues could be collated from faults that have occurred in the past, or published coding guidelines such as the ones appearing in this book. Readers are required to interpret applicability of items on the checklist against each source code construct. This approach has the advantage of giving the reader pointers on what to look for. One disadvantage is that it constrains the reader to look for certain kinds of problems only.
- *Scenario-based reading.* Like checklist reading, scenario-based reading provides custom guidance.[939] However, as well as providing a list of questions, a scenario also provides a description on how to perform the review. Each scenario deals with the detection of the particular defects defined in the custom guidance. The effectiveness of scenario-based reading techniques depends on the quality of the scenarios.
- *Perspective-based reading.* This form of reading checks source code from the point of view of the customers, or consumers, of a document.[98] The rationale for this approach is that an application has many different stakeholders, each with their own requirements. For instance, while everybody can agree that software quality is important, reaching agreement on what the attributes of quality are can be difficult (e.g., timely delivery, cost effective, correct, maintainable, testable). Scenarios are written, for each perspective, listing activities and questions to ask. Experimental results on the effectiveness of perspective-based reading of C source in a commercial environment are given by Laitenberger and Jean-Marc DeBaud.[792]
- *Defect-based reading.* Here different people focus on different defect classes. A scenario, consisting of a set of questions to ask, is created for each defect class; for instance, invalid pointer dereferences might be a class. Questions to ask could include; Has the lifetime of the object pointed to terminated? Could a pointer have the null pointer value in this expression? Will the result of a pointer cast be correctly aligned?
- *Function-point reading.* One study[794] that compared checklist and perspective-based reading of code, using professional developers in an industrial context, found that perspective-based reading had a lower cost per defect found.

This book does not recommend any particular reading technique. It is hoped that the guideline recommendations given here can be integrated into whatever method is chosen by an organization.

10 Applications

coding guidelines applications

Several application issues can affect the kind of guideline recommendations that are considered to be applicable. These include the application domain, the economics behind the usage, and how applications evolve over time. These issues are discussed next.

The use of C as an intermediate language has led to support for constructs that simplify the job of translation from other languages. Some of these constructs are specified in the standard (e.g., a trailing comma in initializer lists), while others are provided as extensions (e.g., `gcc`'s support for taking the address of labels and being able to specify the **`register`** storage class on objects declared with file scope, has influenced the decision made by some translator implementors, of other languages to generate C rather than machine code[345]).

1641 initialization syntax

10.1 Impact of application domain

Does the application domain influence the characteristics of the source code? This question is important because frequency of occurrence of constructs in source is one criterion used in selecting guidelines. There are certainly noticeable differences in language usage between some domains; for instance:

0 Usage 1

- *Floating point.* Many applications make no use of any floating-point types, while some scientific and engineering applications make heavy use of this data type.
- *Large initializers.* Many applications do not initialize objects with long lists of values, while the device driver sources for the Linux kernel contain many long initializer lists.

There have been studies that looked at differences within different industries (e.g., banking, aerospace, chemical[551]). It is not clear to what extent the applications measured were unique to those industries (e.g., some form of accounting applications will be common to all of them), or how representative the applications measured might be to specific industries as a whole.

Given the problems associated with obtaining source code for the myriad of different application domains, and the likely problems with separating out the effects of the domain from other influences, your author decided to ignore this whole issue. A consequence of this decision is that these guideline recommendations are a union of the possible issues that can occur across all application domains. Detailed knowledge of the differences would be needed to build a set of guidelines that would be applicable to each application domain. Managers working within a particular application domain may want to select guidelines applicable to that domain.

10.2 Application economics

Coding guidelines are applicable to applications of all sizes. However, there are economic issues associated with the visible cost of enforcing guideline recommendations. For instance, the cost of enforcement is not likely to be visible when writing new code (the incremental cost is hidden in the cost of writing the code). However, the visible cost of ensuring that a large body of existing, previously unchecked, code can be significant.

The cost/benefit of adhering to a particular guideline recommendation will be affected by the economic circumstances within which the developed application sits. These circumstances include

- short/long expected lifetime of the application,
- relative cost of updating customers,
- quantity of source code,
- acceptable probability of application failure (adherence may not affect this probability, but often plays well in any ensuing court case), and
- expected number of future changes/updates.

There are so many possible combinations that reliable estimates of the effects of these issues, on the applicability of particular guidelines, can only be made by those involved in managing the development projects (the COCOMO cost-estimation model uses 17 cost factors, 5 scale factors, a domain-specific factor, and a count of the lines of code in estimating the cost of developing an application). The only direct economic issues associated with guidelines, in this book, we discussed earlier and through the choice of applications measured.

COCOMO 0
development 0
context
Usage 0

10.3 Software architecture

software architecture

The term *architecture* is used in a variety of software development contexts.[0.3] The analogy with buildings is often made, "firm foundations laying the base for . . . ". This building analogy suggests a sense of direction and stability. Some applications do have these characteristics (in particular many of those studied in early software engineering papers, which has led to the view that most applications are like this). Many large government and institutional applications have this form (these applications are also the source of the largest percentage of published application development research).

To remind readers, the primary aim of these coding guidelines is to minimize the cost of software ownership. Does having a good architecture help achieve this aim? Is it possible to frame coding guidelines that can help in the creation of good architecture? What is a good architecture?

What constitutes good software architecture is still being hotly debated. Perhaps it is not possible to predict in advance what the best architecture for a given application is. However, experience shows that in practice the customer can rarely specify exactly what it is they want in advance, and applications close to what they require are obviously not close enough (or they would not be paying for a different one to be written). Creating a good architecture, for a given application, requires knowledge of the whole and designers who know how to put together the parts to make the whole. In practice applications are very likely to change frequently; it might be claimed that applications only stop changing when they stop being used. Experience has shown that it is almost impossible to predict the future direction of application changes.

The conclusion to be drawn, for these observations, is that there are reasons other than incompetence for applications not to have any coherent architecture (although at the level of individual source files and functions this need not apply). In a commercial environment, profitability is a much stronger motive than the desire for coherent software architecture.

Software architecture, in the sense of organizing components into recognizable structures, is relevant to reading and writing source in that developers' minds also organize the information they hold. People do not store information in long-term memory as unconnected facts. These coding guidelines assume that having programs structured in a way that is compatible with how information is organized in developers' minds, and having the associations between components of a program correspond to how developers make associations between items of information, will reduce the cognitive effort of reading source code. The only architectural and organizational issues considered important by the guideline recommendations in this book are those motivated by the characteristics of developers' long-term memory storage and retrieval.

For a discussion of the pragmatics of software architecture, see Foote.[434]

10.3.1 Software evolution

application evolution

Applications that continue to be used tend to be modified over time. The term *software evolution* is sometimes used to describe this process. Coding guidelines are intended to reduce the costs associated with modifying source. What lessons can be learned from existing applications that have evolved?

There have been several studies that looked at the change histories of some very large (several million

[0.3] Some developers like to refer to themselves as software architects. In the UK such usage is against the law, " . . . punishable by a fine not exceeding level 4 on the standard scale . . . " (Architects Act 1997, Part IV):

Use of title "architect".

20. – (1) A person shall not practise or carry on business under any name, style or title containing the word "architect" unless he is a person registered under this Act.

(2) Subsection (1) does not prevent any use of the designation "naval architect", "landscape architect" or "golf-course architect".

line,[469] or a hundred million[382]) programs over many years,[382, 532, 1031] and significant growth over a few years.[499] Some studies have simply looked at the types of changes and their frequency. Others have tried to correlate faults with the changes made. None have investigated the effect of source characteristics on the effort needed to make the changes.

The one thing that is obvious from the data published to date: Researchers are still in the early stages of working out which factors are associated with software evolution.

- A study[330] at Bell Labs showed the efficiency gains that could be achieved using developers who had experience with previous releases over developers new to a project. The results indicated that developers who had worked on previous releases spent 20% of their time in project discovery work. This 20% was put down as the cost of working on software that was evolving (the costs were much higher for developers not familiar with the project). 0 software development expertise
- Another Bell Labs study[952] looked at predicting the risk of introducing a fault into an existing software system while performing an update on it. They found that the main predictors were the number of source lines affected, developer experience, time needed to make the change, and an attribute they called *diffusion*. Diffusion was calculated from the number of subsystems, modules, and files modified during the change, plus the number of developers involved in the work. Graves[516] also tried to predict faults in an evolving application. He found that the fault potential of a module correlated with a weighted sum of the contributions from all the times the module had been changed (recent changes having the most weight). Similar findings were obtained by Ohlsson.[1030, 1031]
- Lehman has written a number of papers[832] on what he calls the *laws of software evolution*. Although they sound plausible, these "laws" are based on empirical findings from relatively few projects.
- Kemerer and Slaughter[721] briefly review existing empirical studies and also describe the analysis of 25,000 change events in 23 commercial software systems (Cobol-based) over a 20-year period.
- Other studies have looked at the interaction of module coupling and cohesion with product evolution. 1821 coupling and cohesion

11 Developers

The remainder of this coding guidelines subsection has two parts. This first major subsection discusses the tasks that developers perform, the second (the following major subsection) is a review of psychology studies carried out in human characteristics of relevance to reading and writing source code. There is an academic research field that goes under the general title *the psychology of programming*; few of the research results from this field have been used in this book for reasons explained elsewhere. However, without being able to make use of existing research applicable to commercial software development, your author has been forced into taking this two-part approach; which is far from ideal. A consequence of this approach is that it is not possible to point at direct experimental evidence for some of the recommendations made in coding guidelines. The most that can be claimed is that there is a possible causal link between specific research results, cognitive theories, and some software development activities.

coding guidelines developers

0 psychology of programming

Although these coding guidelines are aimed at a particular domain of software development, there is no orientation toward developers having any particular kinds of mental attributes. It is hoped that this discussion will act as a stimulus for research aimed at the needs of commercial software development, which cannot take place unless commercial software developers are willing to give up some of their time to act as subjects (in studies). It is hoped that this book will persuade readers of the importance of volunteering to take part in this research.

0 Usage 1
0 developer differences

11.1 What do developers do?

In this book, we are only interested in developer activities that involve source code. Most studies,[1078] the time spent on these activities does not usually rise above 25%, of the total amount of time developers spend on all activities. The non-source code-related activities, the other 75%, are outside the scope of this

developers what do they do?

book. In this book, the reason for reading source code is taken to be that developers want to comprehend program behavior sufficiently well to be able to make changes to it. Reading programs to learn about software development, or for pleasure, are not of interest here.

The source that is eventually modified may be a small subset of the source that has been read. Developers often spend a significant amount of their time working out what needs to be modified and the impact the changes will have on existing code.[330]

The tools used by developers to help them search and comprehend source tend to be relatively unsophisticated.[1238] This general lack of tool usage needs to be taken into account in that some of the tasks performed in a *manual*-comprehension process will be different from those carried out in a tool-assisted process.

cognitive effort 0
cognitive load 0

The following properties are taken to be important attributes of source code, because they affect developer cognitive effort and load:

reading 770
kinds of

- *Readable.* Source is both scanned, looking for some construct, and read in a booklike fashion. The symbols appearing in the visible source need to be arranged so that they can be easily seen, recognized, and processed.
- *Comprehensible.* Having read a sequence of symbols in the source, their meaning needs to be comprehended.
- *Memorable.* With applications that may consist of many thousands of line of source code (100 KLOC is common), having developers continually rereading what they have previously read because they have forgotten the information they learned is not cost effective. Cognitive psychology has yet to come up with a model of human memory that can be used to calculate the memorability of source code. One practical approach might be to measure developer performance in reconstructing the source of a translation unit (an idea initially proposed by Shneiderman,[1230] who proposed a 90–10 rule—a competent developer should be able to reconstruct functionally 90% of a translation unit after 10 minutes of study).

developer 0
training

- *Unsurprising.* Developers have expectations. Meeting those expectations reduces the need to remember special cases, and it reduces the possibility of faults caused by developers making assumptions (not checking that their expectations are true).

For a discussion of the issues involved in collecting data on developers' activities and some findings, see Dewayne[1079] and Bradac.[149]

11.1.1 Program understanding, not

developer program comprehension

One of the first tasks a developer has to do when given source code is figure out what it does (the word *understand* is often used by developers). What exactly does it mean to understanding a program? The word *understanding* can be interpreted in several different ways; it could imply

- knowing all there is to know about a program. Internally (the source code and data structures) and externally— its execution time behavior.
- knowing the external behavior of a program (or perhaps knowing the external behavior in a particular environment), but having a limited knowledge of the internal behavior.
- knowing the internal details, but having a limited knowledge of the external behavior.

The concept of *understanding a program* is often treated as being a yes/no affair. In practice, a developer will know more than nothing and less than everything about a program. Source code can be thought of as a web of knowledge. By reading the source, developers acquire beliefs about it; these beliefs are influenced by their existing beliefs. Existing beliefs (many might be considered to be knowledge rather than belief, by the person holding them) can involve a programming language (the one the source is written in), general computing algorithms, and the application domain.

belief maintenance 0

When reading a piece of source code for the first time, a developer does not start with an empty set of beliefs. Developers will have existing beliefs, which will affect the interpretation given to the source code read. Developers learn about a program, a continuous process without a well-defined ending. This learning process involves the creation of new beliefs and the modification of existing ones. Using a term (*understanding*) that implies a yes/no answer is not appropriate. Throughout this book, the term *comprehension* is used, not *understanding*.

Program comprehension is not an end in itself. The purpose of the investment in acquiring this knowledge (using the definition of knowledge as "belief plus complete conviction and conclusive justification") is for the developer to be in a position to be able predict the behavior of a program sufficiently well to be able to change it. Program comprehension is not so much knowledge of the source code as the ability to predict the effects of the constructs it contains (developers do have knowledge of the source code; for instance, knowing which source file contains a declaration).

While this book does not directly get involved in theories of how people learn, program comprehension is a learning process. There are two main theories that attempt to explain learning. Empirical learning techniques look for similarities and differences between positive and negative examples of a concept. Explanation-based learning techniques operate by generalizing from a single example, proving that the example is an instance of the concept. The proof is constructed by an inference process, making use of a domain theory, a set of facts, and logical implications. In explanation-based learning, generalizations retain only those attributes of an example that are necessary to prove the example is an instance of the concept. Explanation-based learning is a general term for learning methods, such as knowledge compilation and chunking, that create new concepts that deductively follow from existing concepts. It has been argued that a complete model of concept learning must have both an empirical and an explanation-based component.

What strategies do developers use when trying to build beliefs about (comprehend) a program? The theories that have been proposed can be broadly grouped into the following:

- *The top-down approach.* The developer gaining a top-level understanding of what the program does. Once this is understood, the developer moves down a level to try to understanding the components that implement the top level. This process is repeated for every component at each level until the lowest level is reached. A developer might chose to perform a depth-first or width-first analysis of components.
- *The bottom-up approach.* This starts with small sequences of statements that build a description of what they do. These descriptions are fitted together to form higher-level descriptions, and so on, until a complete description of the program has been built.
- *The opportunistic processors approach.* Here developers use both strategies, depending on which best suits the purpose of what they are trying to achieve.[840]

There have been a few empirical studies, using experienced (in the industrial sense) subjects, of how developers comprehend code (the purely theoretically based models are not discussed here). Including:

- A study by Letovsky[839] asked developers to talk aloud (their thoughts) as they went about the task of adding a new feature to a program. He views developers as *knowledge base understanders* and builds a much more thorough model than the one presented here.
- A study by Littman, Pinto, Letovsky and Soloway[861] found two strategies in use by the developers (minimum of five years experience) they observed: In a systematic strategy the developers seek to obtain information about how the program behaves before modifying it; and in an as-needed strategy developers tried to minimize the effort needed to study the program to be modified by attempting to localize those parts of a program where the changes needed to be made. Littman et al. found that those developers using the systematic strategy outperformed those using the as-needed strategy for the 250-line program used in the experiment. They also noted the problems associated with attempting to use the systematic strategy with much larger programs.

- A study by Pennington[1072] investigated the differences in comprehension strategies used by developers who achieved high and low levels of program comprehension. Those achieving high levels of comprehension tended to think about both the application domain and the program (source code) domain rather than just the program domain. Pennington[1073] also studied mental representations of programs; for small programs she found that professional programmers built models based on control flow rather than data flow.
- A study by von Mayrhauser and Vans[1429, 1430] looked at experienced developers maintaining large, 40,000+ LOC applications and proposed an integrated code comprehension model. This model contained four major components, (1) program model, (2) situated model, (3) top-down model, and (4) knowledge base.
- A study by Shaft and Vessey[1217] gave professional programmer subjects source code from two different application domains (accounting and hydrology). The subjects were familiar with one of the domains but not the other. Some of the subjects used a different comprehension strategy for the different domains.

11.1.1.1 Comprehension as relevance

relevance

Programming languages differ from human languages in that they are generally viewed, by developers, as a means of one-way communication with a computer. Human languages have evolved for interactive communication between two, or more, people who share common ground.[0.4]

One of the reasons why developers sometimes find source code comprehension so difficult is that the original authors did not write it in terms of a communication with another person. Consequently, many of the implicit assumptions present in human communication may not be present in source code. Relevance is a primary example. Sperber and Wilson[1271] list the following principles of human communication:

Sperber and Wilson[1271]

Principle of relevance

1. *Every act of ostensive communication communicates a presumption of its own optimal relevance.*

Presumption of optimal relevance

1. *The set of assumptions **I** which the communicator intends to make manifest to the addressee is relevant enough to make it worth the addressee's while to process the ostensive stimulus.*
2. *The ostensive stimulus is the most relevant one the communicator could have used to communicate **I**.*

program image 141

A computer simply executes the sequence of instructions contained in a program image. It has no conception of application assumptions and relevance. The developer knows this and realizes that including such information in the code is not necessary. A common mistake made by novice developers is to assume that the computer is aware of their intent and will perform the appropriate operations. Teaching developers to write code such that can be comprehended by two very different addressee's is outside the scope of these coding guidelines.

Source code contains lots of details that are relevant to the computer, but often of little relevance to a developer reading it. Patterns in source code can be used as indicators of relevance; recognizing these patterns is something that developers learn with experience. These coding guidelines do not discuss the teaching of such recognition.

Developers often talk of the *intended meaning* of source code, i.e., the meaning that the original author of the code intended to convey. Code comprehension being an exercise in obtaining an intended meaning that is assumed to exist. However, the only warranted assumption that can be made about source code is that the operations specified in it contribute to a meaning.

[0.4] The study of meaning and communication between people often starts with Grice's maxims,[520] but readers might find Sperber and Wilson[1271] easier going.

11.1.2 The act of writing software

The model of developers sitting down to design and then write software on paper, iterating through several versions before deciding their work is correct, then typing it into a computer is still talked about today. This method of working may have been necessary in the past because access to computer terminals was often limited and developers used paper implementations as a method of optimizing the resources available to them (time with, and without, access to a computer).

Much modern software writing is done sitting at a terminal, within an editor. Often no written, paper, notes are used. Everything exists either in the developer's head or on the screen in front of him (or her). However, it is not the intent of this book to suggest alternative working practices. Changing a system that panders to people's needs for short-term gratification,[450] to one that delays gratification and requires more intensive periods of a difficult, painful activity (thinking) is well beyond your author's capabilities.

Adhering to guideline recommendation does not guarantee that high quality software will be written; it can only help reduce the cost of ownership of the software that is written.

These coding guidelines assume that the cost of writing software is significantly less than the cost of developer activities that occur later (testing, rereading, and modification by other developers). Adhering to guideline may increase the cost of writing software. The purpose of this investment is to make savings (which are greater than the costs by an amount proportional to the risk of the investment) in the cost of these later activities. 0 ROI

It is hoped that developers will become sufficiently fluent in using these guideline recommendations and that they will be followed automatically while entering code. A skilled developer should aim to be able to automatically perform as much of the code-writing process as possible. Performing these tasks automatically frees up cognitive resources for use on other problems associated with code development.

It is a profoundly erroneous truism . . . that we should cultivate the habit of thinking of what we are doing. The precise opposite is the case. Civilization advances by extending the number of important operations which we can perform without thinking about them.

Alfred North Whitehead (1861–1947)

It is not suggested that the entire software development process take place without any thinking. The process of writing code can be compared to writing in longhand. The writer thinks of a sentence and his hand automatically writes the words. It is only schoolchildren who need to concentrate on the actual process of writing the words. 0 developer flow

11.2 Productivity

Although much talked about, there has been little research on individual developer productivity. There is the often quoted figure of a 25-to-1 productivity difference between developers; however, this is a misinterpretation of figures presented in two tables of a particular paper.[514] Hopefully the analysis by Prechelt[1117] will finally put a stop to researchers quoting this large, incorrect, figure. The differences in performance found by Prechelt are rarely larger than four, similar to the performance ranges found by the original research. productivity developer

Few measurement programs based on individual developers have been undertaken; many measures are based on complete projects, dividing some quantity (often lines of code) by the number of individuals working on them. See Scacchi[1197] for a review of the empirical software productivity research and Jones[680] provides a good discussion of productivity over the complete life cycle of a project. However, some of the issues discussed (e.g., response time when editing source) are rooted in a mainframe environment and are no longer relevant.

Are there any guideline recommendations that the more productive developers use that we can all learn from? Your author knows of no published research that investigates productivity at this level of detail. Age-related productivity issues[881, 1252] are not discussed in these coding guidelines. The subject of expertise is discussed elsewhere. 0 expertise

12 The new(ish) science of people

It is likely that the formal education of this book's readership will predominantly have been based on the so-called *hard sciences*. The word *hard* being used in the sense of having theories backed by solid experimental results, which are repeatable and have been repeated many times. These sciences, and many engineering disciplines, have also been studied experimentally for a long period of time. The controversies surrounding the basic theory, taught to undergraduates, have been worked through.

Psychology has none of those advantages. There are often unseen, complex interactions going on inside the object being studied (people's responses to questions and problems). Because of this, studies using slightly different experimental situations can obtain very different results. The field is also relatively new, and the basic theory is still being argued over. Consequently, this book cannot provide a definitive account of the underlying theories relating to the subject of immediate interest here— reading and writing source code.

The results of studies, and theories, from psychology are starting to become more widely applied in other fields. For instance, economists are starting to realize that people do not always make rational decisions.[1229] Researchers are also looking at the psychology of programming.

cognitive psychology

The subfield of psychology that is of most relevance to this book is cognitive psychology. The goal of cognitive psychology is to understand the nature of human intelligence and how it works. Other subfields include clinical psychology (understanding why certain thought malfunctions occur) and social psychology (how people behave in groups or with other individuals).[0.5]

12.1 Brief history of cognitive psychology

Topics of interest to cognitive psychology were discussed by the Greeks as part of their philosophical thinking. This connection with philosophy continued through the works of Descartes, Kant, Mill, and others. In 1879, Wilhelm Wundt established the first psychology laboratory in Germany; this date is considered to mark the start of psychology as an independent field. Wundt believed that the workings of the mind were open to self-observation. The method involved introspection by trained observers under controlled conditions. Unfortunately, different researchers obtained different results from these introspection experiments, so the theory lost creditability.

During the 1920s, John Watson and others developed the theory known as *Behaviorism*. This theory was based on the idea that psychology should be based on external behavior, not on any internal workings of the mind. The theory is best known through its use of rats in various studies. Although widely accepted in the US for a long time, behaviorism was not so dominant in Europe, where other theories were also developed.

Measurements on human performance were given a large boost by World War II. The introduction of technology, such as radar, required people to operate it. Information about how people were best trained to use complex equipment, and how they could best maintain their attention on the job at hand, was needed.

Cognitive psychology grew into its current form through work carried out between 1950 and 1970. The inner workings of the mind were center stage again. The invention of the computer created a device, the operation of which was seen as a potential parallel for the human mind. Information theory as a way of processing information started to be used by psychologists. Another influence was linguistics, in particular Noam Chomsky's theories for analyzing the structure of language. The information-processing approach to cognitive psychology is based on carrying out experiments that measured human performance and building models that explained the results. It does not concern itself with actual processes within the brain, or parts of the brain, that might perform these functions.

Since the 1970s, researchers have been trying to create theories that explain human cognition in terms of how the brain operates. These theories are known as *cognitive architectures*. The availability of brain scanners (which enable the flow of blood through the brain to be monitored, equating blood flow to activity) in the 1990s has created the research area of cognitive neuroscience, which looks at brain structure and processes.

[0.5] For a good introduction to the subject covering many of the issues discussed here, see either *Cognitive Psychology: A Student's Handbook* by Eysenck and Keane[405] or *Cognitive Psychology and its Implications* by Anderson.[33]

12.2 Evolutionary psychology

evolutionary psychology

Human cognitive processes are part of the survival package that constitutes a human being. The cognitive processes we have today exist because they increased (or at least did not decrease) the likelihood of our ancestors passing on their genes thorough offspring. Exactly what edge these cognitive processes gave our ancestors, over those who did not possess them, is a new and growing area of research known as *evolutionary psychology*. To quote one of the founders of the field:[286]

Cosmides[286]

> *Evolutionary psychology is an approach to psychology, in which knowledge and principles from evolutionary biology are put to use in research on the structure of the human mind. It is not an area of study, like vision, reasoning, or social behavior. It is a way of thinking about psychology that can be applied to any topic within it.*
>
> *. . . all normal human minds reliably develop a standard collection of reasoning and regulatory circuits that are functionally specialized and, frequently, domain-specific. These circuits organize the way we interpret our experiences, inject certain recurrent concepts and motivations into our mental life, and provide universal frames of meaning that allow us to understand the actions and intentions of others. Beneath the level of surface variability, all humans share certain views and assumptions about the nature of the world and human action by virtue of these human universal reasoning circuits.*

These functionally specialized circuits (the theory often goes by the name of the *massive modularity hypothesis*) work together well enough to give the impression of a powerful, general purpose processor at work. Because they are specialized to perform a given task when presented with a problem that does not have the expected form (the use of probabilities rather than frequency counts in the conjunction fallacy) performance is degraded (peoples behavior appears incompetent, or even irrational, if presented with a reasoning problem). The following are the basic principles:

0 conjunction fallacy

Cosmides[286]

> *Principle 1. The brain is a physical system. It functions as a computer. Its circuits are designed to generate behavior that is appropriate to your environmental circumstances.*
>
> *Principle 2. Our neural circuits were designed by natural selection to solve problems that our ancestors faced during our species' evolutionary history.*
>
> *Principle 3. Consciousness is just the tip of the iceberg; most of what goes on in your mind is hidden from you. As a result, your conscious experience can mislead you into thinking that our circuitry is simpler than it really is. Most problems that you experience as easy to solve are very difficult to solve— they require very complicated neural circuitry.*
>
> *Principle 4. Different neural circuits are specialized for solving different adaptive problems.*
>
> *Principle 5. Our modern skulls house a stone age mind.*

Although this field is very new and has yet to establish a substantial body of experimental results and theory, it is referred to throughout these coding guidelines. The standard reference is Barkow, Cosmides, and Tooby[94] (Mithen[945] provides a less-technical introduction).

12.3 Experimental studies

experimental studies

Much of the research carried out in cognitive psychology has used people between the ages of 18 and 21, studying some form of psychology degree, as their subjects. There has been discussion by psychology researchers on the extent to which these results can be extended to the general populace.[92] However, here we are interested in the extent to which the results obtained using such subjects is applicable to how developers behave?

Given that people find learning to program difficult, and there is such a high failure rate for programming courses[768] it is likely that some kind of ability factors are involved. However, because of the lack of studies investigating this issue, it is not yet possible to know what these programming ability factors might be. There are a large number of developers who did not study for some form of a computing degree at university, so the fact that experimental subjects are often students taking other kinds of courses is unlikely to be an issue.

12.3.1 The importance of experiments

The theories put forward by the established sciences are based on experimental results. Being elegant is not sufficient for a theory to be accepted; it has to be backed by experiments.

Software engineering abounds with theories, and elegance is often cited as an important attribute. However, experimental results for these theories are often very thin on the ground. The computing field is evolving so rapidly that researchers do not seem willing to invest significant amounts of their time gathering experimental data when there is a high probability that many of the base factors will have completely changed by the time the results are published.

Replication is another important aspect of scientific research; others should be able to duplicate the results obtained in the original experiment. Replication of experiments within software research is relatively rare; possible reasons include

- the pace of developments in computing means that there are often more incentives for trying new ideas rather than repeating experiments to verify the ideas of others,
- the cost of performing an experiment can be sufficiently high that the benefit of replication is seen as marginal, and/or
- the nature of experiments involving large-scale, commercial projects are very difficult to replicate. Source code can be duplicated perfectly, so there is no need to rewrite the same software again.

A good practical example of the benefits of replication and the dangers of not doing any is given by Brooks.[162] Another important issue is the statistical power of experiments.[938] Experiments that fail can be as important as those that succeed. Nearly all published, computing-related papers describe successes. The benefits of publishing negative results (i.e., ideas that did not work) has been proposed by Prechelt.[1116] A study[1249] of 5,453 papers published in software engineering journals between 1993 and 2002 found that only 1.9% reported controlled experiments (of which 72.6% used students only as subjects) and even then the statistical power of these experiments fell below expected norms.[373]

12.4 The psychology of programming

psychology of programming

Studies on the psychology of programming have taken their lead from trends in both psychology and software engineering. In the 1960s and 1970s, studies attempted to measure performance times for various tasks. Since then researchers have tried to build models of how people carry out the tasks involved with various aspects of programming.

Several theories about how developers go about the task of comprehending source code have been proposed. There have also been specific proposals about how to reduce developer error rates, or to improve developer performance. Unfortunately, the experimental evidence for these theories and proposals is either based on the use of inexperienced subjects or does not include sufficient data to enable statistically significant conclusions to be drawn. A more detailed, critical analysis of the psychological study of programming is given by Sheil[1222] (the situation does not seem to have changed since this paper was written 20 years ago).

Several studies have investigated how novices write software. This is both an area of research interest and of practical use in a teaching environment. The subjects taking part in these studies also have the characteristics of the population under investigation (i.e., predominantly students). However, this book is aimed at developers who have several years experience writing code; it is not aimed at novices and it does not teach programming skills.

Lethbridge, Sim, and Singer[838] discuss some of the techniques used to perform field studies inside software companies.

12.4.1 Student subjects

Although cognitive psychology studies use university students as their subjects there is an important characteristic they generally have, for these studies, that they don't have for software development studies.[1248] That characteristic is experience— that is, years of practice performing the kinds of actions (e.g., reading text,

making decisions, creating categories, reacting to inputs) they are asked to carry out in the studies. However, students, typically, have very little experience of writing software, perhaps 50 to 150 hours. Commercial software developers are likely to have between 1,000 to 10,000 hours of experience. A study by Moher and Schneider[953] compared the performance of students and professional developers in program comprehension tasks. The results showed that experience was a significant predictor of performance level (greater than aptitude in this study).

Reading and writing software is a learned skill. Any experiments that involve a skill-based performance need to take into account the subjects' skill level. The coding guidelines in this book are aimed at developers in a commercial environment where it is expected that they will have at least two years experience in software development.

Use of very inexperienced developers as subjects in studies means that there is often a strong learning effect in the results. Student subjects taking part in an experiment often get better at the task because they are learning as they perform it. Experienced developers have already acquired the skill in the task being measured, so there is unlikely to be any significant learning during the experiment. An interesting insight into the differences between experiments involving students and professional developers is provided by a study performed by Basili[98] and a replication of it by Ciolkowski.[237]

A note on differences in terminology needs to be made here. Many studies in the psychology of programming use the phrase *expert* to apply to a subject who is a third-year undergraduate or a graduate student (the term *novice* being applied to first-year undergraduates). In a commercial software development environment a recent graduate is considered to be a *novice* developer. Somebody with five or more years of commercial development experience might know enough to be called an *expert*.

12.4.2 Other experimental issues

When an experiment is performed, it is necessary to control all variables except the one being measured. It is also necessary to be able to perform the experiments in a reasonable amount of time. Most commercial programs contain thousands of lines of source code. Nontrivial programs of this size can contain any number of constructs that could affect the results of an experiment; they would also require a significant amount of effort to read and comprehend. Many experiments use programs containing less than 100 lines of source. In many cases, it is difficult to see how results obtained using small programs will apply to much larger programs.

The power of the statistical methods used to analyze experimental data depends on the number of different measurements made. If there are few measurements, the statistical significance of any claim's results will be small. Because of time constraints many experiments use a small number of different programs, sometimes a single program. All that can be said for any results obtained for a single program is that the results apply to that program; there is no evidence of generalization to any other programs.

Is the computer language used in experiments significant? The extent to which the natural language, spoken by a person, affects their thinking has been debated since Boas, Sapir, and Whorf developed the linguistic relativity hypothesis[871]. In this book, we are interested in C, a member of the procedural computer language family. More than 99.9% of the software ever written belongs to languages in this family. However, almost as many experiments seem to use nonprocedural languages, as procedural ones. Whether the language family of the experiment affects the applicability of the results to other language families is unknown. However, it will have an effect on the degree of believability given to these results by developers working in a commercial environment.

792 language affecting thought

12.5 What question is being answered?

Many of the studies carried out by psychologists implicitly include a human language (often English) as part of the experiment. Unless the experiments are carefully constructed, unexpected side-effects may be encountered. These can occur because of the ambiguous nature of words in human language, or because of subjects expectations based on their experience of the nature of human communication.

The following three subsections describe famous studies, which are often quoted in introductory cognitive psychology textbooks. Over time, these experiments have been repeated in various, different ways and the

underlying assumptions made by the original researchers has been challenged. The lesson to be learned from these studies is that it can be very difficult to interpret a subject's answer to what appears to be a simple question. Subjects simply may not have the intellectual machinery designed to answer the question in the fashion it is phrased (base rate neglect), they may be answering a completely different question (conjunction fallacy), or they may be using a completely unexpected method to solve a problem (availability heuristic).

12.5.1 Base rate neglect

base rate neglect
representa-0
tive heuristic

Given specific evidence, possible solutions to a problem can be ordered by the degree to which they are representative of that evidence (i.e., their probability of occurring as the actual solution, based on past experience). While these representative solutions may appear to be more likely to be correct than less-representative solutions, for particular cases they may in fact be less likely to be the solution. Other factors, such as the prior probability of the solution, and the reliability of the evidence can affect the probability of any solution being correct.

A series of studies, Kahneman and Tversky[706] suggested that subjects often seriously undervalue the importance of prior probabilities (i.e., they neglected base-rates). The following is an example from one of these studies. Subjects were divided into two groups, with one group of subjects being presented with the following cover story:

> A panel of psychologists have interviewed and administered personality tests to 30 engineers and 70 lawyers, all successful in their respective fields. On the basis of this information, thumbnail descriptions of the 30 engineers and 70 lawyers have been written. You will find on your forms five descriptions, chosen at random from the 100 available descriptions. For each description, please indicate your probability that the person described is an engineer, on a scale from 0 to 100.

and the other group of subjects presented with identical cover story, except the prior probabilities were reversed (i.e., they were told that the personality tests had been administered to 70 engineers and 30 lawyers). Some of the descriptions provided were designed to be compatible with the subjects' stereotype of engineers, others were designed to be compatible with the stereotypes of lawyers, and one description was intended to be neutral. The following are two of the descriptions used.

> Jack is a 45-year-old man. He is married and has four children. He is generally conservative, careful and ambitious. He shows no interest in political and social issues and spends most of his free time on his many hobbies which include home carpentry, sailing, and mathematical puzzles.
>
> The probability that Jack is one of the 30 engineers in the sample of 100 is ____%.

> Dick is a 30-year-old man. He is married with no children. A man of high ability and high motivation, he promises to be quite successful in his field. He is well liked by his colleagues.
>
> The probability that Dick is one of the 70 lawyers in the sample of 100 is ____%.

Following the five descriptions was this null description.

> Suppose now that you are given no information whatsoever about an individual chosen at random from the sample.
>
> The probability that this man is one of the 30 engineers in the sample of 100 is ____%.

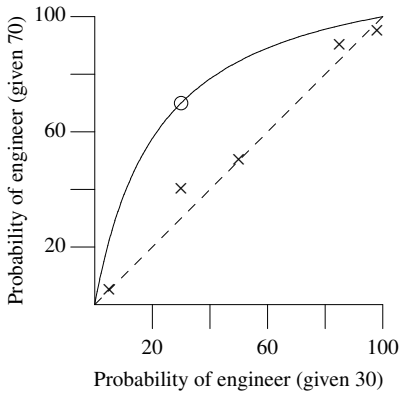

Figure 0.10: Median judged probability of subjects choosing an engineer, for five descriptions and for the null description (unfilled circle symbol). Adapted from Kahneman.[706]

In both groups, half of the subjects were asked to evaluate, for each description, if the person described was an engineer. The other subjects were asked the same question, except they were asked about lawyers.

The probability of a person being classified as an engineer, or lawyer, can be calculated using Bayes' theorem. Assume that, after reading the description, the estimated probability of that person being an engineer is P. The information that there are 30 engineers and 70 lawyers in the sample allows us to modify the estimate, P, to obtain a more accurate estimate (using all the information available to us). The updated probability is $0.3P/(0.3P + 0.7(1 - P))$. If we are told that there are 70 engineers and 30 lawyers, the updated probability is $0.7P/(0.7P + 0.3(1 - P))$. For different values of the estimate P, we can plot a graph using the two updated probabilities as the x and y coordinates. If information on the number of engineers and lawyers is not available, or ignored, the graph is a straight line.

The results (see Figure 0.10) were closer to the straight line than the Bayesian line. The conclusion drawn was that information on the actual number of engineers and lawyers in the sample (the base-rate) had minimal impact on the subjective probability chosen by subjects.

Later studies[756] found that peoples behavior when making decisions that included a base-rate component was complex. Use of base-rate information was found to depend on how problems and the given information was framed (large between study differences in subject performance were also seen). For instance, in some cases subjects were found to use their own experiences to judge the likelihood of certain events occurring rather than the probabilities given to them in the studies. In some cases the ecological validity of using Bayes' theorem to calculate the probabilities of outcomes has been questioned.

To summarize: while people have been found to ignore base-rates when making some decisions, this behavior is far from being universally applied to all decisions.

12.5.2 The conjunction fallacy

An experiment originally performed by Tversky and Kahneman[1375] presented subjects with the following problem. conjunction fallacy

> Linda is 31 years old, single, outspoken, and very bright. She majored in philosophy. As a student, she was deeply concerned with issues of discrimination and social justice, and also participated in anti-nuclear demonstrations.
>
> Please rank the following statements by their probability, using 1 for the most probable and 8 for the least probable.
>
> (a) Linda is a teacher in elementary school.
>
> (b) Linda works in a bookstore and takes Yoga classes.

(c) Linda is active in the feminist movement.
(d) Linda is a psychiatric social worker.
(e) Linda is a member of the League of Women Voters.
(f) Linda is a bank teller.
(g) Linda is an insurance sales person.
(h) Linda is a bank teller and is active in the feminist movement.

In a group of subjects with no background in probability or statistics, 89% judged that statement (h) was more probable than statement (f). Use of simple mathematical logic shows that Linda cannot be a feminist bank teller unless she is also a bank teller, implying that being only a bank teller is at least as likely, if not more so, than being both a bank teller and having some additional attribute. When the subjects were graduate students in the decision science program of the Stanford Business School (labeled as statistically sophisticated by the experimenters), 85% judged that statement (h) was more probable than statement (f).

These results (a compound event being judged more probable than one of its components) have been duplicated by other researchers performing different experiments. A recent series of studies[1233] went as far as checking subjects' understanding of the word *probability* and whether statement (f) might be interpreted to mean *Linda is a bank teller and not active in the feminist movement* (it was not).

This pattern of reasoning has become known as *the conjunction fallacy*.

On the surface many of the subjects in the experiment appear to be reasoning in a nonrational way. How can the probability of the event *A and B* be greater than the probability of event *A*? However, further studies have found that the likelihood of obtaining different answers can be affected by how the problem is expressed. The effects of phrasing the problem in terms of either *probability* or *frequency* were highlighted in a study by Fiedler.[421] The original Tversky and Kahneman study wording was changed to the following:

There are 100 people who fit the description above. How many of them are:
(a) bank tellers?
(b) bank tellers and active in the feminist movement?
. . .

In this case, only 22% of subjects rated the *bank teller and active in the feminist movement* option as being more frequent than the *bank teller* only option. When Fiedler repeated the experiment using wording identical to the original Tversky and Kahneman experiment, 91% of subjects gave the feminist bank teller option as more probable than the bank teller only option. A number of different explanations, for the dependence of the conjunction fallacy on the wording of the problem, have been proposed.

evolutionary psychology 0

Evolutionary psychologists have interpreted these results as showing that people are not very good at reasoning using probability. It is argued that, in our daily lives, events are measured in terms of their frequency of occurrence (e.g., how many times fish were available at a particular location in the river). This event-based measurement includes quantity, information not available when probabilities are used. Following this argument through suggests that the human brain has become specialized to work with frequency information, not probability information.

conjunction fallacy pragmatic interpretation relevance 0

Hertwig and Gigerenzer[569] point out that, in the Linda problem, subjects were not informed that they were taking part in an exercise in probability. Subjects therefore had to interpret the instructions; in particular, what did the experimenter mean by *probability*? Based on Grice's[520] theory of conversational reasoning, they suggested that the likely interpretation given to the word *probability* would be along the lines of "something which, judged by present evidence, is likely to be true, to exist, or to happen," (one of the Oxford English dictionary contemporary definitions of the word), not the mathematical definition of the word.

Grice's theory was used to make the following predictions:

Prediction 1: Probability judgments. If asked for probability judgments, people will infer its nonmathematical meanings, and the proportion of conjunction violations will be high as a result.

Prediction 2: Frequency judgments. If asked for frequency judgments, people will infer mathematical meanings, and the proportion of conjunction violations will decrease as a result.

Prediction 3: Believability judgments. If the term "probability" is replaced by "believability", then the proportion of conjunction violations should be about as prevalent as in the probability judgment.

A series of experiments confirmed these predictions. A small change in wording caused subjects to have a completely different interpretation of the question.

12.5.3 Availability heuristic

availability heuristic

How do people estimate the likelihood of an occurrence of an event? The availability heuristic argues that, in making an estimate, people bring to mind instances of the event; the more instances brought to mind, the more likely it is to occur. Tversky and Kahneman[1373] performed several studies in an attempt to verify that people use this heuristic to estimate probabilities. Two of the more well-known experiments follow.

The first is judgment of word frequency; here subjects are first told that.

> The frequency of appearance of letters in the English language was studied. A typical text was selected, and the relative frequency with which various letters of the alphabet appeared in the first and third positions in words was recorded. Words of less than three letters were excluded from the count.
>
> You will be given several letters of the alphabet, and you will be asked to judge whether these letters appear more often in the first or in the third position, and to estimate the ratio of the frequency with which they appear in these positions.

They were then asked the same question five times, using each of the letters (K, L, N, R, V).

> Consider the letter R.
> Is R more likely to appear in:
>
> - the first position?
> - the third position? (check one)
>
> My estimate for the ratio of these two values is ___:1.

Of the 152 subjects, 105 judged the first position to be more likely (47 the third position more likely). The median estimated ratio was 2:1.

In practice, words containing the letter *R* in the third position occur more frequently in texts than words with *R* in the first position. This is true for all the letters— *K*, *L*, *N*, *R*, *V*.

The explanation given for these results was that subjects could more easily recall words beginning with the letter *R*, for instance, than recall words having an *R* as the third letter. The answers given, being driven by the availability of instances that popped into the subjects' heads, not by subjects systematically counting all the words they knew.

An alternative explanation of how subjects might have reached their conclusion was proposed by Sedlmeier, Hertwig, and Gigerenzer.[1210] First they investigated possible ways in which the availability heuristic might operate; Was it based on availability-by-number (the number of instances that could be recalled) or availability-by-speed (the speed with which instances can be recalled). Subjects were told (the following is an English translation, the experiment took place in Germany and used German students) either:

> Your task is to recall as many words as you can in a certain time. At the top of the following page you will see a letter. Write down as many words as possible that have this letter as the first (second) letter.

or,

> Your task is to recall as quickly as possible one word that has a particular letter as the first (second) letter. You will hear first the position of the letter and then the letter. From the moment you hear the letter, try to recall a respective word and verbalize this word.

Subjects answers were used to calculate an estimate of relative word frequency based on either availability-by-number or on availability-by-speed. These relative frequencies did not correlate with actual frequency of occurrence of words in German. The conclusion drawn was that the availability heuristic was not an accurate estimator of word frequency, and that it could not be used to explain the results obtained by Tversky and Kahneman.

If subjects were not using either of these availability heuristics, what mechanism are they using? Jonides and Jones[691] have shown, based on a large body of results, that subjects are able to judge the number of many kinds of events in a way that reflects the actual relative frequencies of the events with some accuracy.

Sedlmeier et al.[1210] proposed (what they called the *regressed-frequencies hypothesis*) that (a) the frequencies with which individual letters occur at different positions in words are monitored (by people while reading), and (b) the letter frequencies represented in the mind are regressed toward the mean of all letter frequencies. This is a phenomenon often encountered in frequency judgment tasks, where low frequencies tend to be overestimated and high frequencies underestimated; although this bias affects the accuracy of the absolute size of frequency judgments, it does not affect their rank order. Thus, when asked for the relative frequency of a particular letter, subjects should be expected to give judgments of relative letter frequencies that reflect the actual ones, although they will overestimate relative frequencies below the mean and underestimate those above the mean — a simple regressed-frequency heuristic. The studies performed by Sedlmeier et al. consistently showed subjects' judgments conforming best to the predictions of the regressed-frequencies hypothesis.

While it is too soon to tell if the regressed-frequencies hypothesis is the actual mechanism used by subjects, it does offer a better fit to experimental results than the availability heuristic.

13 Categorization

categorization

Children as young as four have been found to use categorization to direct the inferences they make,[480] and many different studies have shown that people have an innate desire to create and use categories (they have also been found to be sensitive to the costs and benefits of using categories[884]). By dividing items in the world into categories of things, people reduce the amount of information they need to learn[1112] by building an indexed data structure that will enable them to lookup information on specific items they may not have encountered before (by assigning that item to one or more categories and extracting information common to items in those categories). For instance, a flying object with feathers and a beak might be assigned to the category *bird*, which suggests the information that it lays eggs and may be migratory.

Source code is replete with examples of categories; similar functions are grouped together in the same source file, objects belonging to a particular category are defined as members of the same structure type, and enumerated types are defined to represent a common set of symbolic names.

translation unit 1810 (syntax)
structure type 530 (sequentially allocated objects)
declaration 1348 (syntax)
enumeration 517 (set of named constants)
symbolic name 822

People seem to have an innate desire to create categories (people have been found to expect random sequences to have certain attributes,[407] e.g., frequent alternation between different values, which from a mathematical perspective represent regularity). There is the danger that developers, reading a program's source code will create categories that the original author was not aware existed. These *new* categories may

represent insights into the workings of a program, or they may be completely spurious (and a source of subsequent incorrect assumptions, leading to faults being introduced).

Categories can be used in many thought processes without requiring significant cognitive effort (a built-in operation). For instance, categorization can be used to perform inductive reasoning (the derivation of generalized knowledge from specific instances), and to act as a memory aid (remembering the members of a category). There is a limit on the cognitive effort that developers have available to be used and making use of a powerful ability, which does not require a lot of effort, helps optimize the use of available resources.

There have been a number of studies[1166] looking at how people use so-called *natural categories* (i.e., those occurring in nature such as mammals, horses, cats, and birds) to make inductive judgments. People's use of categorical-based arguments (e.g., "Grizzly bears love onions." and "Polar bears love onions." therefore "All bears love onions.") has also been studied.[1037]

Source code differs from nature in that it is created by people who have control over how it is organized. Recognizing that people have an innate ability to create and use categories, there is a benefit in trying to maximize positive use (developers being able to infer probable behaviors and source code usage based on knowing small amounts of information) of this ability and to minimize negative use (creating unintended categories, or making inapplicable inductive judgments).

Source code can be organized in a myriad of ways. The problem is finding the optimal organization, which first requires knowing what needs to be optimized. For instance, I might decide to split some functions I have written that manipulate matrices and strings into two separate source files. I could decide that the functions I wrote first will go in the first file and those that I wrote later in the second file, or perhaps the first file will contain those functions used on project X and the second file those functions used on project Y. To an outside observer, a more *natural* organization might be to place the matrix-manipulation functions in the first file and the string-manipulation functions in the second file.

In a project that grows over time, functions may be placed in source files on an as-written basis; a maintenance process that seeks to minimize disruption to existing code will keep this organization. When two separate projects are merged into one, a maintenance process that seeks to minimize disruption to existing code is unlikely to reorganize source file contents based on the data type being manipulated. This categorization process, based on past events, is a major factor in the difficulty developers have in comprehending *old* source. Because category membership is based on historical events, developers either need knowledge of those events or they have to memorize information on large quantities of source. Program comprehension changes from using category-based induction to relying on memory for events or source code.

Even when the developer is not constrained by existing practices the choice of source organization is not always clear-cut. An organization based on the data type being manipulated is one possibility, or there may only be a few functions and an organization based on functionality supported (i.e., printing) may be more appropriate. Selecting which to use can be a difficult decision. The following subsections discuss some of the category formation studies that have been carried out, some of the theories of category formation, and possible methods of calculating similarity to category.

Situations where source code categorization arise include: deciding which structure types should contain which members, which source files should contain which object and function definitions, which source files should be kept in which directories, whether functionality should go in a single function or be spread across several functions, and what is the sequence of identifiers in an enumerated type?

1810 declarations in which source file

Explicitly organizing source code constructs so that future readers can make use of their innate ability to use categories, to perform inductive reasoning, is not meant to imply that other forms of reasoning are not important. The results of deductive reasoning are generally the norm against which developer performance is measured. However, in practice, developers do create categories and use induction. Coding guidelines need to take account of this human characteristic. Rather than treating it as an aberration that developers need to be trained out of, these coding guidelines seek to adapt to this innate ability.

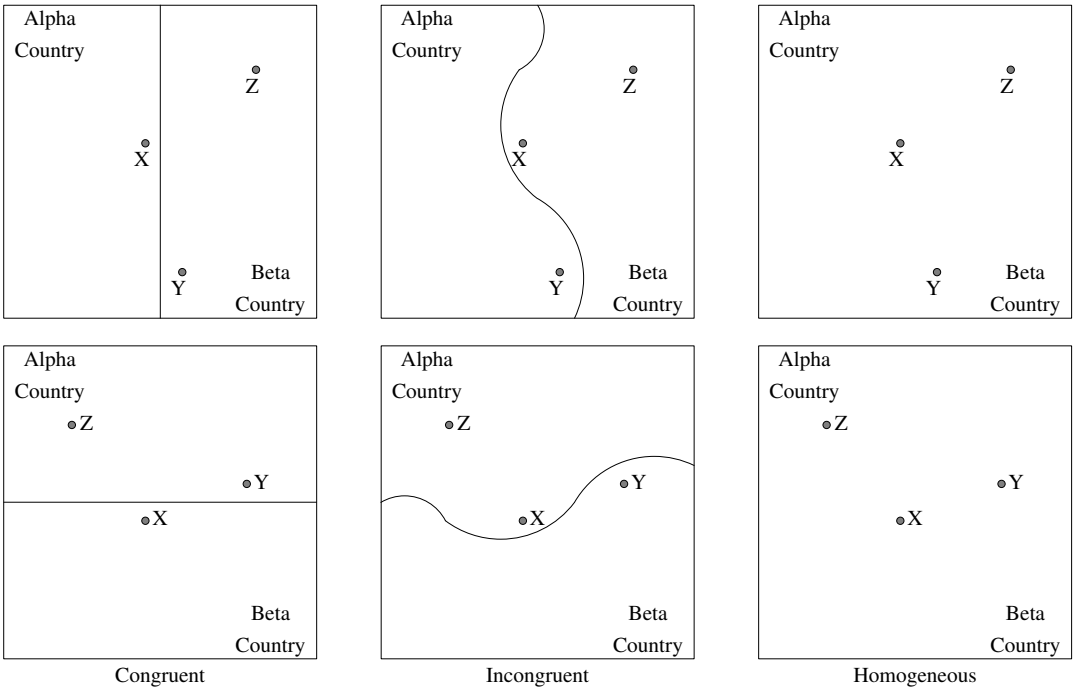

Figure 0.11: Country boundaries distort judgment of relative city locations. Adapted from Stevens.[1295]

13.1 Category formation

How categories should be defined and structured has been an ongoing debate within all sciences. For instance, the methods used to classify living organisms into family, genus, species, and subspecies has changed over the years (e.g., most recently acquiring a genetic basis).

Categories do not usually exist in isolation. Category judgment is often organized according to a hierarchy of relationships between concepts— a taxonomy. For instance, Jack Russell, German Shepherd, and Terrier belong to the category of dog, which in turn belongs to the category of mammal, which in turn belongs to the category of living creature. Organizing categories into hierarchies means that an attribute of a higher-level category can affect the perceived attributes of a subordinate category. This effect was illustrated in a study by Stevens and Coupe.[1295] Subjects were asked to remember the information contained in a series of maps (see Figure 0.11). They were then asked questions such as: "Is X east or west of Y?", and "Is X north or south of Y?" Subjects gave incorrect answers 18% of the time for the congruent maps, but 45% of the time for the incongruent maps (15% for the homogeneous). They were using information about the relative locations of the countries to answer questions about the city locations.

Several studies have shown that people use around three levels of abstraction in creating hierarchical relationships. Rosch[1179] called the highest level of abstraction the *superordinate-level*— for instance, the general category furniture. The next level down is the *basic-level*; this is the level at which most categorization is carried out— for instance, car, truck, chair, or table. The lowest level is the *subordinate-level*, denoting specific types of objects. For instance, a family car, a removal truck, my favourite armchair, a kitchen table. Rosch found that the basic-level categories had properties not shared by the other two categories; adults spontaneously name objects at this level. It is also the abstract level that children acquire first, and category members tend to have similar overall shapes.

- A study by Markman and Wisniewski[896] investigated how people view superordinate-level and basic-level categories as being different. The results showed that basic-level categories, derived from the

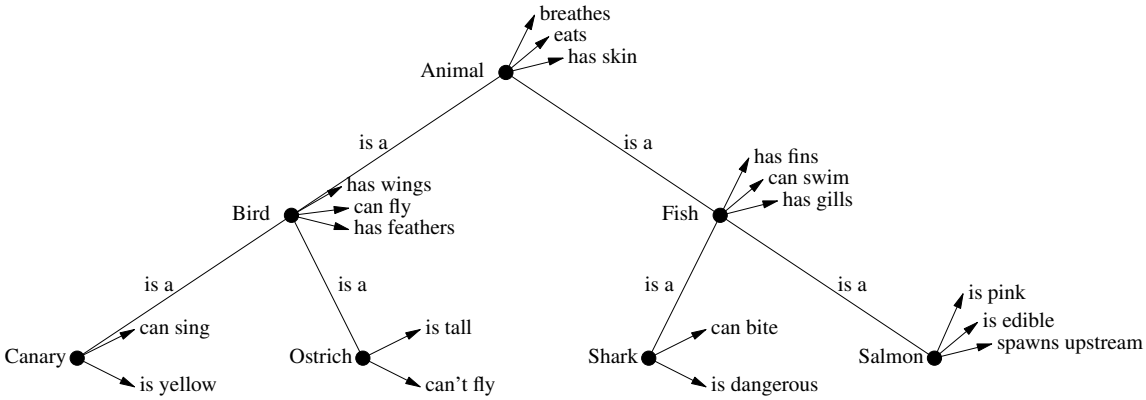

Figure 0.12: Hypothetical memory structure for a three-level hierarchy. Adapted from Collins.[258]

same superordinate-level, had a common structure that made it easy for people to compare attributes; for instance, motorcycle, car, and truck are basic-level categories of vehicle. They all share attributes (so-called *alignable differences*), for instance, number of wheels, method of steering, quantity of objects that can be carried, size of engine, and driver qualifications that differ but are easily compared. Superordinate-level categories differ from each other in that they do not share a common structure. This lack of a common structure means it is not possible to align their attributes to differentiate them. For these categories, differentiation occurs through the lack of a common structure. For instance, the superordinate-level categories — vehicle, musical instrument, vegetable, and clothing — do not share a common structure.

- A study by Tanaka and Taylor[1331] showed that the quantity of a person's knowledge and experience can affect the categories they create and use.
- A study by Johansen and Palmeri[671] showed that representations of perceptual categories can change with categorization experience. While these coding guidelines are aimed at experienced developers, they recognize that many experienced developers are likely to be inexperienced comprehenders of much of the source code they encounter. The guidelines in this book take the default position that, given a choice, they should assume an experienced developer who is inexperienced with the source being read.

There are likely to be different ways of categorizing the various components of source code. These cases are discussed in more detail elsewhere. Commonality and regularities shared between different sections of source code may lead developers to implicitly form categories that were not intended by the original authors. The extent to which the root cause is poor categorization by the original developers, or simply unrelated regularities, is not discussed in this book.

What method do people use to decide which, if any, category a particular item is a member of? Several different theories have been proposed and these are discussed in the following subsections.

13.1.1 The Defining-attribute theory

The defining-attribute theory proposes that members of a category are characterized by a set of defining attributes. This theory predicts that attributes should divide objects up into different concepts whose boundaries are well defined. All members of the concept are equally representative. Also, concepts that are a basic-level of a superordinate-level concept will have all the attributes of that superordinate level; for instance, a sparrow (small, brown) and its superordinate bird (two legs, feathered, lays eggs); see Figure 0.12.

Although scientists and engineers may create and use defining-attribute concept hierarchies, experimental evidence shows that people do not naturally do so. Studies have shown that people do not treat category

members as being equally representative, and some are rated as more typical than others.[1168] Evidence that people do not structure concepts into the neat hierarchies required by the defining-attribute theory was provided by studies in which subjects verified membership of a more distant superordinate more quickly than an immediate superordinate (according to the theory, the reverse situation should always be true).

13.1.2 The Prototype theory

In this theory, categories have a central description, the prototype, that represents the set of attributes of the category. This set of attributes need not be necessary, or sufficient, to determine category membership. The members of a category can be arranged in a typicality gradient, representing the degree to which they represent a typical member of that category. It is also possible for objects to be members of more than one category (e.g., tomatoes as a fruit, or a vegetable).

13.1.3 The Exemplar-based theory

The exemplar-based theory of classification proposes that specific instances, or *exemplars*, act as the prototypes against which other members are compared. Objects are grouped, relative to one another, based on some similarity metric. The exemplar-based theory differs from the prototype theory in that specific instances are the norm against which membership is decided. When asked to name particular members of a category, the attributes of the exemplars are used as cues to retrieve other objects having similar attributes.

13.1.4 The Explanation-based theory

The explanation-based theory of classification proposes that there is an explanation for why categories have the members they do. For instance, the biblical classification of food into *clean* and *unclean* is roughly explained by saying that there should be a correlation between type of habitat, biological structure, and form of locomotion; creatures of the sea should have fins, scales, and swim (sharks and eels don't) and creatures of the land should have four legs (ostriches don't).

From a predictive point of view, explanation-based categories suffer from the problem that they may heavily depend on the knowledge and beliefs of the person who formed the category; for instance, the set of objects a person would remove from their home while it was on fire.

Murphy and Medin[983] discuss how people can use explanations to achieve conceptual coherence in selecting the members of a category (see Table 0.5).

Table 0.5: General properties of explanations and their potential role in understanding conceptual coherence. Adapted from Murphy.[983]

Properties of Explanations	Role in Conceptual Coherence
Explanation of a sort, specified over some domain of observation	Constrains which attributes will be included in a concept representation Focuses on certain relationships over others in detecting attribute correlations
Simplify reality	Concepts may be idealizations that impose more structure than is *objectively* present
Have an external structure— fits in with (or do not contradict) what is already known	Stresses intercategory structure; attributes are considered essential to the degree that they play a part in related theories (external structures)
Have an internal structure— defined in part by relations connecting attributes	Emphasizes mutual constraints among attributes. May suggest how concept attributes are learned
Interact with data and observations in some way	Calls attention to inference processes in categorization and suggests that more than attribute matching is involved

13.2 Measuring similarity

guideline recommendation enforceable

The intent is for these guideline recommendations to be automatically enforceable. This requires an algorithm for calculating similarity, which is the motivation behind the following discussion.

How might two objects be compared for similarity? For simplicity, the following discussion assumes an object can have one of two values for any attribute, yes/no. The discussion is based on material in

Classification and Cognition by W. K. Estes.[398]

similarity product rule

To calculate the similarity of two objects, their corresponding attributes are matched. The product of the similarity coefficient of each of these attributes is computed. A matching similarity coefficient, t (a value in the range one to infinity, and the same for every match), is assigned for matching attributes. A nonmatching similarity coefficient, s_i (a value in the range 0 to 1, and potentially different for each nonmatch), is assigned for each nonmatching coefficient. For example, consider two birds that either have (plus sign), or do not have (minus sign), some attribute (numbered 1 to 6 in Table 0.6). Their similarity, based on these attributes is $t \times t \times s_3 \times t \times s_5 \times t$.

Table 0.6: Computation of pattern similarity. Adapted from Estes.[398]

Attribute	1	2	3	4	5	6
Starling	+	+	-	+	+	+
Sandpiper	+	+	+	+	-	+
Attribute similarity	t	t	s_3	t	s_5	t

When comparing objects within the same category the convention is to give the similarity coefficient, t, for matching attributes, a value of one. Another convention is to give the attributes that differ the same similarity coefficient, s. In the preceding case, the similarity becomes s^2.

Sometimes the similarity coefficient for matches needs to be taken into account. For instance, in the following two examples the similarity between the first two character sequences is ts, while in the second is t^3s. Setting t to be one would result in both pairs of character sequences being considered to have the same similarity, when in fact the second sequence would be judged more similar than the first. Studies on same/different judgments show that both reaction time and error rates increase as a function of the number of items being compared.[777] The value of t cannot always be taken to be unity.

```
A  B          A  B  C  D
A  E          A  E  C  D
```

The previous example computed the similarity of two objects to each other. If we have a category, we can calculate a similarity to category measure. All the members of a category are listed. The similarity of each member, compared with every other member, is calculated in turn and these values are summed for that member. Such a calculation is shown in Table 0.7.

Table 0.7: Computation of similarity to category. Adapted from Estes.[398]

Object	Ro	Bl	Sw	St	Vu	Sa	Ch	Fl	Pe	Similarity to Category
Robin	1	1	1	s	s^4	s	s^5	s^6	s^5	$3+2s+s^4+2s^5+s^6$
Bluebird	1	1	1	s	s^4	s	s^5	s^6	s^5	$3+2s+s^4+2s^5+s^6$
Swallow	1	1	1	s	s^4	s	s^5	s^6	s^5	$3+2s+s^4+2s^5+s^6$
Starling	s	s	s	1	s^3	s^2	s^6	s^5	s^6	$1+3s+s^2+s^3+s^5+2s^6$
Vulture	s^4	s^4	s^4	s^3	1	s^5	s^3	s^2	s^3	$1+s^2+3s^3+3s^4+s^5$
Sandpiper	s	s	s	s^2	s^5	1	s^4	s^5	s^4	$1+3s+s^2+s^4+s^5$
Chicken	s^5	s^5	s^5	s^6	s^3	s^4	1	s	1	$2+s+s^3+s^4+3s^5+s^6$
Flamingo	s^6	s^6	s^6	s^5	s^2	s^5	s	1	s	$1+2s+s^2+2s^5+3s^6$
Penguin	s^5	s^5	s^5	s^6	s^3	s^4	1	s	1	$2+s+s^3+s^4+3s^5+s^6$

Some members of a category are often considered to be more typical of that category than other members. These typical members are sometimes treated as exemplars of that category, and serve as reference points when people are thinking about that category. While there is no absolute measure of typicality, it is possible to compare the typicality of two members of a category. The relative typicality, within a category for two or more objects is calculated from their ratios of similarity to category. For instance, taking the value of s as

0.5, the relative typicality of Robin with respect to Vulture is $4.14/(4.14 + 1.84) = 0.69$, and the relative typicality of Vulture with respect to Robin is $1.84/(4.14 + 1.84) = 0.31$.

It is also possible to create derived categories from existing categories; for instance, large and small birds. For details on how to calculate typicality within those derived categories, see Estes[398] (which also provides experimental results).

similarity contrast model

An alternative measure of similarity is the contrast model. This measure of similarity depends positively on the number of attributes two objects have in common, but negatively on the number of attributes that belong to one but not the other.

$$Contrast\ Sim_{12} = af(F_{12}) - bf(F_1) - cf(F_2) \tag{0.14}$$

where F_{12} is the set of attributes common to objects 1 and 2, F_1 the set of attributes that object 1 has but not object 2, and F_2 the set of attributes that object 2 has but not object 1. The quantities a, b, and c are constants. The function f is some metric based on attributes; the one most commonly appearing in published research is a simple count of attributes.

Taking the example given in Table 0.7, there are four features shared by the starling and sandpiper and one that is unique to each of them. This gives:

$$Contrast\ Sim = 4a - 1b - 1c \tag{0.15}$$

based on bird data we might take, for instance, $a = 1$, $b = 0.5$, and $c = 0.25$ giving a similarity of 3.25.

On the surface, these two models appear to be very different. However, some mathematical manipulation shows that the two methods of calculating similarity are related.

$$Sim_{12} = t^{n_{12}} s^{n_1+n_2} = t^{n_{12}} s^{n_1} s^{n_2} \tag{0.16}$$

Taking the logarithm:

$$\log(Sim_{12}) = n_{12}\log(t) + n_1\log(s) + n_2\log(s) \tag{0.17}$$

letting $a = \log(t)$, $b = \log(s)$, $c = \log(s)$, and noting that the value of s is less than 1, we get:

$$\log(Sim_{12}) = a(n_{12}) - b(n_1) - c(n_2) \tag{0.18}$$

This expression for product similarity has the same form as the expression for contrast similarity. Although b and c have the same value in this example, in a more general form the values of s could be different.

13.2.1 Predicting categorization performance

categorization performance predicting

Studies [1179] have shown that the order in which people list exemplars of categories correlates with their relative typicality ratings. These results lead to the idea that relative typicality ratings could be interpreted as probabilities of categorization responses. However, the algorithm for calculating similarity to category values does not take into account the number of times a subject has encountered a member of the category (which will control the strength of that member's entry in the subject's memory).

For instance, based on the previous example of bird categories when asked to "name the bird which comes most quickly to mind, Robin or Penguin", the probability of Robin being the answer is $4.14/(4.14 + 2.80) = 0.60$, an unrealistically low probability. If the similarity values are weighted according to the frequency

of each member's entry in a subject's memory array (Estes estimated the figures given in Table 0.8), the probability of Robin becomes $1.24/(1.24+0.06) = 0.954$, a much more believable probability. The need to use frequency weightings to calculate a weighted similarity value has been verified by Nosofsky.[1017]

Table 0.8: Computation of weighted similarity to category. From Estes.[398]

Object	Similarity Formula	$s = 0.5$	Relative Frequency	Weighted Similarity
Robin	$3+2s+s^4+2s^5+s^6$	4.14	0.30	1.24
Bluebird	$3+2s+s^4+2s^5+s^6$	4.14	0.20	0.83
Swallow	$3+2s+s^4+2s^5+s^6$	4.14	0.10	0.41
Starling	$1+3s+s^2+s^3+s^5+2s^6$	2.94	0.15	0.44
Vulture	$1+s^2+3s^3+3s^4+s^5$	1.84	0.02	0.04
Sandpiper	$1+3s+s^2+s^4+s^5$	2.94	0.05	0.15
Chicken	$2+s+s^3+s^4+3s^5+s^6$	2.80	0.15	0.42
Flamingo	$1+2s+s^2+2s^5+3s^6$	2.36	0.01	0.02
Penguin	$2+s+s^3+s^4+3s^5+s^6$	2.80	0.02	0.06

The method of measuring similarity just described has been found to be a good predictor of the error probability of people judging which category a stimulus belongs to. The following analysis is based on a study performed by Shepard, Hovland, and Jenkins.[1225]

A simpler example than the bird category is used to illustrate how the calculations are performed. Here, the object attributes are color and shape, made up of the four combinations black/white, triangles/squares. Taking the case where the black triangle and black square have been assigned to category A, and the white triangle and white square have been assigned to category B, we get Table 0.9.

Table 0.9: Similarity to category (black triangle and black square assigned to category A; white triangle and white square assigned to category B).

Stimulus	Similarity to A	Similarity to B
Dark triangle	$1+s$	$s+s^2$
Dark square	$1+s$	$s+s^2$
Light triangle	$s+s^2$	$1+s$
Light square	$s+s^2$	$1+s$

If a subject is shown a stimulus that belongs in category A, the expected probability of them assigning it to that category is:

$$\frac{1+s}{(1+s)+(s+s^2)} \Rightarrow \frac{1}{1+s} \tag{0.19}$$

When s is 1 the expected probability is no better than a random choice; when s is 0 the probability is a certainty.

Assigning different stimulus to different categories can change the expected response probability; for instance, by assigning the black triangle and the white square to category A and assigning the white triangle and black square to category B, we get the category similarities shown in Table 0.10.

Table 0.10: Similarity to category (black triangle and white square assigned to category A; white triangle and black square assigned to category B).

Stimulus	Similarity to A	Similarity to B
Dark triangle	$s+s^2$	$2s$
Dark square	$2s$	$s+s^2$
Light triangle	$2s$	$s+s^2$
Light square	$s+s^2$	$2s$

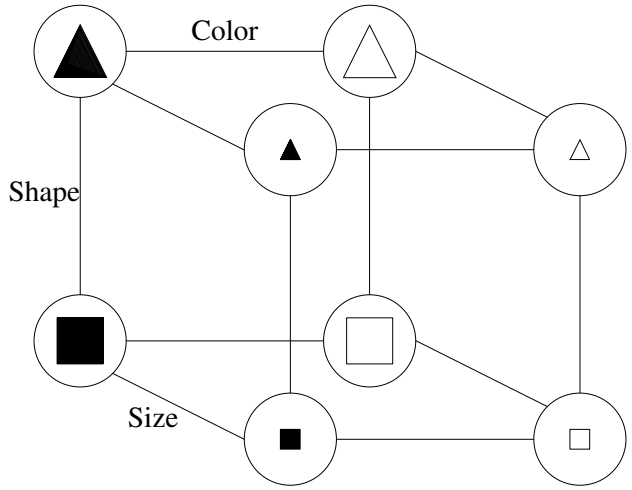

Figure 0.13: Representation of stimuli with shape in the horizontal plane and color in one of the vertical planes. Adapted from Shepard.[1225]

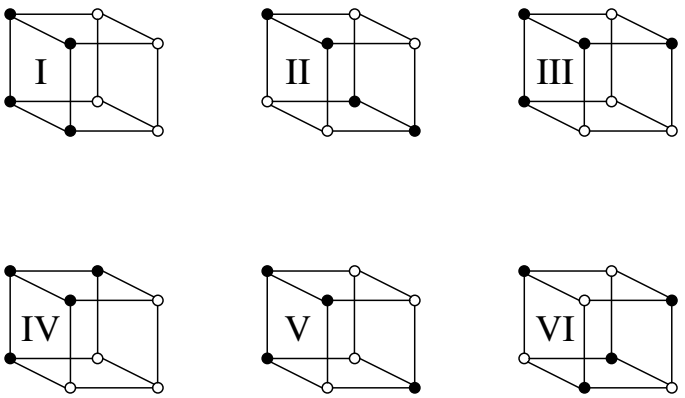

Figure 0.14: One of the six unique configurations (i.e., it is not possible to rotate one configuration into another within the set of six) of selecting four times from eight possibilities. Adapted from Shepard.[1225]

If a subject is shown a stimulus that belongs in category A, the expected probability of them assigning it to that category is:

$$\frac{1+s^2}{(2s)+(1+s^2)} \Rightarrow \frac{1+s^2}{(1+s)^2} \tag{0.20}$$

For all values of s between 0 and 1 (but not those two values), the probability of a subject assigning a stimulus to the correct category is always less than for the category defined previously, in this case.

In the actual study performed by Shepard, Hovland, and Jenkins,[1225] stimuli that had three attributes, color/size/shape, were used. If there are two possible values for each of these attributes, there are eight possible stimuli (see Figure 0.13).

Each category was assigned four different members. There are 70 different ways of taking four things from a choice of eight $(8!/(4!4!))$, creating 70 possible categories. However, many of these 70 different categories share a common pattern; for instance, all having one attribute, like all black or all triangles. If this symmetry is taken into account, there are only six different kinds of categories. One such selection of six

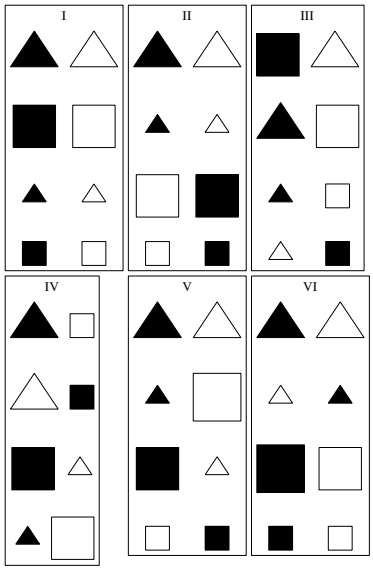

Figure 0.15: Example list of categories. Adapted from Shepard.[1225]

categories is shown in Figure 0.14, the black circles denoting the selected attributes.

Having created these six categories, Shepard et al. trained and measured the performance of subjects in assigning presented stimuli (one of the list of 70 possible combinations of four things— Figure 0.15) to one of them.

Estes[398] found a reasonable level of agreement between the error rates reported by Shepard et al. and the rates predicted by the similarity to category equations. There is also a connection between categorization performance and Boolean complexity; this is discussed elsewhere.

1739 selection statement
syntax

A series of studies by Feldman[414] was able to show a correlation between the difficulty subjects had answering the Shepard classification problems and their boolean complexity (i.e., the length of the shortest logically equivalent propositional formula).

13.3 Cultural background and use of information

The attributes used to organize information (e.g., categorize objects) has been found to vary across cultures[1015] and between experts and non-experts. The following studies illustrate how different groups of people agree or differ in their categorization behavior (a cultural difference in the naming of objects is discussed elsewhere):

categorization
cultural differences

792 naming
cultural differences

- A study by Bailenson, Shum, and Coley[81] asked US bird experts (average of 22.4 years bird watching), US undergraduates, and ordinary Itzaj (Maya Amerindians people from Guatemala) to sort two sets (of US and Maya) of 104 bird species into categories. The results found that the categorization choices made by the three groups of subjects were internally consistent within each group. The correlation between the taxonomies, created by the categories, and a published scientific taxonomy of US experts (0.60 US birds, 0.70 Maya birds), Itzaj (0.45, 0.61), and nonexperts (0.38, 0.34). The US experts correlated highly with the scientific taxonomy for both sets of birds, the Itzaj only correlated highly for Maya birds, and the nonexperts had a low correlation for either set of birds. The reasons given for the Maya choices varied between the expert groups; US experts were based on a scientific taxonomy, Itzaj were based on ecological justifications (the birds relationship with its environment). Cultural differences were found in that, for instance, US subjects were more likely to generalise from songbirds, while the Itzaj were more likely to generalize from perceptually striking birds.

- A study by Proffitt, Coley, and Medin[1126] told three kinds of tree experts (landscape gardeners, parks maintenance workers, scientists researching trees) about a new disease that affected two kinds of tree (e.g., Horsechestnut and Ohio buckeye). Subjects were then asked what other trees they thought might also be affected by this disease. The results showed differences between kinds of experts in the kinds of justifications given for the answers. For instance, landscapers and maintenance workers used more causal/ecological explanations (tree distribution, mechanism of disease transmission, resistance, and susceptibility) and fewer similarity-based justifications (species diversity and family size). For taxonomists this pattern was reversed.

14 Decision making

Writing source code is not a repetitive process. Developers have to think about what they are going to write, which means they have to make decisions. Achieving the stated intent of these coding guidelines (minimizing the cost of ownership source code) requires that they be included in this, developer, decision-making process.

coding 0 guidelines introduction

There has been a great deal of research into how and why people make decisions in various contexts. For instance, consumer research trying to predict how a shopper will decide among packets of soap powder on a supermarket shelf. While the items being compared and their attributes vary (e.g., which soap will wash the whitest, should an **`if`** statement or a **`switch`** statement be used; which computer is best), the same underlying set of mechanisms appear to be used, by people, in making decisions.

The discussion in this section has been strongly influenced by *The Adaptive Decision Maker* by Payne, Bettman, and Johnson.[1065] The model of human decision making proposed by Payne et al. is based on the idea that people balance the predicted cognitive effort required to use a particular decision-making strategy against the likely accuracy achieved by that decision-making strategy. The book lists the following major assumptions:

Payne[1065]

- *Decision strategies are sequences of mental operations that can be usefully represented as productions of the form IF (condition 1, . . . , condition n) THEN (action 1, . . . , action m).*
- *The cognitive effort needed to reach a decision using a particular strategy is a function of the number and type of operators (productions) used by that strategy, with the relative effort levels of various strategies contingent on task environments.*
- *Different strategies are characterized by different levels of accuracy, with the relative accuracy levels of various strategies contingent on task environments.*
- *As a result of prior experiences and training, a decision maker is assumed to have more than one strategy (sequence of operations) available to solve a decision problem of any complexity.*
- *Individuals decide how to decide primarily by considering both the cognitive effort and the accuracy of the various strategies.*
- *Additional considerations, such as the need to justify a decision to others or the need to minimize the conflict inherent in a decision problem, may also impact strategy selection.*
- *The decision of how to decide is sometimes a conscious choice and sometimes a learned contingency among elements of the task and the relative effort and accuracy of decision strategies.*
- *Strategy selection is generally adaptive and intelligent, if not optimal.*

14.1 Decision-making strategies

Before a decision can be made it is necessary to select a decision-making strategy. For instance, a developer who is given an hour to write a program knows there is insufficient time for making complicated trade-offs among alternatives. When a choice needs to be made, the likely decision-making strategy adopted would be to compare the values of a single attribute, the estimated time required to write the code (a decision-making strategy based on looking at the characteristics of a single attribute is known as the lexicographic heuristic).

lexicographic 0 heuristic decision making

Researchers have found that people use a number of different decision-making strategies. In this section we discuss some of these strategies and the circumstances under which people might apply them. The

list of strategies discussed in the following subsections is not exhaustive, but it does cover many of the decision-making strategies used when writing software.

The strategies differ in several ways. For instance, some make trade-offs among the attributes of the alternatives (making it possible for an alternative with several good attributes to be selected instead of the alternative whose only worthwhile attribute is excellent), while others make no such trade-offs. From the human perspective, they also differ in the amount of information that needs to be obtained and the amount of (brain) processing needed to make a decision. A theoretical analysis of the cost of decision making is given by Shugan.[1231]

14.1.1 The weighted additive rule

weighted additive rule

The weighted additive rule requires the greatest amount of effort, but delivers the most accurate result. It also requires that any conflicts among different attributes be confronted. Confronting conflict is something, as we shall see later, that people do not like doing. This rule consists of the following steps:

1. Build a list of attributes for each alternative.
2. Assign a value to each of these attributes.
3. Assign a weight to each of these attributes (these weights could, for instance, reflect the relative importance of that attribute to the person making the decision, or the probability of that attribute occurring).
4. For each alternative, sum the product of each of its attributes' value and weight.
5. Select the alternative with the highest sum.

An example, where this rule might be applied, is in deciding whether an equality test against zero should be made before the division of two numbers inside a loop. Attributes might include performance and reliability. If a comparison against zero is made the performance will be decreased by some amount. This disadvantage will be given a high or low weight depending on whether the loop is time-critical or not. The advantage is that reliability will be increased because the possibility of a divide by zero can be avoided. If a comparison against zero is not made, there is no performance penalty, but the reliability could be affected (it is necessary to take into account the probability of the second operand to the divide being zero).

14.1.2 The equal weight heuristic

The equal weight heuristic is a simplification of the weighted additive rule in that it assigns the same weight to every attribute. This heuristic might be applied when accurate information on the importance of each attribute is not available, or when a decision to use equal weights has been made.

14.1.3 The frequency of good and bad features heuristic

People do not always have an evaluation function for obtaining the value of an attribute. A simple estimate in terms of good/bad is sometimes all that is calculated (looking at things in black and white). By reducing the range of attribute values, this heuristic is a simplification of the equal weight heuristic, which in turn is a simplification of the weighted additive rule. This rule consists of the following steps:

1. List the good and bad attributes of every alternative.
2. Calculate the sum of each attributes good and the sum of its bad attributes.
3. Select the alternative with the highest count of either good or bad attributes, or some combination of the two.

A coding context, where a good/bad selection might be applicable, occurs in choosing the type of an object. If the object needs to hold a fractional part, it is tempting to use a floating type rather than an integer type (perhaps using some scaling factor to enable the fractional part to be represented). Drawing up a list of good and bad attributes ought to be relatively straight-forward; balancing them, to select a final type, might be a little more contentious

14.1.4 The majority of confirming dimensions heuristic

While people may not be able to explicitly state an evaluation function that provides a numerical measure of an attribute, they can often give a yes/no answer to the question: *Is the value of attribute X greater (or less) for alternative A compared to alternative B?*. This enables them to determine which alternative has the most (or least) of each attribute. This rule consists of the following steps:

1. Select a pair of alternatives.
2. Compare each matching attribute in the two alternatives.
3. Select the alternative that has the greater number of winning attributes.
4. Pair the winning alternative with an uncompared alternative and repeat the compare/select steps.
5. Once all alternatives have been compared at least once, the final winning alternative is selected.

In many coding situations there are often only two viable alternatives. Pairwise comparison of their attributes could be relatively easy to perform. For instance, when deciding whether to use a sequence of **`if`** statements or a **`switch`** statement, possible comparison attributes include efficiency of execution, readability, ease of changeability (adding new cases, deleting, or merging existing ones).

14.1.5 The satisficing heuristic

satisficing heuristic decision making

The result of the satisficing heuristic depends on the order in which alternatives are checked and often does not check all alternatives. Such a decision strategy, when described in this way, sounds unusual, but it is simple to perform. This rule consists of the following steps:

1. Assign a cutoff, or aspirational, level that must be met by each attribute.
2. Perform the following for each alternative:
   - Check each of its attributes against the cutoff level, rejecting the alternative if the attribute is below the cutoff.
   - If there are no attributes below the cutoff value, accept this alternative.
3. If no alternative is accepted, revise the cutoff levels associated the attributes and repeat the previous step.

An example of the satisficing heuristic might be seen when selecting a library function to return some information to a program. The list of attributes might include the amount of information returned and the format it is returned in (relative to the format it is required to be in). Once a library function meeting the developer's minimum aspirational level has been found, additional effort is not usually invested in finding a better alternative.

14.1.6 The lexicographic heuristic

lexicographic heuristic decision making

The lexicographic heuristic has a low effort cost, but it might not be very accurate. It can also be intransitive; with X preferred to Y, Y preferred to Z, and Z preferred to X. This rule consists of the following steps:

1. Determine the most important attribute of all the alternatives.
2. Find the alternative that has the best value for the selected most important attribute.
3. If two or more alternatives have the same value, select the next most important attribute and repeat the previous step using the set of alternatives whose attribute values tied.
4. The result is the alternative having the best value on the final, most important, attribute selected.

An example of the intransitivity that can occur, when using this heuristic, might be seen when writing software for embedded applications. Here the code has to fit within storage units that occur in fixed-size increments (e.g., 8 K chips). It may be possible to increase the speed of execution of an application by writing code for specific special cases; or have generalized code that is more compact, but slower. We might have the following, commonly seen, alternatives (see Table 0.11).

Table 0.11: Storage/Execution performance alternatives.

Alternative	Storage Needed	Speed of Execution
X	7 K	Low
Y	15 K	High
Z	10 K	Medium

Based on storage needed, X is preferred to Y. But because storage comes in 8 K increments there is no preference, based on this attribute, between Y and Z; however, Y is preferred to Z based on speed of execution. Based on speed of execution Z is preferred to X.

14.1.6.1 The elimination-by-aspects heuristic

The elimination-by-aspects heuristic uses cutoff levels, but it differs from the satisficing heuristic in that alternatives are eliminated because their attributes fall below these levels. This rule consists of the following steps:

1. The attributes for all alternatives are ordered (this ordering might be based on some weighting scheme).
2. For each attribute in turn, starting with the most important, until one alternative remains:
   - Select a cutoff value for that attribute.
   - Eliminate all alternatives whose value for that attribute is below the cutoff.
3. Select the alternative that remains.

This heuristic is often used when there are resource limitations, for instance, deadlines to meet, performance levels to achieve, or storage capacities to fit within.

14.1.7 The habitual heuristic

The habitual heuristic looks for a match of the current situation against past situations, it does not contain any evaluation function (although there are related heuristics that evaluate the outcome of previous decisions). This rule consists of the step:

1. select the alternative chosen last time for that situation.

Your author's unsubstantiated claim is that this is the primary decision-making strategy used by software developers.

Sticking with a winning solution suggests one of two situations:

1. So little is known that once a winning solution is found, it is better to stick with it than to pay the cost (time and the possibility of failure) of looking for a better solution that might not exist.
2. The developer has extensively analyzed the situation and knows the best solution.

Coding decisions are not usually of critical importance. There are many solutions that will do a satisfactory job. It may also be very difficult to measure the effectiveness of any decision, because there is a significant delay between the decision being made and being able to measure its effect. In many cases, it is almost

impossible to separate out the effect of one decision from the effects of all the other decisions made (there may be a few large coding decisions, but the majority are small ones).

recognition-primed decision making

A study by Klein[747] describes how fireground commanders use their experience to size-up a situation very rapidly. Orders are given to the firefighters under their command without any apparent decisions being made (in their interviews they even found a fireground commander who claimed that neither he, nor other commanders, ever made decisions; they knew what to do). Klein calls this strategy *recognition-primed decision making*.

14.2 Selecting a strategy

Although researchers have uncovered several decision-making strategies that people use, their existence does not imply that people will make use of all of them. The strategies available to individuals can vary depending on their education, training, and experience. A distinction also needs to be made between a person's knowledge of a strategy (through education and training) and their ability to successfully apply it (perhaps based on experience).

The task itself (that creates the need for a decision to be made) can affect the strategy used. These task effects include task complexity, the response mode (how the answer needs to be given), how the information is displayed, and context. The following subsections briefly outline these effects.

14.2.1 Task complexity

task complexity decision making

In general the more complex the decision, the more people will tend to use simplifying heuristics. The following factors influence complexity:

- *Number of alternatives.* As the number of alternatives that need to be considered grows, there are shifts in the decision-making strategy used.
- *Number of attributes.* Increasing the number of attributes increases the confidence of people's judgments, but it also increases their variability. The evidence for changes in the quality of decision making, as the number of attributes increases, is less clear-cut. Some studies show a decrease in quality; it has been suggested that people become overloaded with information. There is also the problem of deciding what constitutes a high-quality decision.
- *Time pressure.* People have been found to respond to time pressure in one of several ways. Some respond by accelerating their processing of information, others respond by reducing the amount of information they process (by filtering the less important information, or by concentrating on certain kinds of information such as negative information), while others respond by reducing the range of ideas and actions considered.

14.2.2 Response mode

There are several different response modes. For instance, a choice response mode frames the alternatives in terms of different choices; a matching response mode presents a list of questions and answers and the decision maker has to provide a matching answer to a question; a bidding response mode requires a value to be given for buying or selling some object. There are also other response modes, that are not listed here.

The choice of response mode, in some cases, has been shown to significantly influence the preferred alternatives. In extreme cases, making a decision may result in X being preferred to Y, while the mathematically equivalent decision, presented using a different response mode, can result in Y being preferred to X. For instance, in gambling situations it has been found that people will prefer X to Y when asked to select between two gambles (where X has a higher probability of winning, but with lower amounts), but when asked to bid on gambles they prefer Y to X (with Y representing a lower probability of winning a larger amount).

Such behavior breaks what was once claimed to be a fundamental principle of rational decision theory, *procedure invariance*. The idea behind this principle was that people had an invariant (relatively) set of internal preferences that were used to make decisions. These experiments showed that sometimes preferences

are constructed on the fly. Observed preferences are likely to take a person's internal preferences and the heuristics used to construct the answer into account.

Code maintenance is one situation where the task can have a large impact on how the answer is selected. When small changes are made to existing code, many developers tend to operate in a matching mode, choosing constructs similar, if not identical, to the ones in the immediately surrounding lines of code. If writing the same code from scratch, there is nothing to match, another response mode will necessarily need to be used in deciding what constructs to use.

A lot of the theoretical discussion on the reasons for these response mode effects has involved distinguishing between judgment and choice. People can behave differently, depending on whether they are asked to make a judgment or a choice. When writing code, the difference between judgment and choice is not always clear-cut. Developers may believe they are making a choice between two constructs when in fact they have already made a judgment that has reduced the number of alternatives to choose between.

Writing code is open-ended in the sense that theoretically there are an infinite number of different ways of implementing what needs to be done. Only half a dozen of these might be considered sensible ways of implementing some given functionality, with perhaps one or two being commonly used. Developers often limit the number of alternatives under consideration because of what they perceive to be overriding external factors, such as preferring an inline solution rather than calling a library function because of alleged quality problems with that library. One possibility is that decision making during coding be considered as a two-stage process, using judgment to select the alternatives, from which one is chosen.

14.2.3 Information display

Studies have shown that how information, used in making a decision, is displayed can influence the choice of a decision-making strategy.[1200] These issues include: only using the information that is visible (the concreteness principle), the difference between available information and processable information (displaying the price of one brand of soap in dollars per ounce, while another brand displays francs per kilogram), the completeness of the information (people seem to weigh common attributes more heavily than unique ones, perhaps because of the cognitive ease of comparison), and the format of the information (e.g., digits or words for numeric values).

What kind of information is on display when code is being written? A screen's worth of existing code is visible on the display in front of the developer. There may be some notes to the side of the display. All other information that is used exists in the developer's head.

Existing code is the result of past decisions made by the developer; it may also be modified by future decisions that need to be made (because of a need to modify the behavior of this existing code). For instance, the case in which another conditional statement needs to be added within a deeply nested series of conditionals. The information display (layout) of the existing code can affect the developer's decision about how the code is to be modified (a function, or macro, might be created instead of simply inserting the new conditional). Here the information display itself is an attribute of the decision making (code wrapping, at the end of a line, is an attribute that has a yes/no answer).

14.2.4 Agenda effects

agenda effects
decision making

The agenda effect occurs when the order in which alternatives are considered influences the final answer. For instance, take alternatives X, Y, and Z and group them into some form of hierarchy before performing a selection. When asked to choose between the pair [X, Y] and Z (followed by a choice between X and Y if that pair is chosen) and asked to choose between the pair [X, Z] and Y (again followed by another choice if that pair is chosen), an agenda effect would occur if the two final answers were different.

An example of the agenda effect is the following. When writing coding, it is sometimes necessary to decide between writing in line code, using a macro, or using a function. These three alternatives can be grouped into a natural hierarchy depending on the requirements. If efficiency is a primary concern, the first decision may be between `[in line, macro]` and `function`, followed by a decision between `in line` and `macro` (if that pair is chosen). If we are more interested in having some degree of abstraction, the first decision is likely to be between `[macro, function]` and `in line` (see Figure 0.16).

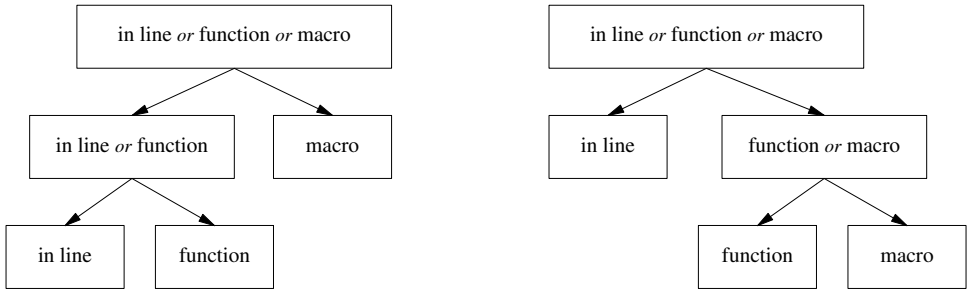

Figure 0.16: Possible decision paths when making pair-wise comparisons on whether to use a inline code, a function, or a macro; for two different pair-wise associations.

In the efficiency case, if performance is important in the context of the decision, `[in line, macro]` is likely to be selected in preference to `function`. Once this initial choice has been made other attributes can be considered (since both alternatives have the same efficiency). We can now decide whether abstraction is considered important enough to select `macro` over `in line`.

If the initial choice had been between `[macro, function]` and `in line`, the importance of efficiency would have resulted in `in line` being chosen (when paired with `function`, `macro` appears less efficient by association).

14.2.5 Matching and choosing

When asked to make a decision based on *matching*, a person is required to specify the value of some variable such that two alternatives are considered to be equivalent. For instance, how much time should be spent testing 200 lines of code to make it as reliable as the 500 lines of code that has had 10 hours of testing invested in it? When asked to make a decision based on *choice*, a person is presented with a set of alternatives and is required to specify one of them.

A study by Tversky, Sattath, and Slovic[1376] investigated the *prominence hypothesis*. This proposes that when asked to make a decision based on choice, people tend to use the prominent attributes of the options presented (adjusting unweighted intervals being preferred for matching options). Their study suggested that there were differences between the mechanisms used to make decisions for matching and choosing.

14.3 The developer as decision maker

The writing of source code would seem to require developers to make a very large number of decisions. However, experience shows that developers do not appear to be consciously making many decisions concerning what code to write. Most decisions being made involve issues related to the mapping from the application domain, choosing algorithms, and general organizational issues (i.e., where functions or objects should be defined).

Many of the coding-level decisions that need to be made occur again and again. Within a year or so, in full-time software development, sufficient experience has usually been gained for many decisions to be reduced to matching situations against those previously seen, and selecting the corresponding solution. For instance, the decision to use a series of **`if`** statements or a **`switch`** statement might require the pattern *same variable tested against integer constant and more than two tests are made* to be true before a **`switch`** statement is used. This is what Klein[747] calls recognition-primed decision making. This code writing methodology works because there is rarely a need to select the optimum alternative from those available.

recognition-primed decision making 0

Some decisions occur to the developer as code is being written. For instance, a developer may notice that the same sequence of statements, currently being written, was written earlier in a different part of the source (or perhaps it will occur to the developer that the same sequence of statements is likely to be needed in code that is yet to be written). At this point the developer has to make a decision about making a decision (metacognition). Should the decision about whether to create a function be put off until the current work item is completed, or should the developer stop what they are currently doing to make a decision on whether to

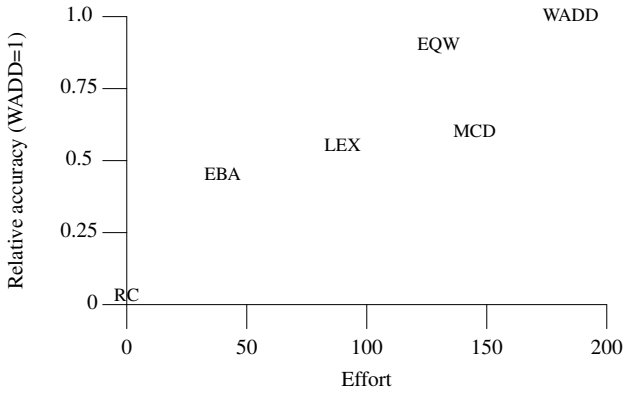

Figure 0.17: Effort and accuracy levels for various decision-making strategies; EBA (Elimination-by-aspects heuristic), EQW (equal weight heuristic), LEX (lexicographic heuristic), MCD (majority of confirming dimensions heuristic), RC (Random choice), and WADD (weighted additive rule). Adapted from Payne.[1065]

turn the statement sequence into a function definition? Remembering work items and metacognitive decision processes are handled by a developer's attention. The subject of *attention* is discussed elsewhere. 0 attention

Just because developers are not making frequent, conscious decisions does not mean that their choices are consistent and repeatable (they will always make the same decision). There are a number of both internal and external factors that may affect the decisions made. Researchers have uncovered a wide range of issues, a few of which are discussed in the following subsections.

14.3.1 Cognitive effort vs. accuracy

People like to make accurate decisions with the minimum of effort. In practice, selecting a decision-making strategy requires trading accuracy against effort (or to be exact, expected effort making the decision; the actual effort required can only be known after the decision has been made). effort vs. accuracy decision making

The fact that people do make effort/accuracy trade-offs is shown by the results from a wide range of studies (this issue is also discussed elsewhere, and Payne et al.[1065] discuss this topic in detail). See Figure 0.17 for a comparison. 0 cost/accuracy trade-off

The extent to which any significant cognitive effort is expended in decision making while writing code is open to debate. A developer may be expending a lot of effort on thinking, but this could be related to problem solving, algorithmic, or design issues.

One way of performing an activity that is not much talked about, is *flow*— performing an activity without any conscious effort— often giving pleasure to the performer. A best-selling book on the subject of flow[302] is subtitled "The psychology of optimal experience", something that artistic performers often talk about. Developers sometimes talk of *going with the flow* or *just letting the writing flow* when writing code; something writers working in any medium might appreciate. However, it is your author's experience that this method of working often occurs when deadlines approach and developers are faced with writing a lot of code quickly. Code written using *flow* is often very much like a river; it has a start and an ending, but between those points it follows the path of least resistance, and at any point readers rarely have any idea of where it has been or where it is going. While works of fiction may gain from being written in this way, the source code addressed by this book is not intended to be read for enjoyment. While developers may enjoy spending time solving mysteries, their employers do not want to pay them to have to do so. developer flow

Code written using *flow* is not recommended, and is not discussed further here. The use of intuition is discussed elsewhere. 0 developer intuition

14.3.2 Which attributes are considered important?

Developers tend to consider mainly technical attributes when making decisions. Economic attributes are often ignored, or considered unimportant. No discussion about attributes would be complete without mentioning developer fun

fun. Developers have gotten used to the idea that they can enjoy themselves at work, doing *fun* things. Alternatives that have a negative value for the fun attribute, and a large positive value for the time to carry out attribute are often quickly eliminated.

The influence of developer enjoyment on decision making, can be seen in many developers' preference for writing code, rather than calling a library function. On a larger scale, the often-heard developer recommendation for rewriting a program, rather than reengineering an existing one, is motivated more by the expected pleasure of writing code than the economics (and frustration) of reengineering.

One reason for the lack of consideration of economic factors is that many developers have no training, or experience in this area. Providing training is one way of introducing an economic element into the attributes used by developers in their decision making.

14.3.3 Emotional factors

developer emotional factors

weighted additive rule

Many people do not like being in a state of conflict and try to avoid it. Making a decision can create conflict, by requiring one attribute to be traded off against another. For instance, having to decide whether it is more important for a piece of code to execute quickly or reliably. It has been argued that people will avoid strategies that involve difficult, emotional, value trade-offs.

Emotional factors relating to source code need not be limited to internal, private developer decision making. During the development of an application involving more than one developer, particular parts of the source are often considered to be *owned* by an individual developer. A developer asked to work on another developers source code, perhaps because that person is away, will sometimes feel the need to adopt the *style* of that developer, making changes to the code in a way that is thought to be acceptable to the absent developer. Another approach is to ensure that the changes stand out from the *owner's* code. On the owning developer's return, the way in which changes were made is explained. Because they stand out, developers can easily see what changes were made to *their* code and decide what to do about them.

People do not like to be seen to make mistakes. It has been proposed[383] that people have difficulty using a decision-making strategy, that makes it explicit that there is some amount of error in the selected alternative. This behavior occurs even when it can be shown that the strategy would lead to better, on average, solutions than the other strategies available.

14.3.4 Overconfidence

overconfidence

A person is overconfident when their belief in a proposition is greater than is warranted by the information available to them. It has been argued that overconfidence is a useful attribute that has been selected for by evolution. Individuals who overestimates their ability are more likely to undertake activities they would not otherwise have been willing to do. Taylor and Brown[1332] argue that a theory of mental health defined in terms of contact with reality does not itself have contact with reality: "Rather, the mentally healthy person appears to have the enviable capacity to distort reality in a direction that enhances self-esteem, maintains beliefs in personal efficacy, and promotes an optimistic view of the future."

confirmation bias

Numerous studies have shown that most people are overconfident about their own abilities compared with others. People can be overconfident in their ability for several reasons: confirmation bias can lead to available information being incorrectly interpreted; a person's inexpert calibration (the degree of correlation between confidence and performance) of their own abilities is another reason. A recent study[746] has also highlighted the importance of the how, what, and whom of questioning in overconfidence studies. In some cases, it has been shown to be possible to make overconfidence disappear, depending on how the question is asked, or on what question is asked. Some results also show that there are consistent individual differences in the degree of overconfidence.

Charles Darwin. In *The descent of man*, 1871, p. 3

ignorance more frequently begets confidence than does knowledge

A study by Glenberg and Epstein[497] showed the danger of a little knowledge. They asked students, who were studying either physics or music, to read a paragraph illustrating some central principle (of physics or music). Subjects were asked to rate their confidence in being able to accurately answer a question about

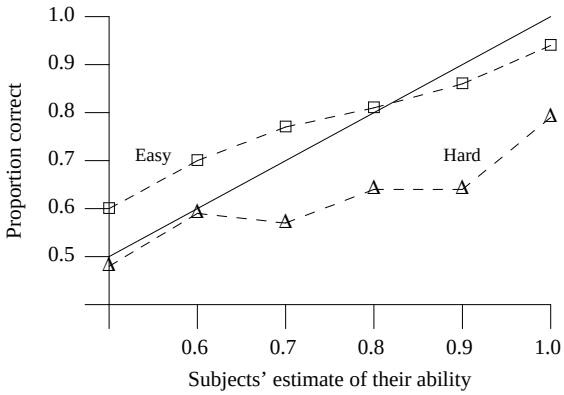

Figure 0.18: Subjects' estimate of their ability (bottom scale) to correctly answer a question and actual performance in answering on the left scale. The responses of a person with perfect self-knowledge is given by the solid line. Adapted from Lichtenstein.[855]

the text. They were then presented with a statement drawing some conclusion about the text (it was either true or false), which they had to answer. They then had to rate their confidence that they had answered the question correctly. This process was repeated for a second statement, which differed from the first in having the opposite true/false status.

The results showed that the more physics or music courses a subject had taken, the more confident they were about their own abilities. However, a subject's greater confidence in being able to correctly answer a question, before seeing it, was not matched by a greater ability to provide the correct answer. In fact as subjects' confidence increased, the accuracy of the calibration of their own ability went down. Once they had seen the question, and answered it, subjects were able to accurately calibrate their performance.

Subjects did not learn from their previous performances (in answering questions). They could have used information on the discrepancy between their confidence levels before/after seeing previous questions to improve the accuracy of their confidence estimates on subsequent questions.

The conclusion drawn by Glenberg and Epstein was that subjects' overconfidence judgments were based on self-classification as an expert, within a domain, not the degree to which they comprehended the text.

A study by Lichtenstein and Fishhoff[855] discovered a different kind of overconfidence effect. As the difficulty of a task increased, the accuracy of people's estimates of their own ability to perform the task decreased. In this study subjects were asked general knowledge questions, with the questions divided into two groups, hard and easy. The results in Figure 0.18 show that subjects' overestimated their ability (bottom scale) to correctly answer (actual performance, left scale) hard questions. On the other hand, they underestimated their ability to answer easy questions. The responses of a person with perfect self-knowledge are given by the solid line.

These, and subsequent results, show that the skills and knowledge that constitute competence in a particular domain are the same skills needed to evaluate one's (and other people's) competence in that domain. People who do not have these skills and knowledge lack metacognition (the name given by cognitive psychologists to the ability of a person to accurately judge how well they are performing). In other words, the knowledge that underlies the ability to produce correct judgment is the same knowledge that underlies the ability to recognize correct judgment.

Some very worrying results, about what overconfident people will do, were obtained in a study performed by Arkes, Dawes, and Christensen.[54] This study found that subjects used a formula that calculated the best decision in a probabilistic context (provided to them as part of the experiment) less when incentives were provided or the subjects thought they had domain expertise. This behavior even continued when the subjects were given feedback on the accuracy of their own decisions. The explanation, given by Arkes et al., was that when incentives were provided, people changed decision-making strategies in an attempt to beat the odds. Langer[809] calls this behavior *the illusion of control*.

Developers overconfidence and their aversion to explicit errors can sometimes be seen in the handling of floating-point calculations. A significant amount of mathematical work has been devoted to discovering the bounds on the errors for various numerical algorithms. Sometimes it has been proved that the error in the result of a particular algorithm is the minimum error attainable (there is no algorithm whose result has less error). This does not seem to prevent some developers from believing that they can design a more accurate algorithm. Phrases, such as *mean error* and *average error*, in the presentation of an algorithm's error analysis do not help. An overconfident developer could take this as a hint that it is possible to do better for the conditions that prevail in his (or her) application (and not having an error analysis does not disprove it is not better).

14.4 The impact of guideline recommendations on decision making

A set of guidelines can be more than a list of recommendations that provide a precomputed decision matrix. A guidelines document can provide background information. Before making any recommendations, the author(s) of a guidelines document need to consider the construct in detail. A good set of guidelines will document these considerations. This documentation provides a knowledge base of the alternatives that might be considered, and a list of the attributes that need to be taken into account. Ideally, precomputed values and weights for each attribute would also be provided. At the time of this writing your author only has a vague idea about how these values and weights might be computed, and does not have the raw data needed to compute them.

justifying 0 decisions

A set of guideline recommendations can act as a lightening rod for decisions that contain an emotional dimension. Adhering to coding guidelines being the justification for the decision that needs to be made. Having to justify decisions can affect the decision-making strategy used. If developers are expected to adhere to a set of guidelines, the decisions they make could vary depending on whether the code they write is independently checked (during code review, or with a static analysis tool).

14.5 Management's impact on developers' decision making

Although lip service is generally paid to the idea that coding guidelines are beneficial, all developers seem to have heard of a case where having to follow guidelines has been counterproductive. In practice, when first introduced, guidelines are often judged by both the amount of additional work they create for developers and the number of faults they immediately help locate. While an automated tool may uncover faults in existing code, this is not the primary intended purpose of using these coding guidelines. The cost of adhering to guidelines in the present is paid by developers; the benefit is reaped in the future by the owners of the software. Unless management successfully deals with this cost/benefit situation, developers could decide it is not worth their while to adhere to guideline recommendations.

What factors, controlled by management, have an effect on developers' decision making? The following subsections discuss some of them.

14.5.1 Effects of incentives

Some deadlines are sufficiently important that developers are offered incentives to meet them. Studies, on use of incentives, show that their effect seems to be to make people work harder, not necessarily smarter.

Increased effort is thought to lead to improved results. Research by Paese and Sniezek[1041] found that increased effort led to increased confidence in the result, but without there being any associated increase in decision accuracy.

Before incentives can lead to a change of decision-making strategies, several conditions need to be met:

- The developer must believe that a more accurate strategy is required. Feedback on the accuracy of decisions is the first step in highlighting the need for a different strategy,[582] but it need not be sufficient to cause a change of strategy.
- A better strategy must be available. The information needed to be able to use alternative strategies may not be available (for instance, a list of attribute values and weights for a weighted average strategy).
- The developer must believe that they are capable of performing the strategy.

14.5.2 Effects of time pressure

Research by Payne, Bettman, and Johnson,[1065] and others, has shown that there is a hierarchy of responses for how people deal with time pressure:

1. They work faster.
2. If that fails, they may focus on a subset of the issues.
3. If that fails, they may change strategies (e.g., from alternative based to attribute based).

If the time pressure is on delivering a finished program, and testing has uncovered a fault that requires changes to the code, then the weighting assigned to attributes is likely to be different than during initial development. For instance, the risk of a particular code change impacting other parts of the program is likely to be a highly weighted attribute, while maintainability issues are usually given a lower weighting as deadlines approach.

14.5.3 Effects of decision importance

Studies investigating at how people select decision-making strategies have found that increasing the benefit for making a correct decision, or having to make a decision that is irreversible, influences how rigorously a strategy is applied, not which strategy is applied.[105]

The same coding construct can have a different perceived importance in different contexts. For instance, defining an object at file scope is often considered to be a more important decision than defining one in block scope. The file scope declaration has more future consequences than the one in block scope.

An irreversible decision might be one that selects the parameter ordering in the declaration of a library function. Once other developers have included calls to this function in their code, it can be almost impossible (high cost/low benefit) to change the parameter ordering.

14.5.4 Effects of training

A developer's training in software development is often done using examples. Sample programs are used to demonstrate the solutions to small problems. As well as learning how different constructs behave, and how they can be joined together to create programs, developers also learn what attributes are considered to be important in source code. They learn the implicit information that is not written down in the text books. Sources of implicit learning include the following:

- *The translator used for writing class exercises.* All translators have their idiosyncrasies and beginners are not sophisticated enough to distinguish these from truly generic behavior. A developer's first translator usually colors his view of writing code for several years.
- *Personal experiences during the first few months of training.* There are usually several different alternatives for performing some operation. A bad experience (perhaps being unable to get a program that used a block scope array to work, but when the array was moved to file scope the program worked) with some construct can lead to a belief that use of that construct was problem-prone and to be avoided (all array objects being declared, by that developer, at file scope and never in block scope).
- *Instructor biases.* The person teaching a class and marking submitted solutions will impart their own views on what attributes are important. Efficiency of execution is an attribute that is often considered to be important. Its actual importance, in most cases, has declined from being crucial 50 years ago to being almost a nonissue today. There is also the technical interest factor in trying to write code as efficiently as possible. A related attribute is program size. Praise is more often given for short programs, rather than longer ones. There are applications where the size of the code is important, but generally time spent writing the shortest program is wasted (and may even be more difficult to comprehend than a longer program).
- *Consideration for other developers.* Developers are rarely given practical training on how to read code, or how to write code that can easily be read by others. Developers generally believe that any difficulty others experience in comprehending their code is not caused by how they wrote it.

- *Preexisting behavior.* Developers bring their existing beliefs and modes of working to writing C source. These can range from behavior that is not software-specific, such as the inability to ignore sunk costs (i.e., wanting to modify an existing piece of code, they wrote earlier, rather than throw it away and starting again; although this does not seem to apply to throwing away code written by other people), to the use of the idioms of another language when writing in C.
- *Technically based.* Most existing education and training in software development tends to be based on purely technical issues. Economic issues are not usually raised formally, although informally time-to-completion is recognized as an important issue.

Unfortunately, once most developers have learned an initial set of attribute values and weightings for source code constructs, there is usually a long period of time before any subsequent major tuning or relearning takes place. Developers tend to be too busy applying their knowledge to question many of the underlying assumptions they have picked up along the way.

Based on this background, it is to be expected that many developers will harbor a few *myths* about what constitutes a good coding decision in certain circumstances. These coding guidelines cannot address all coding myths. Where appropriate, coding myths commonly encountered by your author are discussed.

14.5.5 Having to justify decisions

justifying decisions

Studies have found that having to justify a decision can affect the choice of decision-making strategy to be used. For instance, Tetlock and Boettger[1338] found that subjects who were accountable for their decisions used a much wider range of information in making judgments. While taking more information into account did not necessarily result in better decisions, it did mean that additional information that was both irrelevant and relevant to the decision was taken into account.

It has been proposed, by Tversky,[1372] that the elimination-by-aspects heuristic is easy to justify. However, while use of this heuristic may make for easier justification, it need not make for more accurate decisions.

A study performed by Simonson[1242] showed that subjects who had difficulty determining which alternative had the greatest utility tended to select the alternative that supported the best overall reasons (for choosing it).

Tetlock[1337] included an accountability factor into decision-making theory. One strategy that handles accountability as well as minimizing cognitive effort is to select the alternative that the perspective audience (i.e., code review members) is thought most likely to select. Not knowing which alternative they are likely to select can lead to a more flexible approach to strategies. The exception occurs when a person has already made the decision; in this case the cognitive effort goes into defending that decision.

During a code review, a developer may have to justify why a particular decision was made. While developers know that time limits will make it very unlikely that they will have to justify every decision, they do not know in advance which decisions will have to be justified. In effect, the developer will feel the need to be able to justify most decisions.

Requiring developers to justify why they have not followed a particular guideline recommendation can be a two-edged sword. Developers can respond by deciding to blindly follow guidelines (the path of least resistance), or they can invest effort in evaluating, and documenting, the different alternatives (not necessarily a good thing since the invested effort may not be warranted by the expected benefits). The extent to which some people will blindly obey authority was chillingly demonstrated in a number of studies by Milgram.[934]

14.6 Another theory about decision making

The theory that selection of a decision-making strategy is based on trading off cognitive effort and accuracy is not the only theory that has been proposed. Hammond, Hamm, Grassia, and Pearson[538] proposed that analytic decision making is only one end of a continuum; at the other end is intuition. They performed a study, using highway engineers, involving three tasks. Each task was designed to have specific characteristics (see Table 0.12). One task contained intuition-inducing characteristics, one analysis-inducing, and the third an equal mixture of the two. For the problems studied, intuitive cognition outperformed analytical cognition in terms of the empirical accuracy of the judgments.

Table 0.12: Inducement of intuitive cognition and analytic cognition, by task conditions. Adapted from Hammond.[538]

Task Characteristic	Intuition-Inducing State of Task Characteristic	Analysis-Inducing State of Task Characteristic
Number of cues	Large (>5)	Small
Measurement of cues	Perceptual measurement	Objective reliable measurement
Distribution of cue values	Continuous highly variable distribution	Unknown distribution; cues are dichotomous; values are discrete
Redundancy among cues	High redundancy	Low redundancy
Decomposition of task	Low	High
Degree of certainty in task	Low certainty	High certainty
Relation between cues and criterion	Linear	Nonlinear
Weighting of cues in environmental model	Equal	Unequal
Availability of organizing principle	Unavailable	Available
Display of cues	Simultaneous display	Sequential display
Time period	Brief	Long

One of the conclusions that Hammond et al. drew from these results is that "Experts should increase their awareness of the correspondence between task and cognition". A task having intuition-inducing characteristics is most likely to be out carried using intuition, and similarly for analysis-inducing characteristics.

Many developers sometimes talk of writing code intuitively. Discussion of intuition and flow of consciousness are often intermixed. The extent to which either intuitive or analytic decision making (if that is how developers operate) is more cost effective, or practical, is beyond this author's ability to even start to answer. It is mentioned in this book because there is a bona fide theory that uses these concepts and developers sometimes also refer to them.

0 developer flow

Intuition can be said to be characterized by rapid data processing, low cognitive control (the consistency with which a judgment policy is applied), and low awareness of processing. Its opposite, analysis, is characterized by slow data processing, high cognitive control, and high awareness of processing.

developer intuition

15 Expertise

People are referred to as being experts, in a particular domain, for several reasons, including:

expertise

- Well-established figures, perhaps holding a senior position with an organization heavily involved in that domain.
- Better at performing a task than the average person on the street.
- Better at performing a task than most other people who can also perform that task.
- Self-proclaimed experts, who are willing to accept money from clients who are not willing to take responsibility for proposing what needs to be done.[658]

Schneider[1202] defines a high-performance skill as one for which (1) more than 100 hours of training are required, (2) substantial numbers of individuals fail to develop proficiency, and (3) the performance of an expert is qualitatively different from that of the novice.

In this section, we are interested in why some people (the experts) are able to give a task performance that is measurably better than a non-expert (who can also perform the task).

There are domains in which those acknowledged as experts do not perform significantly better than those considered to be non-experts.[193] For instance, in typical cases the performance of medical experts was not much greater than those of doctors after their first year of residency, although much larger differences were seen for difficult cases. Are there domains where it is intrinsically not possible to become significantly better than one's peers, or are there other factors that can create a large performance difference between expert and non-expert performances? One way to help answer this question is to look at domains where the gap between expert and non-expert performance can be very large.

It is a commonly held belief that experts have some innate ability or capacity that enables them to do what they do so well. Research over the last two decades has shown that while innate ability can be a factor in performance (there do appear to be genetic factors associated with some athletic performances), the main factor in acquiring expert performance is time spent in *deliberate practice*.[393]

Deliberate practice is different from simply performing the task. It requires that people monitor their practice with full concentration and obtain feedback[582] on what they are doing (often from a professional teacher). It may also involve studying components of the skill in isolation, attempting to improve on particular aspects. The goal of this practice being to improve performance, not to produce a finished product.

Studies of the backgrounds of recognized experts, in many fields, found that the elapsed time between them starting out and carrying out their best work was at least 10 years, often with several hours of deliberate practice every day of the year. For instance, Ericsson, Krampe, and Tesch-Romer[394] found that, in a study of violinists (a perceptual-motor task), by age 20 those at the top level had practiced for 10,000 hours, those at the next level down 7,500 hours, and those at the lowest level of expertise had practiced for 5,000 hours. They also found similar quantities of practice being needed to attain expert performance levels in purely mental activities (e.g., chess).

People often learn a skill for some purpose (e.g., chess as a social activity, programming to get a job) without the aim of achieving expert performance. Once a certain level of proficiency is achieved, they stop trying to learn and concentrate on using what they have learned (in work, and sport, a distinction is made between training for and performing the activity). During everyday work, the goal is to produce a product or to provide a service. In these situations people need to use well-established methods, not try new (potentially dead-end, or leading to failure) ideas to be certain of success. Time spent on this kind of practice does not lead to any significant improvement in expertise, although people may become very fluent in performing their particular subset of skills.

What of individual aptitudes? In the cases studied by researchers, the effects of aptitude, if there are any, have been found to be completely overshadowed by differences in experience and deliberate practice times. What makes a person willing to spend many hours, every day, studying to achieve expert performance is open to debate. Does an initial aptitude or interest in a subject lead to praise from others (the path to musical and chess expert performance often starts in childhood), which creates the atmosphere for learning, or are other issues involved? IQ does correlate to performance during and immediately after training, but the correlation reduces over the years. The IQ of experts has been found to be higher than the average population at about the level of college students.

In many fields expertise is acquired by memorizing a huge amount of, domain-specific, knowledge and having the ability to solve problems using pattern-based retrieval on this knowledge base. The knowledge is structured in a form suitable for the kind of information retrieval needed for problems in a domain.[395]

A study by Carlson, Khoo, Yaure, and Schneider[200] examined changes in problem-solving activity as subjects acquired a skill (trouble shooting problems with a digital circuit). Subjects started knowing nothing, were given training in the task, and then given 347 problems to solve (in 28 individual, two-hour sessions, over a 15-week period). The results showed that subjects made rapid improvements in some areas (and little thereafter), extended practice produced continuing improvement in some of the task components, subjects acquired the ability to perform some secondary tasks in parallel, and transfer of skills to new digital circuits was substantial but less than perfect. Even after 56 hours of practice, the performance of subjects continued to show improvements and had not started to level off. Where are the limits to continued improvements? A study by Crossman[300] of workers producing cigars showed performance improving according to the power law of practice for the first five years of employment. Thereafter performance improvements slow; factors cited for this slow down include approaching the speed limit of the equipment being used and the capability of the musculature of the workers.

power law of learning 0

15.1 Knowledge

developer knowledge

A distinction is often made between different kinds of knowledge. Declarative knowledge are the facts; procedural knowledge are the skills (the ability to perform learned actions). Implicit memory is defined as

memory without conscious awareness— it might be considered a kind of knowledge.

0 implicit learning

15.1.1 Declarative knowledge

This consists of knowledge about facts and events. For instance, the keywords used to denote the integer types are **char**, **short**, **int**, and **long**. This kind of knowledge is usually explicit (we know what we know), but there are situations where it can be implicit (we make use of knowledge that we are not aware of having[849]). The coding guideline recommendations in this book have the form of declarative knowledge.

declarative knowledge

It is the connections and relationships between the individual facts, for instance the relative sizes of the integer types, that differentiate experts from novices (who might know the same facts). This kind of knowledge is rather like web pages on the Internet; the links between different pages corresponding to the connections between facts made by experts. Learning a subject is more about organizing information and creating connections between different items than it is about remembering information in a rote-like fashion.

This was demonstrated in a study by McKeithen, Reitman, Ruster, and Hirtle,[917] who showed that developers with greater experience with a language organized their knowledge of language keywords in a more structured fashion. Education can provide the list of facts, it is experience that provides the connections between them.

The term *knowledge base* is sometimes used to describe a collection of information and links about a given topic. The C Standard document is a knowledge base. Your author has a C knowledge base in his head, as do you the reader. This book is another knowledge base dealing with C. The difference between this book and the C Standard document is that it contains significantly more explicit links connecting items, and it also contains information on how the language is commonly implemented and used.

15.1.2 Procedural knowledge

This consists of knowledge about how to perform a task; it is often implicit.

procedural knowledge

Knowledge can start off by being purely declarative and, through extensive practice, becomes procedural; for instance, the process of learning to drive a car. An experiment by Sweller, Mawer, and Ward[1325] showed how subjects' behavior during mathematical problem solving changed as they became more proficient. This suggested that some aspects of what they were doing had been proceduralized.

Some of the aspects of writing source code that can become proceduralized are discussed elsewhere.

15.2 Education

What effect does education have on people who go on to become software developers?

developer education

> *Education should not be thought of as replacing the rules that people use for understanding the world but rather as introducing new rules that enter into competition with the old ones. People reliably distort the new rules in the direction of the old ones, or ignore them altogether except in the highly specific domains in which they were taught.*

Page 206 of Holland et al.[585]

Education can be thought of as trying to do two things (of interest to us here)— teach students skills (procedural knowledge) and providing them with information, considered important in the relevant field, to memorize (declarative knowledge). To what extent does education in subjects not related to software development affect a developer's ability to write software?

Some subjects that are taught to students are claimed to teach general reasoning skills; for instance, philosophy and logic. There are also subjects that require students to use specific reasoning skills, for instance statistics requires students to think probabilistically. Does attending courses on these subjects actually have any measurable effect on students' capabilities, other than being able to answer questions in an exam. That is, having acquired some skill in using a particular system of reasoning, do students apply it outside of the domain in which they learnt it? Existing studies have supplied a *No* answer to this question.[922, 1011] This *No* was even found to apply to specific skills; for instance, statistics (unless the problem explicitly involves statistical thinking within the applicable domain) and logic.[224]

A study by Lehman, Lempert, and Nisbett[831] measured changes in students' statistical, methodological, and conditional reasoning abilities (about everyday-life events) between their first and third years. They

found that both psychology and medical training produced large effects on statistical and methodological reasoning, while psychology, medical, and law training produced effects on the ability to perform conditional reasoning. Training in chemistry had no affect on the types of reasoning studied. An examination of the skills taught to students studying in these fields showed that they correlated with improvements in the specific types of reasoning abilities measured. The extent to which these reasoning skills transferred to situations that were not everyday-life events was not measured. Many studies have found that in general people do not transfer what they have learned from one domain to another.

expertise 0
transfer to another domain

It might be said that passing through the various stages of the education process is more like a filter than a learning exercise. Those that already have the abilities being the ones that succeed.[1401] A well-argued call to arms to improve students' general reasoning skills, through education, is provided by van Gelder.[1400]

Good education aims to provide students with an overview of a subject, listing the principles and major issues involved; there may be specific cases covered by way of examples. Software development does require knowledge of general principles, but most of the work involves a lot of specific details: specific to the application, the language used, and any existing source code, while developers may have been introduced to the C language as part of their education. The amount of exposure is unlikely to have been sufficient for the building of any significant knowledge base about the language.

15.2.1 Learned skills

Education provides students with *learned knowledge*, which relates to the title of this subsection *learned skills*. Learning a skill takes practice. Time spent by students during formal education practicing their programming skills is likely to total less than 60 hours. Six months into their first development job they could very well have more than 600 hours of experience. Although students are unlikely to complete their education with a lot of programming experience, they are likely to continue using the programming beliefs and practices they have acquired. It is not the intent of this book to decry the general lack of good software development training, but simply to point out that many developers have not had the opportunity to acquire good habits, making the use of coding guidelines even more essential.

developer 0
expertise

Can students be taught in a way that improves their general reasoning skills? This question is not directly relevant to the subject of this book; but given the previous discussion, it is one that many developers will be asking. Based on the limited researched carried out to date the answer seems to be yes. Learning requires intense, quality practice. This would be very expensive to provide using human teachers, and researchers are looking at automating some of the process. Several automated training aids have been produced to help improve students' reasoning ability and some seem to have a measurable affect.[1401]

15.2.2 Cultural skills

Cultural skills include the use of language and category formation. Nisbett and Norenzayan[1015] provide an overview of culture and cognition. A more practical guide to cultural differences and communicating with people from different cultures, from the perspective of US culture, is provided by Wise, Hannaman, Kozumplik, Franke, and Leaver.[1475]

cultural differences

15.3 Creating experts

To become an expert a person needs motivation, time, economic resources, an established body of knowledge to learn from, and teachers to guide.

One motivation is to be the best, as in chess and violin playing. This creates the need to practice as much as others at that level. Ericsson found[394] that four hours per day was the maximum concentrated training that people could sustain without leading to exhaustion and burnout. If this is the level of commitment, over a 10-year period, that those at the top have undertaken, then anybody wishing to become their equal will have to be equally committed. The quantity of practice needed to equal expert performance in less competitive fields may be less. One should ask of an expert whether they attained that title because they are simply as good as the best, or because their performance is significantly better than non-experts.

In many domains people start young, between three and eight in some cases,[394] their parents' interest being critical in providing equipment, transport to practice sessions, and the general environment in which to

study.

An established body of knowledge to learn from requires that the domain itself be in existence and relatively stable for a long period of time. The availability of teachers requires a domain that has existed long enough for them to have come up through the ranks; and one where there are sufficient people interested in it that it is possible to make as least as much from teaching as from performing the task.

The research found that domains in which the performance of experts was not significantly greater than non-experts lacked one or more of these characteristics.

15.3.1 Transfer of expertise to different domains

expertise transfer to another domain

Research has shown that expertise within one domain does not confer any additional skills within another domain.[33] This finding has been duplicated for experts in real-world domains, such as chess, and in laboratory-created situations. In one series of experiments, subjects who had practiced the learning of sequences of digits (after 50–100 hours of practice they could commit to memory, and recall later, sequences containing more than 20 digits) could not transfer their expertise to learning sequences of other items.[217]

15.4 Expertise as mental set

Software development is a new field that is still evolving at a rapid rate. Most of the fields in which expert performance has been studied are much older, with accepted bodies of knowledge, established traditions, and methods of teaching.

Sometimes knowledge associated with software development does not change wholesale. There can be small changes within a given domain; for instance, the move from K&R C to ISO C.

In a series of experiments Wiley,[1465] showed that in some cases non-experts could outperform experts within their domain. She showed that an expert's domain knowledge can act as a mental set that limits the search for a solution; the expert becomes fixated within the domain. Also, in cases where a new task does not fit the pattern of highly proceduralized behaviors of an expert, a novice's performance may be higher.

15.5 Software development expertise

software development expertise

Given the observation that in some domains the acknowledged experts do not perform significantly better than non-experts, we need to ask if it is possible that any significant performance difference could exist in software development. Stewart and Lusk[1297] proposed a model of performance that involves seven components. The following discussion breaks down expertise in software development into five major areas.

1. *Knowledge (declarative) of application domain.* Although there are acknowledged experts in a wide variety of established application domains, there are also domains that are new and still evolving rapidly. The use to which application expertise, if it exists, can be put varies from high-level design to low-level algorithmic issues (i.e., knowing that certain cases are rare in practice when tuning a time-critical section of code).

2. *Knowledge (declarative) of algorithms and general coding techniques.* There exists a large body of well-established, easily accessible, published literature about algorithms. While some books dealing with general coding techniques have been published, they are usually limited to specific languages, application domains (e.g., embedded systems), and often particular language implementations. An important issue is the rigor with which some of the coding techniques have been verified; it often leaves a lot to be desired, including the level of expertise of the author.

3. *Knowledge (declarative) of programming language.* The C programming language is regarded as an established language. Whether 25 years is sufficient for a programming language to achieve the status of being established, as measured by other domains, is an open question. There is a definitive document, the ISO Standard, that specifies the language. However, the sales volume of this document has been extremely low, and most of the authors of books claiming to teach C do not appear to have read the standard. Given this background, we cannot expect any established community of expertise in the C language to be very large.

4. *Ability (procedural knowledge) to comprehend and write language statements and declarations that implement algorithms.* Procedural knowledge is acquired through practice. While university students may have had access to computers since the 1970s, access for younger people did not start to occur until the mid 1980s. It is possible for developers to have had 25 years of software development practice.
5. *Development environment.* The development environment in which people have to work is constantly changing. New versions of operating systems are being introduced every few years; new technologies are being created and old ones are made obsolete. The need to keep up with development is a drain on resources, both in intellectual effort and in time. An environment in which there is a rapid turnover in applicable knowledge and skills counts against the creation of expertise.

Although the information and equipment needed to achieve a high-level of expertise might be available, there are several components missing. The motivation to become the best software developer may exist in some individuals, but there is no recognized measure of what *best* means. Without the measuring and scoring of performances it is not possible for people to monitor their progress, or for their efforts to be rewarded. While there is a demand for teachers, it is possible for those with even a modicum of ability to make substantial amounts of money doing (not teaching) development work. The incentives for good teachers are very poor.

Given this situation we would not expect to find large performance differences in software developers through training. If training is insufficient to significantly differentiate developers the only other factor is individual ability. It is certainly your author's experience— individual ability is a significant factor in a developer's performance.

Until the rate of change in general software development slows down, and the demand for developers falls below the number of competent people available, it is likely that ability will continue to the dominant factor (over training) in developer performance.

15.6 Software developer expertise

developer expertise

Having looked at expertise in general and the potential of the software development domain to have experts, we need to ask how expertise might be measured in people who develop software. Unfortunately, there are no reliable methods for measuring software development expertise currently available. However, based on the previously discussed issues, we can isolate the following technical competencies (social competencies[1007] are not covered here, although they are among the skills sought by employers,[83] and software developers have their own opinions[837, 1268]):

- Knowledge (declarative) of application domain.
- Knowledge (declarative) of algorithms and general coding techniques.
- Knowledge (declarative) of programming languages.
- Cognitive ability (procedural knowledge) to comprehend and write language statements and declarations that implement algorithms (a specialized form of general analytical and conceptual thinking).
- Knowledge (metacognitive) about knowledge (i.e., judging the quality and quantity of one's expertise).

Your author has firsthand experience of people with expertise individually within each of these components, while being non-experts in all of the others. People with application-domain expertise and little programming knowledge or skill are relatively common. Your author once implemented the semantics phase of a CHILL (Communications HIgh Level Language) compiler and acquired expert knowledge in the semantics of that language. One day he was shocked to find he could not write a CHILL program without reference to some existing source code (to *refresh* his memory of general program syntax); he had acquired an extensive knowledge based of the semantics of the language, but did not have the procedural knowledge needed to write a program (the compiler was written in another language).[0.6]

[0.6] As a compiler writer, your author is sometimes asked to help fix problems in programs written in languages he has never seen before (how can one be so expert and not know every language?). He now claims to be an expert at comprehending programs written in unknown languages for application domains he knows nothing about (he is helped by the fact that few languages have any truly unique constructs).

A developer's knowledge of an application domain can only be measured using the norms of that domain. One major problem associated with measuring overall developer expertise is caused by the fact that different developers are likely to be working within different domains. This makes it difficult to cross correlate measurements.

A study at Bell Labs[330] showed that developers who had worked on previous releases of a project were much more productive than developers new to a project. They divided time spent by developers into discovery time (finding out information) and work time (doing useful work). New project members spent 60% to 80% of their time in discovery and 20% to 40% doing useful work. Developers experienced with the application spent 20% of their time in discovery and 80% doing useful work. The results showed a dramatic increase in efficiency (useful work divided by total effort) from having been involved in one project cycle and less dramatic an increase from having been involved in more than one release cycle. The study did not attempt to separate out the kinds of information being sought during discovery.

Another study at Bell Labs[952] found that the probability of a fault being introduced into an application, during an update, correlated with the experience of the developer doing the work. More experienced developers seemed to have acquired some form of expertise in an application that meant they were less likely to introduce a fault into it.

A study of development and maintenance costs of programs written in C and Ada[1504] found no correlation between salary grade (or employee rating) and rate of bug fix/add feature rate.

Your author's experience is that developers' general knowledge of algorithms (in terms of knowing those published in well-known text-books) is poor. There is still a strongly held view, by developers, that it is permissible for them to invent their own ways of doing things. This issue is only of immediate concern to these coding guidelines as part of the widely held, developers', belief that they should be given a free hand to write source as they see fit.

There is a group of people who might be expected to be experts in a particular programming languages—those who have written a compiler for it (or to be exact those who implemented the semantics phase of the compiler, anybody working on others parts [e.g., code generation] does not need to acquire detailed knowledge of the language semantics). Your author knows a few people who are C language experts and have not written a compiler for that language. Based on your author's experience of implementing several compilers, the amount of study needed to be rated as an expert in one computer language is approximately 3 to 4 hours per day (not even compiler writers get to study the language for every hour of the working day; there are always other things that need to be attended to) for a year. During that period, every sentence in the language specification will be read and analyzed in detail several times, often in discussion with colleagues. Generally developer knowledge of the language they write in is limited to the subset they learned during initial training, perhaps with some additional constructs learned while reading other developers' source or talking to other members of a project. The behavior of the particular compiler they use also colors their view of those constructs.

Expertise in the act of comprehending and writing software is hard to separate from knowledge of the application domain. There is rarely any need to understand a program without reference to the application domain it was written for. When computers were centrally controlled, before the arrival of desktop computers, many organizations offered a programming support group. These support groups were places where customers of the central computer (usually employees of the company or staff at a university) could take programs they were experiencing problems with. The staff of such support groups were presented with a range of different programs for which they usually had little application-domain knowledge. This environment was ideal for developing program comprehension skills without the need for application knowledge (your author used to take pride in knowing as little as possible about the application while debugging the presented programs). Such support groups have now been reduced to helping customers solve problems with packaged software. Environments in which pure program-understanding skills can be learned now seem to have vanished.

What developers do is discussed elsewhere. An expert developer could be defined as a person who is 0 developers what do they do? able to perform these tasks better than the majority of their peers. Such a definition is open-ended (how is

productivity 0
developer

better defined for these tasks?) and difficult to measure. In practice, it is productivity that is the sought-after attribute in developers.

Some studies have looked at how developers differ (which need not be the same as measuring expertise), including their:

developers 0
organized knowledge
developer 0
personality

- ability to remember more about source code they have seen,
- personality differences,
- knowledge of the computer language used, and
- ability to estimate the effort needed to implement the specified functionality.[693]

A study by Jørgensen and Sjøberg[694] looked at maintenance tasks (median effort 16-work hours). They found that developers' skill in predicting maintenance problems improved during their first two years on the job; thereafter there was no correlation between increased experience (average of 7.7 years' development experience, 3.4 years on maintenance of the application) and increased skill. They attributed this lack of improvement in skill to a lack of learning opportunities (in the sense of deliberate practice and feedback on the quality of their work).

Job advertisements often specify that a minimum number of years of experience is required. Number of years is known not to be a measure of expertise, but it provides some degree of comfort that a person has had to deal with many of the problems that might occur within a given domain.

15.6.1 Is software expertise worth acquiring?

Most developers are not professional programmers any more than they are professional typists. Reading and writing software is one aspect of their job. The various demands on their time is such that most spend a small portion of their time writing software. Developers need to balance the cost of spending time becoming more skillful programmers against the benefits of possessing that skill. Experience has shown that software can be written by relatively unskilled developers. One consequence of this is that few developers ever become experts in any computer language.

When estimating benefit over a relatively short period of time, time spent learning more about the application domain frequently has a greater return than honing programming skills.

15.7 Coding style

coding guidelines
coding style

As an Englishman, your author can listen to somebody talking and tell if they are French, German, Australian, or one of many other nationalities (and sometimes what part of England they were brought up in). From what they say, I might make an educated guess about their educational level. From their use of words like *cool*, *groovy*, and so on, I might guess age and past influences (young or ageing hippie).

source code
accent

Source code written by an experienced developer sometimes has a recognizable style. Your author can often tell if a developer's previous language was Fortran, Pascal, or Basic. But he cannot tell if their previous language was Lisp or APL (anymore than he can distinguish regional US accents, nor can many US citizens tell the difference among an English, Scottish, Irish, or Australian accent), because he has not had enough exposure to those languages.

Is coding style a form of expertise (a coherent framework that developers use to express their thoughts), or is it a ragbag of habits that developers happen to have? Programs have been written that can accurately determine the authorship of C source code (success rates of 73% have been reported[775]). These experiments used, in part, source code written by people new to software development (i.e., students). Later work using neural networks[776] was able to get the failure rate down to 2%. That it was possible to distinguish programs written by very inexperienced developers suggests that style might simply be a ragbag of habits (these developers not having had time to put together a coherent way of writing source).

The styles used by inexperienced developers can even be detected after an attempt has been made to hide the original authorship of the source. Plagiarism is a persistent problem in many universities' programming courses and several tools have been produced that automatically detect source code plagiarisms.[1120, 1417]

One way for a developer to show mastery of coding styles would be to have the ability to write source using a variety of different styles, perhaps even imitating the style of others. The existing author analysis tools are being used to verify that different, recognizable styles were being used.

It was once thought (and still is by some people) that there is a correct way to speak. Received Pronunciation (as spoken on the BBC many years ago) was once promoted as correct usage within the UK.

Similarly, many people believe that source code can be written in a good style or a bad style. A considerable amount of time has been, and will probably continue to be, spent discussing this issue. Your authors' position is the following:

- Identifiable source code styles exist.
- It is possible for people to learn new coding styles.
- It is very difficult to explain style to non-expert developers.
- Learning a new style is sufficiently time-consuming, and the benefits are likely to be sufficiently small, that a developer is best advised to invest effort elsewhere.

Students of English literature learn how to recognize writing styles. There are many more important issues that developers need to learn before they reach the stage where learning about stylistic issues becomes worthwhile.

The phrase coding guidelines and coding style are sometimes thought of, by developers of as being synonymous. This unfortunate situation has led to coding guidelines acquiring a poor reputation. While recognizing the coding style does exist, they are not the subject of these coding guidelines. The term *existing practice* refers to the kinds of constructs often found in existing programs. Existing practice is dealt with as an issue in its own right, independent of any concept of style.

0 coding guidelines introduction

16 Human characteristics

human characteristics

Humans are not ideal machines, an assertion that may sound obvious. However, while imperfections in physical characteristics are accepted, any suggestion that the mind does not operate according to the laws of mathematical logic is rarely treated in the same forgiving way. For instance, optical illusions are accepted as curious anomalies of the eye/brain system; there is no rush to conclude that human eyesight is faulty.

Optical illusions are often the result of preferential biases in the processing of visual inputs that, in most cases, are beneficial (in that they simplify the processing of ecologically common inputs). In Figure 0.19, which of the two squares indicated by the arrows is the brighter one? Readers can verify that the indicated squares have exactly the same grayscale level. Use a piece of paper containing two holes, that display only the two squares pointed to.

This effect is not caused by low-level processing, by the brain, of the input from the optic nerve; it is caused by high-level processing of the scene (recognizing the recurring pattern and that some squares are within a shadow). Anomalies caused by this high-level processing are not limited to grayscales. The brain is thought to have specific areas dedicated to the processing of faces. The, so-called, *Thatcher illusion* is an example of this special processing of faces. The two faces in Figure 0.20 look very different; turn the page upside down and they look almost identical.

Music is another input stimulus that depends on specific sensory input/brain affects occurring. There is no claim that humans cannot hear properly, or that they should listen to music derived purely from mathematical principles.

Studies have uncovered situations where the behavior of human cognitive processes does not correspond to some generally accepted norm, such as Bayesian inference. However, it cannot be assumed that cognitive limitations are an adaption to handle the physical limitations of the brain. There is evidence to suggest that some of these so-called cognitive limitations provide near optimal solutions for some real-world problems.[570]

0 evolutionary psychology

The ability to read, write, and perform complex mathematical reasoning are very recent (compared to several million years of evolution) cognitive skill requirements. Furthermore, there is no evidence to suggest

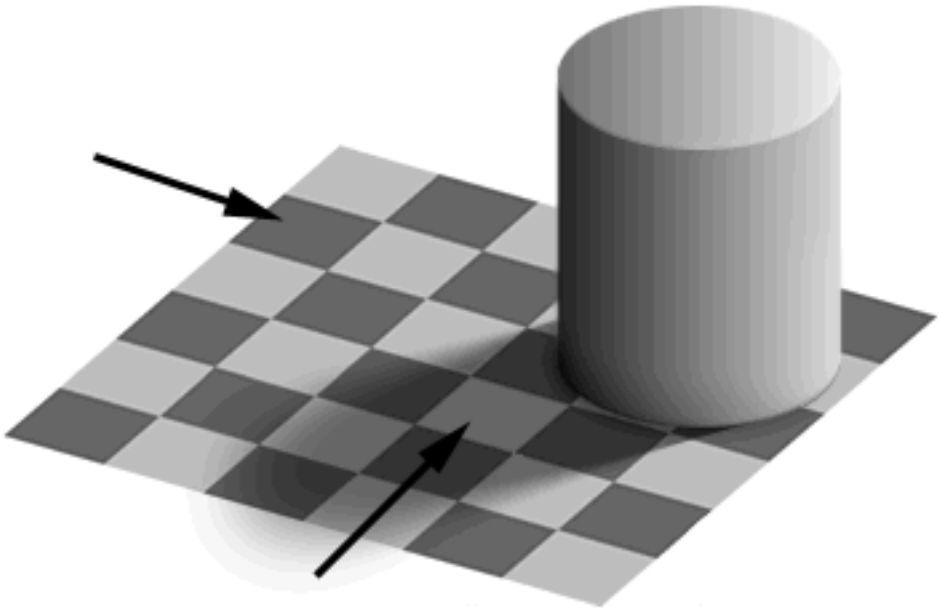

Figure 0.19: Checker shadow (by Edward Adelson). Which of the two squares indicated by the arrows is the brighter one (following inverted text gives answer)? Both squares reflect the same amount of light (this can be verified by covering all of squares except the two indicated), but the human visual system assigns a relative brightness that is consistent with the checker pattern.

Figure 0.20: The Thatcher illusion. With permission from Thompson.[1351] The facial images look very similar when viewed in one orientation and very different when viewed in another (turn page upside down).

that possessing these skills improves the chances of a person passing on their genes to subsequent generations (in fact one recent trend suggests otherwise[1236]). So we should not expect human cognitive processes to be tuned for performing these activities.

Table 0.13: Cognitive anomalies. Adapted from McFadden.[914]

Effect	Description
CONTEXT	
Anchoring	Judgments are influenced by quantitative cues contained in the statement of the decision task
Context	Prior choices and available options in the decision task influence perception and motivation
Framing	Selection between mathematically equivalent solutions to a problem depends on how their outcome is framed.
Prominence	The format in which a decision task is stated influences the weight given to different aspects
REFERENCE POINT	
Risk asymmetry	Subjects show risk-aversion for gains, risk-preference for losses, and weigh losses more heavily
Reference point	Choices are evaluated in terms of changes from an endowment or status quo point
Endowment	Possessed goods are valued more highly than those not possessed; once a function has been written
developers are loath to throw it away and start again	
AVAILABILITY	
Availability	Responses rely too heavily on readily retrievable information and too little on background information
Certainty	Sure outcomes are given more weight than uncertain outcomes
Experience	Personal history is favored relative to alternatives not experienced
Focal	Quantitative information is retrieved or reported categorically
Isolation	The elements of a multiple-part or multi-stage lottery are evaluated separately
Primacy and Recency	Initial and recently experienced events are the most easily recalled
Regression	Idiosyncratic causes are attached to past fluctuations, and regression to the mean is underestimated
Representativeness	High conditional probabilities induce overestimates of unconditional probabilities
Segregation	Lotteries are decomposed into a sure outcome and a gamble relative to this sure outcome
SUPERSTITION	
Credulity	Evidence that supports patterns and causal explanations for coincidences is accepted too readily
Disjunctive	Consumers fail to reason through or accept the logical consequences of actions
Superstition	Causal structures are attached to coincidences, and "quasi-magical" powers to opponents
Suspicion	Consumers mistrust offers and question the motives of opponents, particularly in unfamiliar situations
PROCESS	
Rule-Driven	Behavior is guided by principles, analogies, and exemplars rather than utilitarian calculus
Process	Evaluation of outcomes is sensitive to process and change
Temporal	Time discounting is temporally inconsistent, with short delays discounted too sharply relative to long delays
PROJECTION	
Misrepresentation	Subjects may misrepresent judgments for real or perceived strategic advantage
Projection	Judgments are altered to reinforce internally or project to others a self-image

Table 0.13 lists some of the cognitive anomalies (difference between human behavior and some idealized norm) applicable to writing software. There are other cognitive anomalies, some of which may also be applicable, and others that have limited applicability; for instance, writing software is a private, not a social activity. Cognitive anomalies relating to herd behavior and conformity to social norms are unlikely to be of

interest.

16.1 Physical characteristics

developer physical characteristics

Before moving on to the main theme of this discussion, something needs to be said about physical characteristics.

The brain is the processor that the software of the mind executes on. Just as silicon-based processors have special units that software can make use of (e.g., floating point), the brain appears to have special areas that perform specific functions.[1088] This book treats the workings of the brain/mind combination as a black box. We are only interested in the outputs, not the inner workings (brain-imaging technology has not yet reached the stage where we can deduce functionality by watching the signals travelling along neurons).

Eyes are the primary information-gathering sensors for reading and writing software. A lot of research has been undertaken on how the eyes operate and interface with the brain.[1047] Use of other information-gathering sensors has been proposed, hearing being the most common (both spoken and musical[1421]). These are rarely used in practice, and they are not discussed further in this book.

typing 792 mistakes

Hands/fingers are the primary output-generation mechanism. A lot of research on the operation of limbs has been undertaken. The impact of typing on error rate is discussed elsewhere.

Developers are assumed to be physically mature (we do not deal with code written by children or adolescents) and not to have any physical (e.g., the impact of dyslexia on reading source code is not known; another unknown is the impact of deafness on a developer's ability to abbreviate identifiers based on their sound) or psychiatric problems.

Issues such as genetic differences (e.g., male vs. female[1111]) or physical changes in the brain caused by repeated use of some functional unit (e.g., changes in the hippocampi of taxi drivers[887]) are not considered here.

16.2 Mental characteristics

developer mental characteristics

memory 0 developer

This section provides an overview of those mental characteristics that might be considered important in reading and writing software. Memory, particularly short-term memory, is an essential ability. It might almost be covered under physical characteristics, but knowledge of its workings has not quite yet reached that level of understanding. An overview of the characteristics of memory is given in the following subsection. The consequences of these characteristics are discussed throughout the book.

The idealization of developers aspiring to be omnipotent logicians gets in the way of realistically approaching the subject of how best to make use of the abilities of the human mind. Completely rational, logical, and calculating thought may be considered to be the ideal tools for software development, but they are not what people have available in their heads. Builders of bridges do not bemoan the lack of unbreakable materials available to them, they have learned how to work within the limitations of the materials available. This same approach is taken in this book, work with what is available.

This overview is intended to provide background rationale for the selection of, some, coding guidelines. In some cases, this results in recommendations against the use of constructs that people are likely to have problems processing correctly. In other cases this results in recommendations to do things in a particular way. These recommendations could be based on, for instance, capacity limitations, biases/heuristics (depending on the point of view), or some other cognitive factors.

Some commentators recommend that ideal developer characteristics should be promoted (such ideals are often accompanied by a list of tips suggesting activities to perform to help achieve these characteristics, rather like pumping iron to build muscle). This book contains no exhortations to try harder, or tips on how to become better developers through mental exercises. In this book developers are taken as they are, not some idealized vision of how they should be.

Hopefully the reader will recognize some of the characteristics described here in themselves. The way forward is to learn to deal with these characteristics, not to try to change what could turn out to be intrinsic properties of the human brain/mind.

Software development is not the only profession for which the perceived attributes of practitioners do not

correspond to reality. Darley and Batson[317] performed a study in which they asked subjects (theological seminary students) to walk across campus to deliver a sermon. Some of the subjects were told that they were late and the audience was waiting, the remainder were not told this. Their journey took them past a *victim* moaning for help in a doorway. Only 10% of subjects who thought they were late stopped to help the victim; of the other subjects 63% stopped to help. These results do not match the generally perceived behavior pattern of theological seminary students.

Most organizations do not attempt to measure mental characteristics in developer job applicants; unlike many other jobs for which individual performance can be an important consideration. Whether this is because of an existing culture of not measuring, lack of reliable measuring procedures, or fear of frightening off prospective employees is not known.

16.2.1 Computational power of the brain

developer computational power

One commonly used method of measuring the performance of silicon-based processors is to quote the number of instructions (measured in millions) they can execute in a second. This is known to be an inaccurate measure, but it provides an estimate.

The brain might simply be a very large neural net, so there will be no instructions to count as such. Merkle[926] used various approaches to estimate the number of synaptic operations per second; the followings figures are taken from his article:

- Multiplying the number of synapses (10^{15}) by their speed of operation (about 10 impulses/second) gives 10^{16} synapse operations per second.
- The retina of the eye performs an estimated 10^{10} analog add operations per second. The brain contains 10^2 to 10^4 times as many nerve cells as the retina, suggesting that it can perform 10^{12} to 10^{14} operations per second.
- A total brain power dissipation of 25 watts (an estimated 10 watts of useful work) and an estimated energy consumption of 5×10^{-15} joules for the switching of a nerve cell membrane provides an upper limit of 2×10^{15} operations per second.

A synapse switching on and off is rather like a transistor switching on and off. They both need to be connected to other switches to create a larger functional unit. It is not known how many synapses are used to create functional units in the brain, or even what those functional units might be. The distance between synapses is approximately 1 mm. Simply sending a signal from one part of the brain to another part requires many synaptic operations, for instance, to travel from the front to the rear of the brain requires at least 100 synaptic operations to propagate the signal. So the number of synaptic operations per high-level, functional operation is likely to be high. Silicon-based processors can contain millions of transistors. The potential number of transistor-switching operations per second might be greater than 10^{14}, but the number of instructions executed is significantly smaller.

Although there have been studies of the information-processing capacity of the brain (e.g., visual attention,[1419] storage rate into long-term memory,[801] and correlations between biological factors and intelligence[1405]), we are a long way from being able to deduce the likely work rates of the components of the brain used during code comprehension. The issue of overloading the computational resources of the brain is discussed elsewhere.

0 cognitive effort

There are several executable models of how various aspects of human cognitive processes operate. The ACT-R model[35] has been applied to a wide range of problems, including learning, the visual interface, perception and action, cognitive arithmetic, and various deduction tasks.

Developers are familiar with the idea that a more powerful processor is likely to execute a program more quickly than a less powerful one. Experience shows that some minds are quicker at solving some problems than other minds and other problems (a correlation between what is known as *inspection time* and IQ has been found[335]). For these coding guidelines, speed of mental processing is not a problem in itself. The problem of limited processing resources operating in a time-constrained environment, leading to errors being

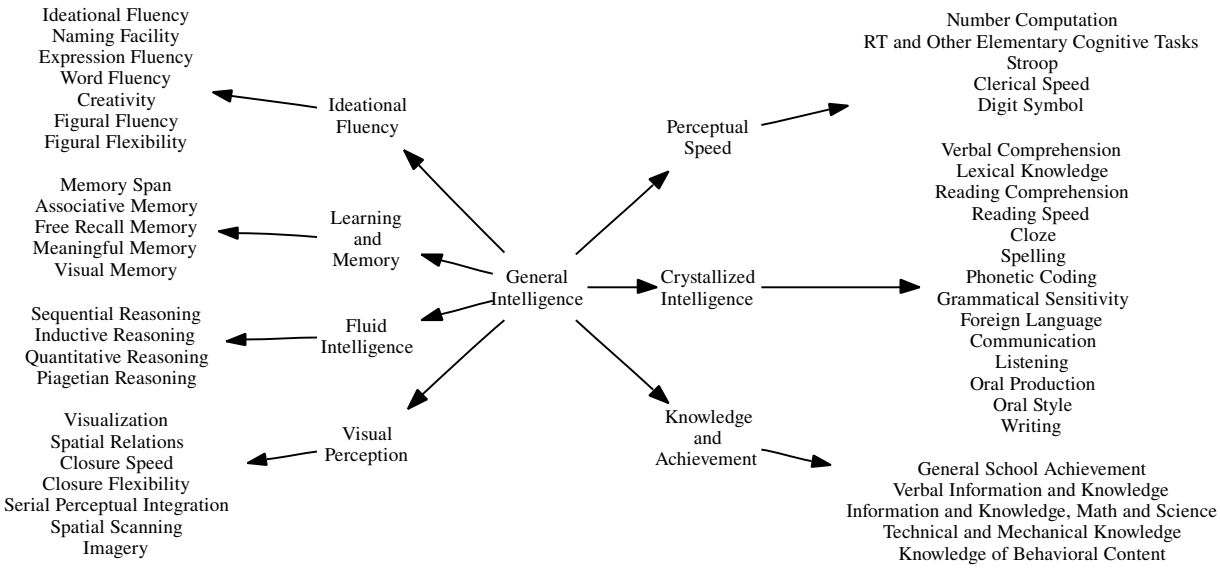

Figure 0.21: A list of and structure of ability constructs. Adapted from Ackerman.[2]

made, could be handled if the errors were easily predicted. It is the fact that different developers have ranges of different abilities that cause the practical problems. Developer A can have trouble understanding the kinds of problems another developer, B, could have understanding the code he, A, has written. The problem is how does a person, who finds a particular task easy, relate to the problems a person, who finds that task difficult, will have?

The term *intelligence* is often associated with performance ability (to carry out some action in a given amount of time). There has been a great deal of debate about what intelligence is, and how it can be measured. Gardner[471] argues for the existence of at least six kinds of intelligence— bodily kinesthetic, linguistic, mathematical, musical, personal, and spatial. Studies have shown that there can be dramatic differences between subjects rated high and low in these intelligences (linguistic[501] and spatial[883]). Ackerman and Heggestad[2] review the evidence for overlapping traits between intelligence, personality, and interests (see Figure 0.21). An extensive series of tests carried out by Süß, Oberauer, Wittmann, Wilhelm, and Schulze[1317] found that intelligence was highly correlated to working memory capacity. The strongest relationship was found for reasoning ability.

The failure of so-called intelligence tests to predict students' job success on leaving college or university is argued with devastating effect by McClelland,[909] who makes the point that the best testing is criterion sampling (for developers this would involve testing those attributes that distinguish *betterness* in developers). Until employers start to measure those employees who are involved in software development, and a theory explaining how these relate to the problem of developing software-based applications is available, there is little that can be said. At our current level of knowledge we can only say that developers having different abilities may exhibit different failure modes when solving problems.

16.2.2 Memory

memory developer

Studies have found that human memory might be divided into at least two (partially connected) systems, commonly known as *short-term memory* (STM) and *long-term memory* (LTM). The extent to which STM and LTM really are different memory systems, and not simply two ends of a continuum of memory properties, continues to be researched and debated. Short-term memory tends to operate in terms of speech sounds and have a very limited capacity; while long-term memory tends to be semantic- or episodic-based and is often treated as having an infinite capacity (a lifetime of memories is estimated to be represented in 10^9 bits;[801]

memory 0 episodic

this figure takes forgetting into account).

There are two kinds of query that are made against the contents of memory. During *recall* a person attempts to use information immediately available to them to access other information held in memory. During *recognition*, a person decides whether they have an existing memory for information that is being presented.

Much of the following discussion involves human memory performance with unchanging information. Developers often have to deal with changing information (e.g., the source code may be changing on a daily basis; the value of variables may be changing as developers run through the execution of code in their heads). Human memory performance has some characteristics that are specific to dealing with changing information.[295, 712] However, due to a lack of time and space, this aspect of developer memory performance is not covered in any detail in this book.

Miller 7±2

As its name implies, STM is an area of memory that stores information for short periods of time. For more than 100 years researchers have been investigating the properties of STM. Early researchers started by trying to measure its capacity. A paper by Miller[935] entitled *The magical number seven, plus or minus two: Some limits on our capacity for processing information* introduced the now-famous 7±2 rule. Things have moved on, during the 47 years since the publication of his paper[684] (not that Miller ever proposed 7±2 as the capacity of STM; he simply drew attention to the fact that this range of values fit the results of several experiments).

memory digit span

Readers might like to try measuring their STM capacity. Any Chinese-speaking readers can try this exercise twice, using the English and Chinese words for the digits.[591] Use of Chinese should enable readers to apparently increase the capacity of STM (explanation follows). The digits in the outside margin can be used. Slowly and steadily read the digits in a row, out loud. At the end of each row, close your eyes and try to repeat the sequence of digits in the same order. If you make a mistake, go on to the next row. The point at which you cannot correctly remember the digits in any two rows of a given length indicates your capacity limit— the number of digits in the previous rows.

Measuring working memory capacity using sequences of digits relies on several assumptions. It assumes that working memory treats all items the same way (what if letters of the alphabet had been used instead), and it also assumes that individual concepts are the unit of storage. Studies have shown that both these assumptions are incorrect. What the preceding exercise measured was the amount of *sound* you could keep in working memory. The sound used to represent digits in Chinese is shorter than in English. The use of Chinese should enable readers to maintain information on more digits (average 9.9[592]) using the same amount of sound storage. A reader using a language for which the sound of the digits is longer would be able to maintain information on fewer digits (e.g., average 5.8 in Welsh[384]). The average for English is 6.6.

Studies have shown that performance on the *digit span* task is not a good predictor of performance on other short- or long-term memory for items. However, a study by Martin[898] found that it did correlate with memory for the temporal occurrence of events.

In the 1970s Baddeley asked what purpose short-term memory served. He reasoned that its purpose was to act as a temporary area for activities such as mental arithmetic, reasoning, and problem solving. The model of *working memory* he proposed is shown in Figure 0.22. There are three components, each with its own independent temporary storage areas, each holding and using information in different ways.

What does the central executive do? It is assumed to be the system that handles attention, controlling the phonological loop, the visuo-spatial sketch pad, and the interface to long-term memory. The central executive needs to remember information while performing tasks such as text comprehension and problem solving. The potential role of this central executive is discussed elsewhere.

Sequences of single digits containing 4 to 10 digits.

Visual information held in the visuo-spatial sketch pad decays very rapidly. Experiments have shown that people can recall four or five items immediately after they are presented with visual information, but that this recall rate drops very quickly after a few seconds. From the source code reading point of view, the visuo-spatial sketch pad is only operative for the source code currently being looked at.

0 attention
visuo-spatial memory

While remembering digit sequences, readers may have noticed that the sounds used for them went around

phonological loop

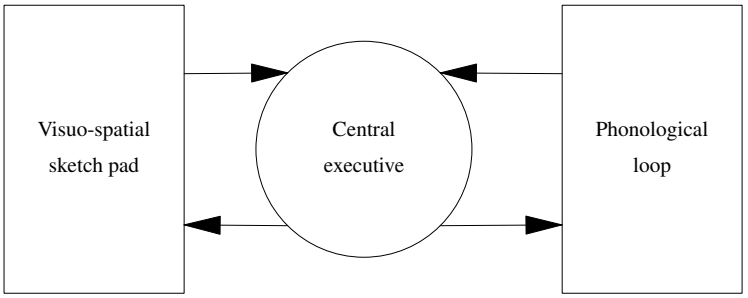

Figure 0.22: Model of working memory. Adapted from Baddeley.[75]

in their heads. Research has uncovered a system known as the phonological (or articulatory) loop. This kind of memory can be thought of as being like a loop of tape. Sounds can be recorded onto this tape, overwriting the previous contents, as it goes around and around. An example of the functioning of this loop can be found, by trying to remember lists of words that vary by the length of time it takes to say them.

Table 0.14 contains lists of words; those at the top of the table contain a single syllable, those at the bottom multiple syllables. Readers should have no problems remembering a sequence of five single-syllable words, a sequence of five multi-syllable words should prove more difficult. As before, read each word slowly out loud.

Table 0.14: Words with either one or more than one syllable (and thus varying in the length of time taken to speak).

List 1	List 2	List 3	List 4	List 5
one	cat	card	harm	add
bank	lift	list	bank	mark
sit	able	inch	view	bar
kind	held	act	fact	few
look	mean	what	time	sum
ability	basically	encountered	laboratory	commitment
particular	yesterday	government	acceptable	minority
mathematical	department	financial	university	battery
categorize	satisfied	absolutely	meaningful	opportunity
inadequate	beautiful	together	carefully	accidental

It has been found that fast talkers have better short-term memory. The connection is the phonological loop. Short-term memory is not limited by the number of items that can be held. The limit is the length of sound this loop can store, about two seconds.[76] Faster talkers can represent more information in that two seconds than those who do not talk as fast.

An analogy between *phonological loop* and a loop of tape in a tape recorder, suggests the possibility that it might only be possible to extract information as it goes past a *read-out point*. A study by Sternberg[1294] looked at how information in the phonological loop could be accessed. Subjects were asked to hold a sequences of digits, for instance 4185, in memory. They were then asked if a particular digit was in the sequence being held. The time taken to respond yes/no was measured. Subjects were given sequences of different length to hold in memory. The results showed that the larger the number of digits subjects had to hold in memory, the longer it took them to reply (see Figure 0.23). The other result was that the time to respond was not affected by whether the answer was yes or no. It might be expected that a yes answer would enable the search to be terminated. This suggests that all digits were always being compared.

memory span

A study by Cavanagh[210] found that different kinds of information, held in memory, has different search response times (see Figure 0.24).

A good example of using the different components of working memory is mental arithmetic; for example, multiply 23 by 15 without looking at this page. The numbers to be multiplied can be held in the phonological

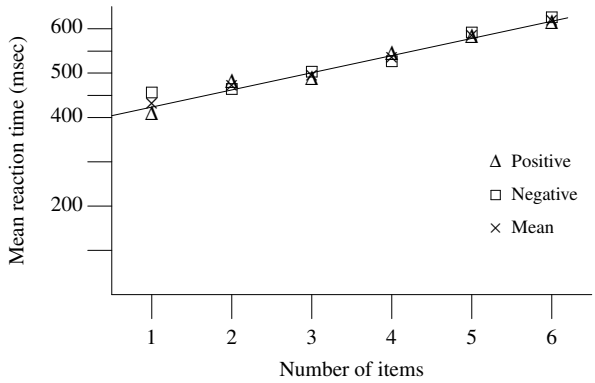

Figure 0.23: Judgment time (in milliseconds) as a function of the number of digits held in memory. Adapted from Sternberg.[1294]

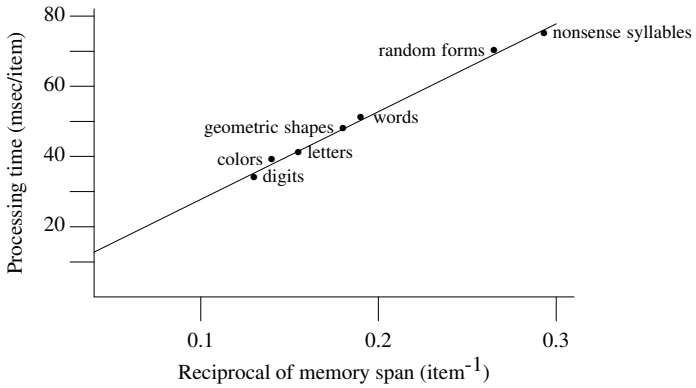

Figure 0.24: Judgment time (msec per item) as a function of the number of different items held in memory. Adapted from Cavanagh[210]

loop, while information such as carries and which two digits to multiple next can be held within the central executive. Now perform another multiplication, but this time look at the two numbers being multiplied (see margin for values) while performing the multiplication.

26
12
Two numbers to multiply.

While performing this calculation the visuo-spatial sketch pad can be used to hold some of the information, the values being multiplied. This frees up the phonological loop to hold temporary results, while the central executive holds positional information (used to decide which pairs of digits to look at). Carrying out a multiplication while being able to look at the numbers being multiplied seems to require less cognitive effort.

Recent research on working memory has begun to question whether it does have a capacity limit. Many studies have shown that people tend to organize items in memory in chunks of around four items. The role that attention plays in working memory, or rather the need for working memory in support of attention, has also come to the fore. It has been suggested that the focus of attention is capacity-limited, but that the other temporary storage areas are time-limited (without attention to rehearse them, they fade away). Cowan[296] proposed the following:

0 attention

1. The focus of attention is capacity-limited.
2. The limit in this focus averages about four chunks in normal adult humans.
3. No other mental faculties are capacity-limited, although some are limited by time and susceptibility to interference.

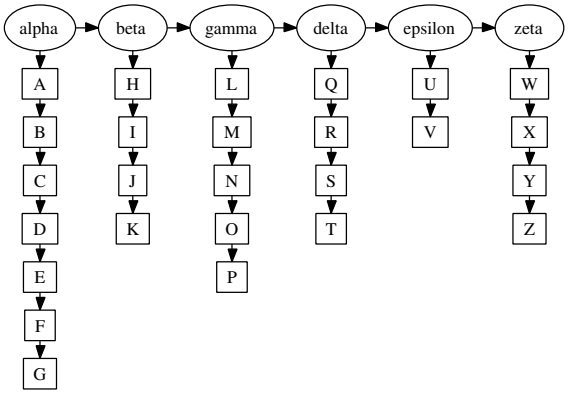

Figure 0.25: Semantic memory representation of alphabetic letters (the Greek names assigned to nodes by Klahr are used by the search algorithm and are not actually held in memory). Readers may recognize the structure of a nursery rhyme in the letter sequences. Derived from Klahr.[744]

4. Any information that is deliberately recalled, whether from a recent stimulus or from long-term memory, is restricted to this limit in the focus of attention.

Other studies[1022] have used the results from multiple tasks to distinguish the roles (e.g., storage, processing, supervision, and coordination) of different components of working memory.

memory chunking

Chunking is a technique commonly used by people to help them remember information. A chunk is a small set of items (4±1 is seen in many studies) having a common, strong, association with each other (and a much weaker one to items in other chunks). For instance, Wickelgren[1458] found that people's recall of telephone numbers is optimal if numbers are grouped into chunks of three digits. An example from random-letter sequences is *fbicbsibmirs*. The trigrams (*fbi*, *cbs*, *ibm*, *irs*) within this sequence of 12 letters are well-known acronyms. A person who notices this association can use it to aid recall. Several theoretical analyses of memory organizations have shown that chunking of items improves search efficiency ([360] optimal chunk size 3–4), ([880] number items at which chunking becomes more efficient than a single list, 5–7).

An example of chunking of information is provided by a study performed by Klahr, Chase, and Lovelace[744] who investigated how subjects stored letters of the alphabet in memory. Through a series of time-to-respond measurements, where subjects were asked to name the letter that appeared immediately before or after the presented probe letter, they proposed the alphabet-storage structure shown in Figure 0.25. They also proposed two search algorithms that described the process subjects used to answer the before/after question.

feeling of knowing

One of the characteristics of human memory is that it has knowledge of its own knowledge. People are good at judging whether they know a piece of information or not, even if they are unable to recall that information at a particular instant. Studies have found that so-called *feeling of knowing* is a good predictor of subsequent recall of information (see Koriat[765] for a discussion and a model).

working memory information representation

phonology 792

Several models of working memory are based on it only using a phonological representation of information. Any semantic effects in short-term memory come from information recalled from long-term memory. However, a few models of short-term memory do include a semantic representation of information (see Miyake and Shah[947] for detailed descriptions of all the current models of working memory, and Baddeley for a comprehensive review[71]).

A study by Hambrick and Engle[537] asked subjects to remember information relating to baseball games. The subjects were either young, middle age, or old adult who knew little about baseball or were very knowledgeable about baseball. The largest factor (54.9%) in the variance of subject performance was expertise, with working memory capacity and age making up the difference.

Source code constructs differ in their likelihood of forming semantically meaningful chunks. For instance,

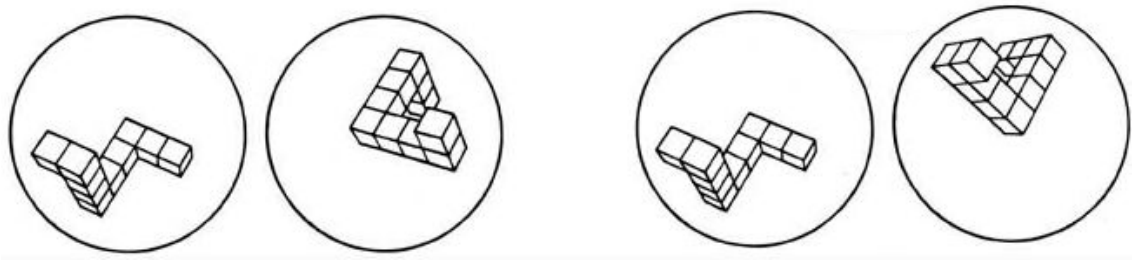

Figure 0.26: One of the two pairs are rotated copies of each other.

the ordering of a sequence of statements is often driven by the operations performed by those statements, while the ordering of parameters is often arbitrary.

Declarative memory is a long-term memory (information may be held until a person dies) that has a huge capacity (its bounds are not yet known) and holds information on facts and events (declarative knowledge is discussed elsewhere). Two components of declarative memory of interest to the discussion here are episodic and semantic memory. Episodic memory[72] is a past-oriented memory system concerned with *remembering*, while semantic memory is a present-oriented memory system concerned with *knowing*.

memory semantic memory episodic
0 declarative knowledge

Having worked on a program, a developer may remember particular sections of source code through their interaction with it (e.g., deducing how it interacted with other source code, or inserting traces to print out values of objects referenced in the code). After working on the same program for an extended period of time, a developer is likely to be able to recall information about it without being able to remember exactly when they learned that information.[565]

16.2.2.1 Visual manipulation

developer visual manipulation

How are visual images held in the brain? Are they stored directly in some way (like a bitmap), or are they held using an abstract representation (e.g., a list of objects tagged with their spatial positions). A study performed by Shepard[1226] suggested the former. He showed subjects pairs of figures and asked them if they were the same. Some pairs were different, while others were the same but had been rotated relative to each other. The results showed a linear relationship between the angle of rotation (needed to verify that two objects were the same) and the time taken to make a matching comparison. Readers might like to try there mind at rotating the pairs of images in Figure 0.26 to find out if they are the same.

Kosslyn[767] performed a related experiment. Subjects were shown various pictures and asked questions about them. One picture was of a boat. Subjects were asked a question about the front of the boat and then asked a question about the rear of the boat. The response time, when the question shifted from the front to the rear of the boat, was longer than when the question shifted from one about portholes to one about the rear. It was as if subjects had to scan their image of the boat from one place to another to answer the questions.

A study by Presson and Montello[1122] asked two groups of subjects to memorize the locations of objects in a room. Both groups of subjects were then blindfolded and asked to point to various objects. The results showed their performance to be reasonably fast and accurate. Subjects in the first group were then asked to imagine rotating themselves 90°, then they were asked to point to various objects. The results showed their performance to be much slower and less accurate. Subjects in the second group were asked to actually rotate 90°; while still blindfolded, they were then asked to point to various objects. The results showed that the performance of these subjects was as good as before they rotated. These results suggest that mentally keeping track of the locations of objects, a task that many cognitive psychologists would suspect as being cognitive and divorced from the body, is in fact strongly affected by literal body movements (this result is more evidence for *the embodied mind* theory[1411] of the human mind).

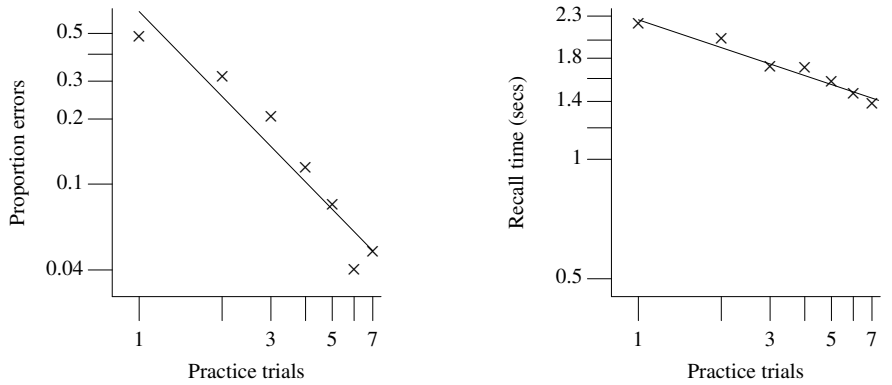

Figure 0.27: Proportion of errors (left) and time to recall (right) for recall of paired associate words (log scale). Based on Anderson.[32]

16.2.2.2 Longer term memories

People can store large amounts of information for long periods of time in their long-term memory. Landauer[801] attempts to estimate the total amount of learned information in LTM. Information written to LTM may not be held there for very long (storage), or it may be difficult to find (retrieval). This section discusses storage and retrieval of information in LTM.

One of the earliest memory research results was that practicing an item, after it had been learned, improves performance of recall at a later time (first published by Ebbinghaus in 1885, and reprinted several times since[374]). The relationship between practice, P, and time, T, to recall has been found to follow a power law $T = aP^b$ (where a and b are constants). This relationship has become known as *the power law of learning*. A similar relationship has been found for error rates— more practice, fewer errors.

How is information stored in LTM? The brain contains neurons and synapses; information can only be represented as some kind of change in their state. The term *memory trace* is used to describe this changed state, representing the stored information. Accessing an information item in LTM is thought to increase the strength of its associated *memory trace* (which could mean that a stronger signal is returned by subsequent attempts at recall, or that the access path to that information is smoothed; nobody knows yet).

Practice is not the only way of improving recall. How an item has been studied, and its related associations, can affect how well it is recalled later. The meaning of information to the person doing the learning, so-called *depth of processing*, can affect their recall performance. Learning information that has a meaning is thought to create more access methods to its storage location(s) in LTM.

synonym 792

The *generation effect* refers to the process whereby people are involved in the generation of the information they need to remember. A study by Slamecka and Graf[1253] asked subjects to generate a synonym, or rhyme, of a target word that began with a specified letter. For instance, generate a synonym for *sea* starting with the letter *o* (e.g., *ocean*). The subjects who had to generate the associated word showed a 15% improvement in recall, compared to subjects who had simply been asked to read the word pair (e.g., *sea–ocean*).

memory information elaboration

An example of the effect of additional, meaningful information was provided by a study by Bradshaw and Anderson.[150] Subjects were given information on famous people to remember. For instance, one group of subjects was told:

> Newton became emotionally unstable and insecure as a child

while other groups were given two additional facts to learn. These facts either elaborated on the first sentence or were unrelated to it:

Newton became emotionally unstable and insecure as a child
Newton's father died when he was born
Newton's mother remarried and left him with his grandfather

After a delay of one week, subjects were tested on their ability to recall the target sentence. The results showed that subjects percentage recall was higher when they had been given two additional sentences, that elaborated on the first one (the performance of subjects given related sentences being better than those given unrelated ones). There was no difference between subjects, when they were presented with the original sentence and asked if they recognized it.

The preceding studies involved using information that had a verbal basis. A study by Standing, Conezio, and Haber[1280] involved asking subjects to remember visual information. The subjects were shown 2,560 photographs for 10 seconds each (640 per day over a 4-day period). On each day, one hour after being shown the pictures, subjects were shown a random sample of 70 pairs of pictures (one of which was in the set of 640 seen earlier). They had to identify which of the pair they had seen before. Correct identification exceeded 90%. This and other studies have confirmed people's very good memory for pictures.

16.2.2.3 Serial order

memory
serial lists

The order in which items or events occur is often important when comprehending source code. For instance, the ordering of a function's parameters needs to be recalled when passing arguments, and the order of statements within the source code of a function specifies an order of events during program execution. Two effects are commonly seen in human memory recall performance:

1. The *primacy effect* refers to the better recall performance for items at the start of a list. primacy effect memory
2. The *recency effect* refers to the better recall performance for items at the end of a list. recency effect memory

A number of models have been proposed to explain people's performance in the serial list recall task. Henson[563] describes the *start–end model*.

16.2.2.4 Forgetting

forgetting

While people are unhappy about the fact that they forget things, never forgetting anything may be worse. The Russian mnemonist Shereshevskii found that his ability to remember everything, cluttered up his mind.[878] Having many similar, not recently used, pieces of information matching during a memory search would be counterproductive; forgetting appears to be a useful adaptation. For instance, a driver returning to a car wants to know where it was last parked, not the location of all previous places where it was parked. Anderson and Milson[36] proposed that human memory is optimized for information retrieval based on the statistical properties of information use, in people's everyday lives; their work was based on a model developed by Burrell[185] (who investigated the pattern of book borrowings in several libraries; which were also having items added to their stock). The rate at which the mind forgets seems to mirror the way that information tends to lose its utility in the real world over time.

It has only recently been reliably established[1185] that forgetting, like learning, follows a power law (the results of some studies could be fitted using exponential functions). The general relationship between the retention of information, R, and the time, T, since the last access has the form $R = aD^{-b}$ (where a and b are constants). It is known as the *power law of forgetting*. The constant a depends on the amount of initial learning. A study by Bahrick[80] (see Figure 0.28) looked at subjects' retention of English–Spanish vocabulary (the drop-off after 25 years may be due to physiological deterioration[33]).

The following are three theories of how forgetting occurs:

1. Memory traces simply fade away.
2. Memory traces are disrupted or obscured by newly formed memory traces created by new information being added to memory.

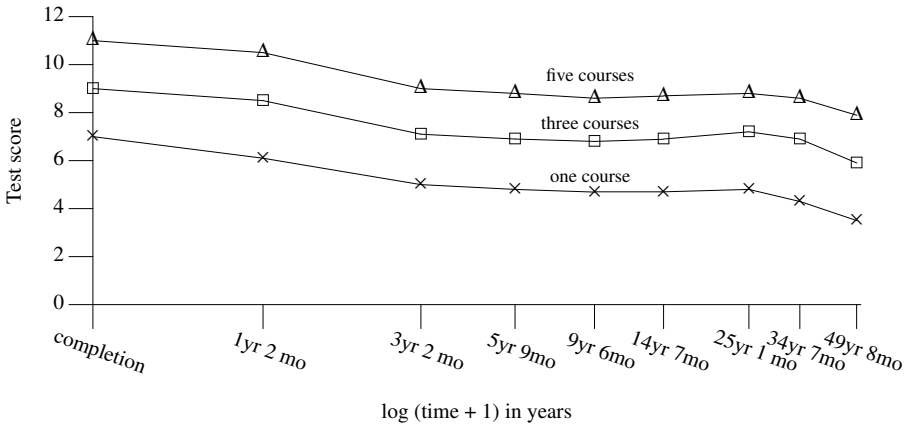

Figure 0.28: Effect of level of training on the retention of recognition of English–Spanish vocabulary. Adapted from Bahrick.[80]

3. The retrieval cues used to access memory traces are lost.

The process of learning new information is not independent of already-learned information. There can be mutual inference between the two items of information. The interference of old information, caused by new information, is known as *retroactive interference*. It is not yet known whether the later information weakens the earlier information, or whether it is simply stronger and overshadows access to the earlier information. The opposite effect of retroactive interference is *proactive interference*. In this case, past memories interfere with more recent ones.

Table 0.15 and Table 0.16 (based on Anderson[34]) are examples of the word-pair association tests used to investigate interference effects. Subjects are given a single pair of words to learn and are tested on that pair only (in both tables, Subject 3 is the control). The notation $A \Rightarrow B$ indicates that subjects have to learn to respond with B when given the cue A. An example of a word-pair is *sailor–tipsy*. The Worse/Better comparison is against the performance of the control subjects.

Table 0.15: Proactive inhibition. The third row indicates learning performance; the fifth row indicates recall performance, relative to that of the control. Based on Anderson.[34]

Subject 1	Subject 2	Subject 3
Learn A⇒B	Learn C⇒D	Rest
Learn A⇒D	Learn A⇒B	Learn A⇒D
Worse	Better	
Test A⇒D	Test A⇒D	Test A⇒D
Worse	Worse	

Table 0.16: Retroactive inhibition. The fourth row indicates subject performance relative to that of the control. Based on Anderson.[34]

Subject 1	Subject 2	Subject 3
Learn A⇒B	Learn A⇒B	Learn A⇒B
Learn A⇒D	Learn C⇒D	Rest
Test A⇒B	Test A⇒B	Test A⇒B
Much worse	Worse	

The general conclusion from the, many, study results is that interference occurs in both learning and recall

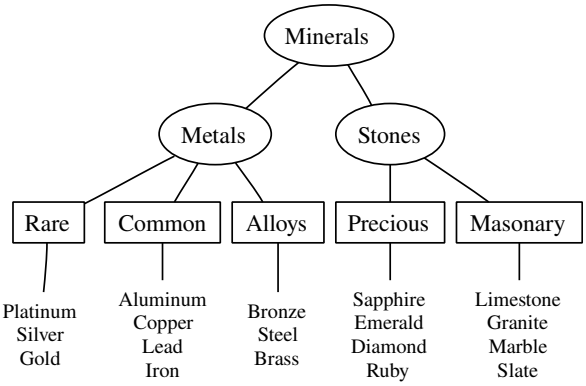

Figure 0.29: Words organized according to their properties— the *minerals* conceptual hierarchy. Adapted from Bower, Clark, Lesgold, and Winzenz.[147]

when there are multiple associations for the same item. The improvement in performance of subjects in the second category, of proactive inhibition, is thought to occur because of a practice effect.

16.2.2.5 Organized knowledge

Information is not stored in people's LTM in an unorganized form (for a detailed discussion, see[34]). This section provides a brief discussion of the issues. More detailed discussions are provided elsewhere in the specific cases that apply to reading and writing source code.

developers
organized
knowledge
792 identifier
memorability

Whenever possible, the coding guidelines given in this book aim to take account of the abilities and limitations that developers have. An example of how it is possible to use an ability of the mind (organizing information in memory) to overcome a limitation (information held in LTM becoming inaccessible) is provided by the following demonstration.

Readers might like to try remembering words presented in an organized form and as a simple list. Read the words in Figure 0.29 out loud, slowly and steadily. Then try to recall as many as possible. Then repeat the process using the words given below. It is likely that a greater number of words will be recalled from the organized structure. The words in the second list could be placed into the same structure as the first list, instead they appear in a random order.

```
      pine elm pansy garden wild banyan plants
   delphinium conifers dandelion redwood palm ash
violet daisy tropical chestnut flowers spruce lupin
   buttercup trees deciduous mango willow rose
```

Familiarity with information being learned and recalled can also make a difference. Several studies have shown that experts perform better than non-experts in remembering information within their domain of expertise. For instance, McKeithen, Reitman, Ruster, and Hirtle[917] measured developers' ability to memorize program source code. Subjects were presented with two listings; one consisted of a sequence of lines that made up a well-formed program, the other contained the same lines but the order in which they appeared on the listing had been randomized. Experienced developers (more than 2,000 hr of general programming and more than 400 hr experience with the language being used in the experiment) did a much better job at recalling source lines from the listing that represented a well-formed program and inexperienced developers. Both groups did equally well in recalling lines from the randomized listing. The experiments also looked at how developers remembered lists of language keywords they were given. How the information was organized was much more consistent across experienced developers than across inexperienced developers (experienced developers also had a slightly deeper depth of information chunking, 2.26 vs. 1.88).

16.2.2.6 Memory accuracy

Until recently experimental studies of memory have been dominated by a quantity-oriented approach. Memory was seen as a storehouse of information and is evaluated in terms of how many items could be successfully retrieved. The issue of accuracy of response was often ignored. This has started to change and there has been a growing trend for studies to investigate accuracy.[766] Coding guidelines are much more interested in factors that affect memory accuracy than those, for instance, affecting rate of recall. Unfortunately, some of the memory studies described in this book do not include information on error rates.

16.2.2.7 Errors caused by memory overflow

developer errors memory overflow

Various studies have verified that limits on working memory can lead to an increase in a certain kind of error when performing a complex task. Byrne and Bovair[188] looked at postcompletion errors (an example of this error is leaving the original in the photocopy machine after making copies, or the ATM card in the machine after withdrawing money) in complex tasks. A task is usually comprised of several goals that need to be achieved. It is believed that people maintain these goals using a stack mechanism in working memory. Byrne and Bovair were able to increase the probability of subjects making postcompletion errors in a task assigned to them. They also built a performance model that predicted postcompletion errors that were consistent with those seen in the experiments.

conditional statement 1739

The possible impact of working memory capacity-limits in other tasks, related to reading and writing source code, is discussed elsewhere. However, the complexity of carrying out studies involving working memory should not be underestimated. There can be unexpected interactions from many sources. A study by Lemaire, Abdi, and Fayol[833] highlighted the complexity of trying to understand the affects of working memory capacity limitations. The existing models of the performance of simple arithmetic operations, involve an interrelated network in long-term memory (built during the learning of arithmetic facts, such as the multiplication table, and reinforced by constant practice). Lemaire et al. wanted to show that simple arithmetic also requires working memory resources.

To show that working memory resources were required, they attempted to overload those resources. Subjects were required to perform another task at the same time as answering a question involving simple arithmetic (e.g., $4 + 8 = 12$, true or false?). The difficulty of the second task varied between experiments. One required subjects to continuously say the word *the*, another had them continuously say the letters *abcdef*, while the most difficult task required subjects to randomly generate letters from the set *abcdef* (this was expected to overload the central executive system in working memory).

phonological loop

The interesting part of the results (apart from confirming the authors' hypothesis that working memory was involved in performing simple arithmetic) was how the performances varied depending on whether the answer to the simple arithmetic question was true or false. The results showed that performance for problems that were true was reduced when both the phonological loop and the central executive were overloaded, while performance on problems that were false was reduced when the central executive was overloaded.

A conditional expression requires that attention be paid to it if a developer wants to know under what set of circumstances it is true or false. What working memory resources are needed to answer this question; does keeping the names of identifiers in the phonological loop, or filling the visuo-spatial sketch pad (by looking at the code containing the expression) increase the resources required; does the semantics associated with identifiers or conditions affect performance? Your author does not know the answers to any of these questions but suspects that these issues, and others, are part of the effort cost that needs to be paid in extracting facts from source code.

16.2.2.8 Memory and code comprehension

As the results from the studies just described show, human memory is far from perfect. What can coding guidelines do to try to minimize potential problems caused by these limitations? Some authors of other coding guideline documents have obviously heard of Miller's[935] 7±2 paper (although few seem to have read it), often selecting five as the maximum bound on the use of some constructs.[684] However, the effects of working memory capacity-limits cannot be solved by such simple rules. The following are some of the many issues that need to be considered:

- What code is likely to be written as a consequence of a guideline recommendation that specifies some limit on the use of a construct? Would following the guideline lead to code that was more difficult to comprehend?
- Human memory organizes information into related chunks (which can then be treated as a single item) multiple chunks may in turn be grouped together, forming a structured information hierarchy. The visibility of this structure in the visible source may be beneficial.
- There are different limits for different kinds of information.
- All of the constructs in the source can potentially require working memory resources. For instance, identifiers containing a greater number of syllables consume more resources in the phonological loop.

792 identifier cognitive resource usage

There has been some research on the interaction between human memory and software development. For instance, Altmann[18] built a computational process model based on SOAR, and fitted it to 10.5 minutes of programmer activity (debugging within an `emacs` window). The simulation was used to study the memories, called near-term memory by Altmann, built up while trying to solve a problem. However, the majority of studies discussed in this book are not directly related to reading and writing source code (your author has not been able to locate many). They can, at best, be used to provide indicators. The specific applications of these results occur throughout this book. They include reducing interference between information chunks and reducing the complexity of reasoning tasks.

792 identifier syntax
1739 selection statement syntax

16.2.2.9 Memory and aging

A study by Swanson[1322] investigated how various measures of working memory varied with the age of the subject. The results from diverse working memory tasks were reasonably intercorrelated. The following are the general conclusions:

memory ageing

- Age-related differences are better predicted by performance on tasks that place high demands on accessing information or maintaining old information in working memory than on measures of processing efficiency.
- Age-related changes in working memory appear to be caused by changes in a general capacity system.
- Age-related performance for both verbal and visuo-spatial working memory tasks showed similar patterns of continuous growth that peak at approximately age 45.

0 visuo-spatial memory

16.2.3 Attention

Attention is a limited resource provided by the human mind. It has been proposed that the age we live in is not the information age, but the attention age.[321] Viewed in resource terms there is often significantly more information available to a person than attention resources (needed to process it). This is certainly true of the source code of any moderately large application.

attention

Much of the psychology research on attention has investigated how inputs from our various senses handled. It is known that they operate in parallel and at some point there is a serial bottleneck, beyond which point it is not possible to continue processing input stimuli in parallel. The point at which this bottleneck occurs is a continuing subject of debate. There are early selection theories, late selection theories, and theories that combine the two.[1060] In this book, we are only interested in the input from one sense, the eyes. Furthermore, the scene viewed by the eyes is assumed to be under the control of the viewer. There are no objects that spontaneously appear or disappear; the only change of visual input occurs when the viewer turns a page or scrolls the source code listing on a display.

Read the bold print in the following paragraph:

Somewhere **Among** hidden **the** in **most** the **spectacular** Rocky Mountains **cognitive** near **abilities** Central City **is** Colorado **the** an **ability** old **to** miner **select** hid **one** a **message** box **from** of **another.** gold. **We** Although **do** several **this** hundred **by** people **focusing** have **our** looked **attention** for **on** it, **certain** they **cues** have **such** not **as** found **type** it **style**.

What do you remember from the regular, non-bold, text? What does this tell you about selective attention?

People can also direct attention to their internal thought processes and memories. Internal thought processes are the main subject of this section. The issue of automatization (the ability to perform operations automatically after a period of training) is also covered; visual attention is discussed elsewhere.

automatization 0

Ideas and theories of attention and conscious thought are often intertwined. While of deep significance, these issues are outside the scope of this book. The discussion in this section treats attention as a resource available to a developer when reading and writing source code. We are interested in knowing the characteristics of this resource, with a view to making the best use of the what is available. Studies involving attention have looked at capacity limits, the cost of changes of attention, and why some thought-conscious processes require more effort than others.

The following are two attention resource theories:

- *The single-capacity theory.* This proposes that performance depends on the availability of resources; more information processing requires more resources. When people perform more than one task at the same time, the available resources per task is reduced and performance decreases.
- *The multiple-resource theory.* This proposes that there are several different resources. Different tasks can require different resources. When people perform more than one task at the same time, the effect on the response for each task will depend on the extent to which they need to make use of the same resource at the same time.

Many of the multiple-resource theory studies use different sensory input tasks; for instance, subjects are required to attend to a visual and an audio channel at the same time. Reading source code uses a single sensory input, the eyes. However, the input is sufficiently complex that it often requires a great deal of thought. The extent to which code reading *thought* tasks are sufficiently different that they will use different cognitive resources is unknown. Unless stated otherwise, subsequent discussion of attention will assume that the tasks being performed, in a particular context, call on the same resources.

memory 0 developer

As discussed previously, the attention, or rather the focus of attention is believed to be capacity-limited. Studies suggest that this limit is around four chunks.[296] Studies[1420] have also found that attention performance has an age-related component.

power law of learning

Power law of learning

Studies have found that nearly every task that exhibits a practice effect follows the *power law of learning*; which has the form:

$$RT = a + bN^{-c} \tag{0.21}$$

where RT is the response time; N is the number of times the task has been performed; and a, b, and c are constants. There were good theoretical reasons for expecting the equation to have an exponential form (i.e., $a + be^{-cN}$); many of the experimental results could be fitted to such an equation. However, if chunking is assumed to play a part in learning, a power law is a natural consequence (see Newell[1008] for a discussion).

16.2.4 Automatization

automatization culture of C 0

Source code contains several frequently seen patterns of usage. Experienced developers gain a lot of experience writing (or rather typing in) these constructs. As experience is gained, developers learn to type in these constructs without giving much thought to what they are doing. This process is rather like learning to write at school; children have to concentrate on learning to form letters and the combination of letters that form a word. After sufficient practice, many words only need to be briefly thought before they appear on the page without conscious effort.

The *instance theory* of automatization[864] specifies that novices begin by using an algorithm to perform a task. As they gain experience they learn specific solutions to specific problems. These solutions are retrieved

from memory when required. Given sufficient experience, the solution to all task-related problems can be obtained from memory and the algorithmic approach, to that task, is abandoned. The underlying assumptions of the theory are that encoding of problem and solution in memory is an unavoidable consequence of attention. Attending to a stimulus is sufficient to cause it to be committed to memory. The theory also assumes that retrieval of the solution from memory is an unavoidable consequence of attending to the task (this retrieval may not be successful, but it occurs anyway). Finally, each time the task is encountered (the instances) it causes encoding, storing, and retrieval, making it a learning-based theory.

Automatization (or automaticity) is an issue for coding guidelines in that many developers will have learned to use constructs whose use is recommended against. Developers' objections to having to stop using constructs that they know so well, and having to potentially invest in learning new techniques, is something that management has to deal with.

16.2.5 Cognitive switch

cognitive switch

Some cognitive processes are controlled by a kind of *executive* mechanism. The nature of this executive is poorly understood and its characteristics are only just starting to be investigated.[731] The process of comprehending source code can require switching between different tasks. Studies[959] have found that subjects responses are slower and more error prone immediately after switching tasks. The following discussion highlights the broader research results.

A study by Rogers and Monsell[1177] used the two tasks of classifying a letter as a consonant or vowel, and classifying a digit as odd or even. The subjects were split into three groups. One group was given the latter classification task, the second group the digit classification task, and the third group had to alternate (various combinations were used) between letter and digit classification. The results showed that having to alternate tasks slowed the response times by 200 to 250 ms and the error rates went up from 2% to 3% to 6.5% to 7.5%. A study by Altmann[19] found that when the new task shared many features in common with the previous task (e.g., switching from classifying numbers as odd or even, to classifying them as less than or greater than five) the memories for the related tasks interfered, causing a reduction in subject reaction time and an increase in error rate.

The studies to date have suggested the following conclusions:[406]

- When it occurs the alternation cost is of the order of a few hundred milliseconds, and greater for more complex tasks.[1187]
- When the two tasks use disjoint stimulus sets, the alternation cost is reduced to tens of milliseconds, or even zero. For instance, the tasks used by Spector and Biederman[1270] were to subtract three from Arabic numbers and name antonyms of written words.

792 antonym

- Adding a cue to each item that allows subjects to deduce which task to perform reduces the alternation cost. In the Spector and Biederman study, they suffixed numbers with "+3" or "-3" in a task that required them to add or subtract three from the number.
- An alternation cost can be found in tasks having disjoint stimulus sets when those stimulus sets occurred in another pair of tasks that had recently been performed in alternation.

These conclusions raise several questions in a source code reading context. To what extent do different tasks involve different stimulus sets and how prominent must a cue be (i.e., is the 0x on the front of a hexadecimal number sufficient to signal a change of number base)? These issues are discussed elsewhere under the C language constructs that might involve cognitive task switches.

884 character constant value
945 bitwise operators

Probably the most extreme form of cognitive switch is an external interruption. In some cases, it may be necessary for developers to perform some external action (e.g., locating a source file containing a needed definition) while reading source code. Latorella[813] discusses the impact of interruptions on the performance of flight deck personnel (in domains where poor performance in handling interruptions can have fatal consequences), and McFarlane[915] provides a human-computer interruption taxonomy.

16.2.6 Cognitive effort

cognitive effort

Why do some mental processes seem to require more mental effort than others? Why is effort an issue in mental operations? The following discussion is based on Chapter 8 of Pashler.[1060]

One argument is that mental effort requires energy, and the body's reaction to concentrated thinking is to try to conserve energy by creating a sense of effort. Studies of blood flow show that the brain accounts for 20% of heart output, and between 20% to 25% of oxygen and glucose requirements. But, does concentrated thinking require a greater amount of metabolic energy than sitting passively? The answer from PET scans of the brain appears to be no. In fact the energy consumption of the visual areas of the brain while watching television are higher than the consumption levels of those parts of the brain associated with *difficult thinking*.

Another argument is that the repeated use of neural systems produces a temporary reduction in their efficiency. A need to keep these systems in a state of readiness (fight or flight) could cause the sensation of mental effort. The results of some studies are not consistent with this repeated use argument.

The final argument, put forward by Pashler, is that *difficult thinking* puts the cognitive system into a state where it is close to failing. It is the internal recognition of a variety of signals of impending cognitive failure that could cause the feeling of mental effort.

At the time of this writing there is no generally accepted theory of the root cause of cognitive effort. It is a recognized effect and developers' reluctance to experience it is a factor in the specification some of the guideline recommendations.

What are the components of the brain that are most likely to be resource limited when performing a source code comprehension task? Source code comprehension involves many of the learning and problem solving tasks that students encounter in the class room. Studies have found a significant correlation between the working memory requirements of a problem and students' ability to solve it[1279] and teenagers academic performance in mathematics and science subjects (but not English).[474]

Most existing research has attempted to find a correlation between a subjects learning and problem solving performance and the capacity of their working memory.[259] Some experiments have measured subjects recall performance, after performing various tasks. Others have measured subjects ability to make structure the information they are given into a form that enables them to answer questions about it[534] (e.g., who met who in "The boy the girl the man saw met slept.").

cognitive load

Cognitive load might be defined as the total amount of mental activity imposed on working memory at any instant of time. The cognitive effort needed to solve a problem being the sum of all the cognitive loads experienced by the person seeking the solution.

$$Cognitive\ effort = \sum_{i=i}^{t} Cognitive\ load_i \tag{0.22}$$

Possible techniques for reducing the probability that a developers working memory capacity will be exceeded during code comprehension include:

memory 0 chunking

- organizing information into chunks that developers are likely to recognize and have stored in their long-term memory,

identifier 792 cognitive resource usage

- minimizing the amount of information that developers need to simultaneously keep in working memory during code comprehension (i.e., just in time information presentation),
- minimizing the number of relationships between the components of a problem that need to be considered (i.e., break it up into smaller chunks that can be processed independently of each other). Algorithms based on database theory and neural networks[534] have been proposed as a method of measuring the *relational complexity* of a problem.

16.2.7 Human error

The discussion in this section has been strongly influenced by *Human Error* by Reason.[1149] Models of errors made by people have been broken down, by researchers, into different categories.

developer errors

Table 0.17: Main failure modes for skill-based performance. Adapted from Reason.[1149]

Inattention	Over Attention
Double-capture slips	Omissions
Omissions following interruptions	Repetitions
Reduced intentionality	Reversals
Perceptual confusions	
Interference errors	

- *Skill*-based errors (see Table 0.17) result from some failure in the execution and/or the storage stage of an action sequence, regardless of whether the plan which guided when was adequate to achieve its objective. Those errors that occur during execution of an action are called *slips* and those that occur because of an error in memory are called *lapses*.

- *Mistakes* can be defined as deficiencies or failures in the judgmental and/or inferential processes involved in the selection of an objective or in the specification of the means to achieve it, irrespective of whether the actions directed by this decision-scheme run according to plan. *Mistakes* are further categorized into one of two kinds— *knowledge-based* mistakes (see Table 0.18) mistakes and *rule based* mistakes (see Table 0.19).

Table 0.18: Main failure modes for knowledge-based performance. Adapted from Reason.[1149]

Knowledge-based Failure Modes
Selectivity
Workspace limitations
Out of, sight out of mind
Confirmation bias
Overconfidence
Biased reviewing
Illusory correlation
Halo effects
Problems with causality
Problems with complexity
Problems with delayed feed-back
Insufficient consideration of processes in time
Difficulties with exponential developments
Thinking in causal series not causal nets (unaware of side-effects of action)
Thematic vagabonding (flitting from issue to issue)
Encysting (lingering in small detail over topics)

This categorization can be of use in selecting guideline recommendations. It provides a framework for matching the activities of developers against existing research data on error rates. For instance, developers would make skill-based errors while typing into an editor or using cut-and-paste to move code around.

Table 0.19: Main failure modes for rule-base performance. Adapted from Reason.[1149]

Misapplication of Good Rules	Application of Bad Rules
First exceptions	Encoding deficiencies
Countersigns and nosigns	Action deficiencies
Information overload	Wrong rules
Rule strength	Inelegant rules
General rules	Inadvisable rules
Redundancy	
Rigidity	

16.2.7.1 Skill-based mistakes

The consequences of possible skill-based mistakes may result in a coding guideline being created. However, by their very nature these kinds of mistakes cannot be directly recommended against. For instance, mistypings of identifier spellings leads to a guideline recommendation that identifier spellings differ in more than one significant character. A guideline recommending that identifier spellings not be mistyped being pointless.

identifier typed form 792.5

Information on instances of this kind of mistake can only come from experience. They can also depend on development environments. For instance, cut-and-paste mistakes may vary between use of line-based and GUI-based editors.

16.2.7.2 Rule-based mistakes

rule-base mistakes

Use of rules to perform a task (a rule-based performance) does not imply that if a developer has sufficient expertise within the given area that they no longer need to expend effort thinking about it (a knowledge-based performance), only that a rule has been retrieved, from the memory, and a decision made to use it (rending a knowledge-based performance).

The starting point for the creation of guideline recommendations intended to reduce the number of rule-based mistakes, made by developers is an extensive catalog of such mistakes. Your author knows of no such catalog. An indication of the effort needed to build such a catalog is provided by a study of subtraction mistakes, done by VanLehn.[1409] He studied the mistakes made by children in subtracting one number from another, and built a computer model that predicted many of the mistakes seen. The surprising fact, in the results, was the large number of diagnosed mistakes (134 distinct diagnoses, with 35 occurring more than once). That somebody can write a 250-page book on subtraction mistakes, and the model of procedural errors built to explain them, is an indication that the task is not trivial.

Holland, Holyoak, Nisbett, and Thagard[585] discuss the use of rules in solving problems by induction and the mistakes that can occur through different rule based performances.

16.2.7.3 Knowledge-based mistakes

Mistakes that occur when people are forced to use a knowledge-based performance have two basic sources: bounded rationality and an incomplete or inaccurate mental model of the problem space.

bounded rationality 0

A commonly used analogy of knowledge-based performances is that of a beam of light (working memory) that can be directed at a large canvas (the mental map of the problem). The direction of the beam is partially under the explicit control of its operator (the human conscious). There are unconscious influences pulling the beam toward certain parts of the canvas and avoiding other parts (which may, or may not, have any bearing on the solution). The contents of the canvas may be incomplete or inaccurate.

People adopt a variety of strategies, or heuristics, to overcome limitations in the cognitive resources available to them to perform a task. These heuristics appear to work well in the situations encountered in everyday human life, especially so since they are widely used by large numbers of people who can share in a common way of thinking.

Reading and writing source code is unlike everyday human experiences. Furthermore, the reasoning methods used by the non-carbon-based processor that executes software are wholly based on mathematical logic, which is only one of the many possible reasoning methods used by people (and rarely the preferred one at that).

There are several techniques for reducing the likelihood of making knowledge-based mistakes. For instance, reducing the size of the canvas that needs to be scanned and acknowledging the effects of heuristics.

940 expressions
0 availability heuristic
0 representative heuristic

16.2.7.4 Detecting errors

The modes of control for both skill-based and rule-based performances are feed-forward control, while the mode for knowledge-based performances is feed-back control. Thus, the detection of any skill-based or rule-based mistakes tends to occur as soon as they are made, while knowledge-based mistakes tend to be detected long after they have been made.

There have been studies looking at how people diagnose problems caused by knowledge-based mistakes.[522] However, these coding guidelines are intended to provide advice on how to reduce the number of mistakes, not how to detect them once they have been made. Enforcement of coding guidelines to ensure that violations are detected is a very important issue.

0 guideline recommendation enforceable

16.2.7.5 Error rates

people error rates

There have been several studies of the quantity of errors made by people performing various tasks. It is relatively easy to obtain this information for tasks that involve the creation of something visible (e.g., written material, of a file on a computer). Obtaining reliable error rates for information that is read and stored (or not) in people's memory is much harder to obtain. The following error rates may be applicable to writing source code:

792 typing mistakes

- Touch typists, who are performing purely data entry:[903] with no error correction 4% (per keystroke), typing nonsense words (per word) 7.5%.
- Typists using a line-oriented word processor:[1203] 3.40% of (word) errors were detected and corrected by the typist while typing, 0.95% were detected and corrected during proofreading by the typist, and 0.52% were not detected by the typist.
- Students performing calculator tasks and table lookup tasks: per multipart calculation, per table lookup, 1% to 2%.[925]

16.2.8 Heuristics and biases

Heuristics and Biases

In the early 1970s Amos Tversky, Daniel Kahneman, and other psychologists[705] performed studies, the results of which suggested people reason and make decisions in ways that systematically violate (mathematical based) rules of rationality. These studies covered a broad range of problems that might occur under quite ordinary circumstances. The results sparked the growth of a very influential research program often known as the *heuristics and biases* program.

There continues to be considerable debate over exactly what conclusions can be drawn from the results of these studies. Many researchers in the heuristics and biases field claim that people lack the underlying rational competence to handle a wide range of reasoning tasks, and that they exploit a collection of simple heuristics to solve problems. It is the use of these heuristics that make them prone to non-normative patterns of reasoning, or biases. This position, sometimes called the *standard picture*, claims that the appropriate norms for reasoning must be derived from mathematical logic, probability, and decision theory. An alternative to the standard Picture is proposed by evolutionary psychology. These researchers hold that logic and probability are not the norms against which human reasoning performance should be measured.

0 evolutionary psychology

When reasoning about source code the appropriate norm is provided by the definition of the programming language used (which invariably has a basis in at least first order predicate calculus). This is not to say that probability theory is not used during software development. For instance, a developer may choose to make use of information on commonly occurring cases (such usage is likely to be limited to ordering by frequency or probability; Bayesian analysis is rarely seen).

What do the results of the heuristics and biases research have to do with software development, and do they apply to the kind of people who work in this field? The subjects used in these studies were not, at the time of the studies, software developers. Would the same results have been obtained if software developers

developer 0 mental characteristics

had been used as subjects? This question implies that developers' cognitive processes, either through training or inherent abilities, are different from those of the subjects used in these studies. The extent to which developers are susceptible to the biases, or use the heuristics, found in these studies is unknown. Your author assumes that they are guilty until proven innocent.

Another purpose for describing these studies is to help the reader get past the idea that people exclusively apply mathematical logic and probability in problem solving.

16.2.8.1 Reasoning

developer reasoning

Comprehending source code involves performing a significant amount of reasoning over a long period of time. People generally consider themselves to be good at reasoning. However, anybody who has ever written a program knows how many errors are made. These errors are often claimed, by the author, to be caused by any one of any number of factors, except poor reasoning ability. In practice people are good at certain kinds of reasoning problems (the kind seen in everyday life) and very poor at others (the kind that occur in mathematical logic).

The basic mechanisms used by the human brain, for reasoning, have still not been sorted out and are an area of very active research. There are those who claim that the mind is some kind of general-purpose processor, while others claim that there are specialized units designed to carry out specific kinds of tasks (such as solving specific kinds of reasoning problems). Without a general-purpose model of human reasoning, there is no more to be said in this section. Specific constructs involving specific reasoning tasks are discussed in the relevant sentences.

selection statement 1739 syntax
logical-AND-expression 1248 syntax
logical-OR-expression 1256 syntax

16.2.8.2 Rationality

developer rationality

Many of those who study software developer behavior (there is no generic name for such people) have a belief in common with many economists. Namely, that their subjects act in a rational manner, reaching decisions for well-articulated goals using mathematical logic and probability, and making use of all the necessary information. They consider decision making that is not based on these norms as being *irrational*.

bounded rationality

Deciding which decisions are the rational ones to make requires a norm to compare against. Many early researchers assumed that mathematical logic and probability were the norm against which human decisions should be measured. The term *bounded rationality*[1240] is used to describe an approach to problem solving performed when limited cognitive resources are available to process the available information. A growing number of studies[489] are finding that the methods used by people to make decisions and solve problems are often optimal, given the resources available to them. A good discussion of the issues, from a psychology perspective, is provided by Samuels, Stich and Faucher.[1195]

For some time a few economists have been arguing that people do not behave according to mathematical norms, even when making decisions that will affect their financial well-being.[914] Evidence for this heresy has been growing. If people deal with money matters in this fashion, how can their approach to software development fare any better? Your author takes the position, in selecting some of the guideline recommendations in this book, that developers' cognitive processes when reading and writing source are no different than at other times.

When reading and writing source code written in the C language, the rationality norm is defined in terms of the output from the C abstract machine. Some of these guideline recommendations are intended to help ensure that developers' comprehension of source agrees with this norm.

16.2.8.3 Risk asymmetry

risk asymmetry

The term *risk asymmetry* refers to the fact that people are *risk averse* when deciding between alternatives that have a positive outcome, but are *risk seeking* when deciding between alternatives that have a negative outcome.

Making a decision using uncertain information involves an element of risk; the decision may not be the correct one. How do people handle risk?

Kahneman and Tversky[709] performed a study in which subjects were asked to make choices about gaining or losing money. The theory they created, *prospect theory*, differed from the accepted theory of the day,

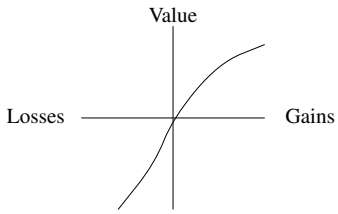

Figure 0.30: Relationship between subjective value to gains and to losses. Adapted from Kahneman.[709]

expected utility theory (which still has followers). Subjects were presented with the following problems:

> Problem 1: In addition to whatever you own, you have been given 1,000. You are now asked to choose between:
> A: Being given a further 1,000, with probability 0.5
> B: Being given a further 500, unconditionally
> Problem 2: In addition to whatever you own, you have been given 2,000. You are now asked to choose between:
> C: Loosing 1,000, with probability 0.5
> D: Loosing 500, unconditionally

The majority of the subjects chose B (84%) in the first problem, and C (69%) in the second. These results, and many others like them, show that people are risk averse for positive prospects and risk seeking for negative ones (see Figure 0.30).

In the following problem the rational answer, based on knowledge of probability, is E; however, 80% of subjects chose F.

> Problem 3: You are asked to choose between:
> E: Being given 4,000, with probability 0.8
> F: Being given 3,000, unconditionally

Kahneman and Tversky also showed that people's subjective probabilities did not match the objective probabilities. Subjects were given the following problems:

> Problem 4: You are asked to choose between:
> G: Being given 5,000, with probability 0.001
> H: Being given 5, unconditionally
> Problem 5: You are asked to choose between:
> I: Loosing 5,000, with probability 0.001
> J: Loosing 5, unconditionally

Most the subjects chose G (72%) in the first problem and J (83%) in the second.

Problem 4 could be viewed as a lottery ticket (willing to forego a small amount of money for the chance of wining a large amount), while Problem 5 could be viewed as an insurance premium (willingness to pay a small amount of money to avoid the possibility of having to pay out a large amount).

The decision weight given to low probabilities tends to be higher than that warranted by the evidence. The decision weight given to other probabilities tends to be lower than that warranted by the evidence (see Figure 0.31).

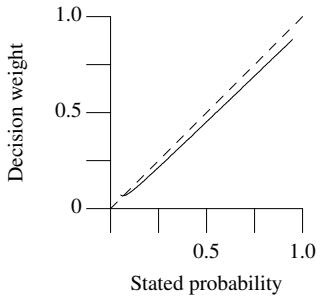

Figure 0.31: Possible relationship between subjective and objective probability. Adapted from Kahneman.[709]

16.2.8.4 Framing effects

framing effect

The framing effect occurs when alternative framings of what is essentially the same decision task cause predictably different choices.

Kahneman and Tversky[708] performed a study in which subjects were asked one of the following question:

> Imagine that the U.S. is preparing for the outbreak of an unusual Asian disease, which is expected to kill 600 people. Two alternative programs to combat the disease have been proposed. Assume that the exact scientific estimates of the consequences of the programs are as follows:
>
> If Program A is adopted, 200 people will be saved.
>
> If Program B is adopted, there is a one-third probability that 600 people will be saved and a two thirds probability that no people will be saved.
>
> Which of the two programs would you favor?

This problem is framed in terms of 600 people dying, with the option being between two programs that save lives. In this case subjects are risk averse with a clear majority, 72%, selecting Program A. For the second problem the same cover story was used, but subjects were asked to select between differently worded programs:

> If Program C is adopted, 400 people will die.
>
> If Program D is adopted, there is a one-third probability that nobody will die and two-thirds probability that 600 people will die.

In terms of their consequences Programs A and B are mathematically the same as C and D, respectively. However, this problem is framed in terms of no one dying. The best outcome would be to maintain this state of affairs. Rather than accept an unconditional loss, subjects become risk seeking with a clear majority, 78%, selecting Program D.

Even when subjects were asked both questions, separated by a few minutes, the same reversals in preference were seen. These results have been duplicated in subsequent studies by other researchers.

16.2.8.5 Context effects

context effects

The standard analysis of the decision's people make assumes that they are procedure-invariant; that is, assessing the attributes presented by different alternatives should always lead to the same one being selected. Assume, for instance, that in a decision task, a person chooses alternative X, over alternative Y. Any previous decisions they had made between alternatives similar to X and Y would not be thought to affect later decisions. Similarly, the addition of a new alternative to the list of available alternatives should not cause Y to be selected, over X.

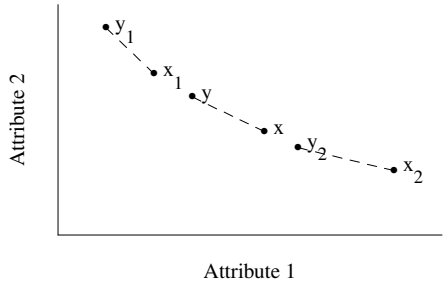

Figure 0.32: Text of background trade-off. Adapted from Tversky.[1377]

People will show procedure-invariance if they have well-defined values and strong beliefs. In these cases the appropriate values might be retrieved from a master list of preferences held in a person's memory. If preferences are computed using some internal algorithm, each time a person has to make a decision, then it becomes possible for context to have an affect on the outcome.

Context effects have been found to occur because of the prior history of subjects answering similar questions, background context, or because of presentation of the problem itself, local context. The following two examples are taken from a study by Tversky and Simonson.[1377]

To show that prior history plays a part in a subjects judgment, Tversky and Simonson split a group of subjects in two. The first group was asked to decide between the alternatives X_1 and Y_1, while the second group was asked to select between the options X_2 and Y_2. Following this initial choice all subjects were asked to chose between X and Y.

Table 0.20: Percentage of each alternative selected by subject groups S_1 and S_2. Adapted from Tversky.[1377]

Warranty	Price	S_1	S_2
X_1	\$85	12%	
Y_1	\$91	88%	
X_2	\$25		84%
Y_2	\$49		16%
X	\$60	57%	33%
Y	\$75	43%	67%

Subjects previously exposed to a decision where a small difference in price (see Table 0.20) (\$85 vs. \$91) was associated with a large difference in warranty (55,000 miles vs. 75,000 miles), were more likely to select the less-expensive tire from the target set (than those exposed to the other background choice, where a large difference in price was associated with a small difference in warranty).

In a study by Simonson and Tversky,[1243] subjects were asked to decide between two microwave ovens. Both were on sale at 35% off the regular price, at sale prices of \$109.99 and \$179.99. In this case 43% of the subjects selected the more expensive model. For the second group of subjects, a third microwave oven was added to the selection list. This third oven was priced at \$199.99, 10% off its regular price. The \$199.99 microwave appeared inferior to the \$179.99 microwave (it had been discounted down from a lower regular price by a smaller amount), but was clearly superior to the \$109.99 model. In this case 60% selected the \$179.99 microwave (13% chose the more expensive microwave). The presence of a third alternative had caused a significant number of subjects to switch the model selected.

16.2.8.6 Endowment effect

Studies have shown that losses are valued far more than gains. This asymmetry in the value assigned, by people, to goods can be seen in the endowment effect. A study performed Knetsch[749] illustrates this effect.

endowment effect
0 risk asymmetry

Subjects were divided into three groups. The first group of was given a coffee mug, the second group

was given a candy bar, and the third group was given nothing. All subjects were then asked to complete a questionnaire. Once the questionnaires had been completed, the first group was told that they could exchange their mugs for a candy bar, the second group that they could exchange their candy bar for a mug, while the third group was told they could decide between a mug or a candy bar. The mug and the candy bar were sold in the university bookstore at similar prices.

Table 0.21: Percentage of subjects willing to exchange what they had been given for an equivalently priced item. Adapted from Knetsch.[749]

Group	Yes	No
Give up mug to obtain candy	89%	11%
Give up candy to obtain mug	90%	10%

The decisions made by the third group, who had not been given anything before answering the questionnaire, were: mug 56%, candy 44%. This result showed that the perceived values of the mug and candy bar were close to each other.

The decisions made by the first and second groups (see Table 0.21) showed that they placed a higher value on a good they owned than one they did not own (but could obtain via a simple exchange).

The endowment effect has been duplicated in many other studies. In some studies, subjects required significantly more to sell a good they owned than they would pay to purchase it.

16.2.8.7 Representative heuristic

representative heuristic

The representative heuristic evaluates the probability of an uncertain event, or sample, by the degree to which it

- is similar in its essential attributes to the population from which it is drawn, and
- reflects the salient attributes of the process that generates it

given two events, X and Y. The event X is judged to be more probable than Y when it is more representative. The term *subjective probability* is sometimes used to describe these probabilities. They are subjective in the sense that they are created by the people making the decision. *Objective probability* is the term used to describe the values calculated from the stated assumptions, according to the axioms of mathematical probability.

base rate neglect

Selecting alternatives based on the representativeness of only some of their attributes can lead to significant information being ignored; in particular the nonuse of base-rate information provided as part of the specification of a problem.

Treating representativeness as an operator, it is a (usually) directional relationship between a family, or process M, and some instance or event X, associated with M. It can be defined for (1) a value and a distribution, (2) an instance and a category, (3) a sample and a population, or (4) an effect and a cause. These four basic cases of representativeness occur when (Tversky[1375]):

1. M is a family and X is a value of a variable defined in this family. For instance, the representative value of the number of lines of code in a function. The most representative value might be the mean for all the functions in a program, or all the functions written by one author.
2. M is a family and X is an instance of that family. For instance, the number of lines of code in the function *foo_bar*. It is possible for an instance to be a family. The *Robin* is an instance of the bird family and a particular individual can be an instance of the Robin family.
3. M is a family and X is a subset of M. Most people would agree that the population of New York City is less representative of the US than the population of Illinois. The criteria for representativeness in

a subset is not the same as for one instance. A single instance can represent the primary attributes of a family. A subset has its own range and variability. If the variability of the subset is small, it might be regarded as a category of the family, not a subset. For instance, the selected subset of the family birds might only include Robins. In this case, the set of members is unlikely to be regarded as a representative subset of the bird family.

4. M is a (causal) system and X is a (possible) instance generated by it. Here M is no longer a family of objects, it is a system for generating instances. An example would be the mechanism of tossing coins to generate instances of heads and tails.

16.2.8.7.1 Belief in the law of small numbers

law of small numbers

Studies have shown that people have a strong belief in what is known as the law of small numbers. This "law" might be stated as: "Any short sequence of events derived from a random process shall have the same statistical properties as that random process." For instance, if a fairly balanced coin is tossed an infinite number of times the percentage of heads seen will equal the percentage of tails seen. However, according to the law of small numbers, any short sequence of coin tosses will also have this property. Statistically this is not true, the sequences *HHHHHHHHHH* and *THHTHTTHTH* are equally probable, but one of them does not appear to be representative of a random sequence.

Readers might like to try the following problem.

> The mean IQ of the population of eighth graders in a city is *known* to be 100. You have selected a random sample of 50 children for a study of educational achievement. The first child tested has an IQ of 150.
>
> What do you expect the mean IQ to be for the whole sample?

Did you believe that because the sample of 50 children was randomly chosen from a large population, with a known property, that it would also have this property?; that is, the answer would be 100? The effect of a child with a high IQ being canceled out by a child with a very low IQ? The correct answer is 101; the known information, from which the mean should be calculated, is that we have 49 children with an estimated average of 100 and one child with a known IQ of 150.

16.2.8.7.2 Subjective probability

subjective probability

In a study by Kahneman and Tversky,[707] subjects were divided into two groups. Subjects in one group were asked the *more than* question, and those in the other group the *less than* question.

> An investigator studying some properties of a language selected a paperback and computed the average word-length in every page of the book (i.e., the number of letters in that page divided by the number of words). Another investigator took the first line in each page and computed the line's average word-length. The average word-length in the entire book is four. However, not every line or page has exactly that average. Some may have a higher average word-length, some lower.
>
> The first investigator counted the number of pages that had an average word-length of 6 or (more/less) and the second investigator counted the number of lines that had an average word-length of 6 or (more/less). Which investigator do you think recorded a larger number of such units (pages for one, lines for the other)?

Table 0.22: Percentage of subjects giving each answer. Correct answers are starred. Adapted from Kahneman.[707]

Choice	Less than 6	More than 6
The page investigator	20.8%*	16.3%
The line investigator	31.3%	42.9%*
About the same (i.e., within 5% of each other)	47.9%	40.8%

The results (see Table 0.22) showed that subjects judged equally representative outcomes to be equally likely, the size of the sample appearing to be ignored.

When dealing with samples, those containing the smaller number of members are likely to exhibit the largest variation. In the preceding case, the page investigator is using the largest sample size and is more likely to be closer to the average (4), which is less than 6. The line investigator is using a smaller sample of the book's contents and is likely to see a larger variation in measured word length (more than 6 is the correct answer here).

16.2.8.8 Anchoring

Anchoring

Answers to questions can be influenced by completely unrelated information. This was dramatically illustrated in a study performed by Tversky and Kahneman.[1374] They asked subjects to estimate the percentage of African countries in the United Nations. But, before stating their estimate, subjects were first shown an arbitrary number, which was determined by spinning a *wheel of fortune* in their presence. In some cases, for instance, the number 65 was selected, at other times the number 10. Once a number had been determined by the *wheel of fortune* subjects were asked to state whether the percentage of African countries in the UN was higher or lower than this number, and their estimate of the percentage. The median estimates were 45% of African countries for subjects whose *anchoring* number was 65, and 25% for subjects whose *anchoring* number was 10.

The implication of these results is that people's estimates can be substantially affected by a numerical *anchoring* value, even when they are aware that the anchoring number has been randomly generated.

16.2.8.9 Belief maintenance

belief maintenance

Belief comes in various forms. There is *disbelief* (believing a statement to be false), *nonbelief* (not believing a statement to be true), *half-belief*, *quarter-belief*, and so on (the degrees of belief range from barely accepting a statement, to having complete conviction a statement is true). Knowledge could be defined as belief plus complete conviction and conclusive justification.

The following are two approaches as to how beliefs might be managed.

1. The *foundation approach* argues that beliefs are derived from reasons for these beliefs. A belief is justified if and only if (1) the belief is self-evident and (2) the belief can be derived from the set of other justified beliefs (circularity is not allowed).

2. The *coherence approach* argues that where beliefs originated is of no concern. Instead, beliefs must be logically coherent with other beliefs (believed by an individual). These beliefs can mutually justify each other and circularity is allowed. A number of different types of coherence have been proposed, Including *deductive coherence* (requires a logically consistent set of beliefs), *probabilistic coherence* (assigns probabilities to beliefs and applies the requirements of mathematical probability to them), *semantic coherence* (based on beliefs that have similar meanings), and *explanatory coherence* (requires that there be a consistent explanatory relationship between beliefs).

The *foundation approach* is very costly (in cognitive effort) to operate. For instance, the reasons for beliefs need to be remembered and applied when considering new beliefs. Studies[1181] show that people exhibit a belief preservation effect; they continue to hold beliefs after the original basis for those beliefs no longer

holds. The evidence suggests that people use some form of *coherence approach* for creating and maintaining their beliefs.

There are two different ways doubt about a fact can occur. When the truth of a statement is not known because of a lack of information, but the behavior in the long run is known, we have *uncertainty*. For instance, the outcome of the tossing of a coin is uncertain, but in the long run the result is known to be heads (or tails) 50% of the time. The case in which truth of a statement can never be precisely specified (indeterminacy of the average behavior) is known as *imprecision*; for instance, "it will be sunny tomorrow". It is possible for a statement to contain both uncertainty and imprecision. For instance, the statement, "It is likely that John is a young fellow", is uncertain (John may not be a *young fellow*) and imprecise (*young* does not specify an exact age). For a mathematical formulation, see Paskin.[1061]

Coding guidelines need to take into account that developers are unlikely to make wholesale modifications to their existing beliefs to make them consistent with any guidelines they are expected to adhere to. Learning about guidelines is a two-way process. What a developer already knows will influence how the guideline recommendations themselves will be processed, and the beliefs formed about their meaning. These beliefs will then be added to the developer's existing personal beliefs.[1472]

16.2.8.9.1 The Belief-Adjustment model

A belief may be based on a single piece of evidence, or it may be based on many pieces of evidence. How is an existing belief modified by the introduction of new evidence? The belief-adjustment model of Hogarth and Einhorn[581] offers an answer to this question. This subsection is based on that paper. The basic equation for this model is:

$$S_k = S_{k-1} + w_k[s(x_k) - R] \tag{0.23}$$

where: S_k is the degree of belief (a value between 0 and 1) in some hypothesis, impression, or attitude after evaluating k items of evidence; S_{k-1} is the anchor, or prior opinion ($S_0 i$ denotes the initial belief). $s(x_k)$ is the subjective evaluation of the kth item of evidence (different people may assign different values for the same evidence, x_k); R is the reference point, or background, against which the impact of the kth item of evidence is evaluated. w_k is the adjustment weight (a value between zero and one) for the kth item of evidence.

The encoding process

When presented with a statement, people can process the evidence it contains in several ways. They can use an *evaluation* process or an *estimation* process.

The *evaluation* process encodes new evidence relative to a fixed point— the hypothesis addressed by a belief. If the new evidence supports the hypothesis, a person's belief is increased, but that belief is decreased if it does not support the hypothesis. This increase, or decrease, occurs irrespective of the current state of a person's belief. For this case $R = 0$, and the belief-adjustment equation simplifies to:

$$S_k = S_{k-1} + w_k s(x_k) \tag{0.24}$$

where: $-1 \leq s(x_k) \leq 1$

An example of an evaluation process might be the belief that the object `X` always holds a value that is numerically greater than `Y`.

The *estimation* process encodes new evidence relative to the current state of a person's beliefs. For this case $R = S_{k-1}$, and the belief-adjustment equation simplifies to:

$$S_k = S_{k-1} + w_k(s(x_k) - S_{k-1}) \tag{0.25}$$

where: $0 \leq s(x_k) \leq 1$

In this case the degree of belief, in a hypothesis, can be thought of as a moving average. For an estimation process, the order in which evidence is presented can be significant. While reading source code written by somebody else, a developer will form an opinion of the quality of that person's work. The judgment of each code sequence will be based on the readers current opinion (at the time of reading) of the person who wrote it.

Processing

It is possible to consider $s(x_k)$ as representing either the impact of a single piece of evidence (so-called *Step-by-Step*, SbS), or the impact of several pieces of evidence (so-called *End-of-Sequence*, EoS).

$$S_k = S_0 + w_k[s(x_1, \ldots, x_k) - R] \tag{0.26}$$

where $s(x_1, \ldots, x_k)$ is some function, perhaps a weighted average, of the individual subjective evaluations.

If a person is required to give a Step-by-Step response when presented with a sequence of evidence, they obviously have to process the evidence in this mode. A person who only needs to give an End-of-Sequence response can process the evidence using either SbS or EoS. The process used is likely to depend on the nature of the problem. Aggregating, using EoS, evidence from a long sequence of items of evidence, or a sequence of complex evidence, is likely to require a large amount of cognitive processing, perhaps more than is available to an individual. Breaking a task down into smaller chunks by using an SbS process, enables it to be handled by a processor having a limited cognitive capacity. Hogarth and Einhorn proposed that when people are required to provide an EoS response they use an EoS process when the sequence of items is short and simple. As the sequence gets longer, or more complex, they shift to an SbS process, to keep the peak cognitive load (of processing the evidence) within their capabilities.

Adjustment weight

The adjustment weight, w_k, will depend on the sign of the impact of the evidence, $[s(x_k) - R]$, and the current level of belief, S_k. Hogarth and Einhorn argue that when $s(x_k) \leq R$:

$$w_k = \alpha S_{k-1} \tag{0.27}$$
$$S_k = S_{k-1} + \alpha S_{k-1} s(x_k) \tag{0.28}$$

and that when $s(x_k) > R$:

$$w_k = \beta(1 - S_{k-1}) \tag{0.29}$$
$$S_k = S_{k-1} + \beta(1 - S_{k-1}) s(x_k) \tag{0.30}$$

where α and β ($0 \leq \alpha, \beta \leq 1$) represent sensitivity toward positive and negative evidence. Small values indicating low sensitivity to new evidence and large values indicating high sensitivity. The values of α and β will also vary between people. For instance, some people have a tendency to give negative evidence greater weight than positive evidence. People having strong attachments to a particular point of view may not give evidence that contradicts this view any weight.[1339]

Order effects

It can be shown[581] that use of an SbS process when $R = S_{k-1}$ leads to a recency effect. When $R = 0$, a recency effect only occurs when there is a mixture of positive and negative evidence (there is no recency effect if the evidence is all positive or all negative).

The use of an EoS process leads to a primacy effect; however, a task may not require a response until all the evidence is seen. If the evidence is complex, or there is a lot of it, people may adopt an SbS process. In this case, the effect seen will match that of an SbS process.

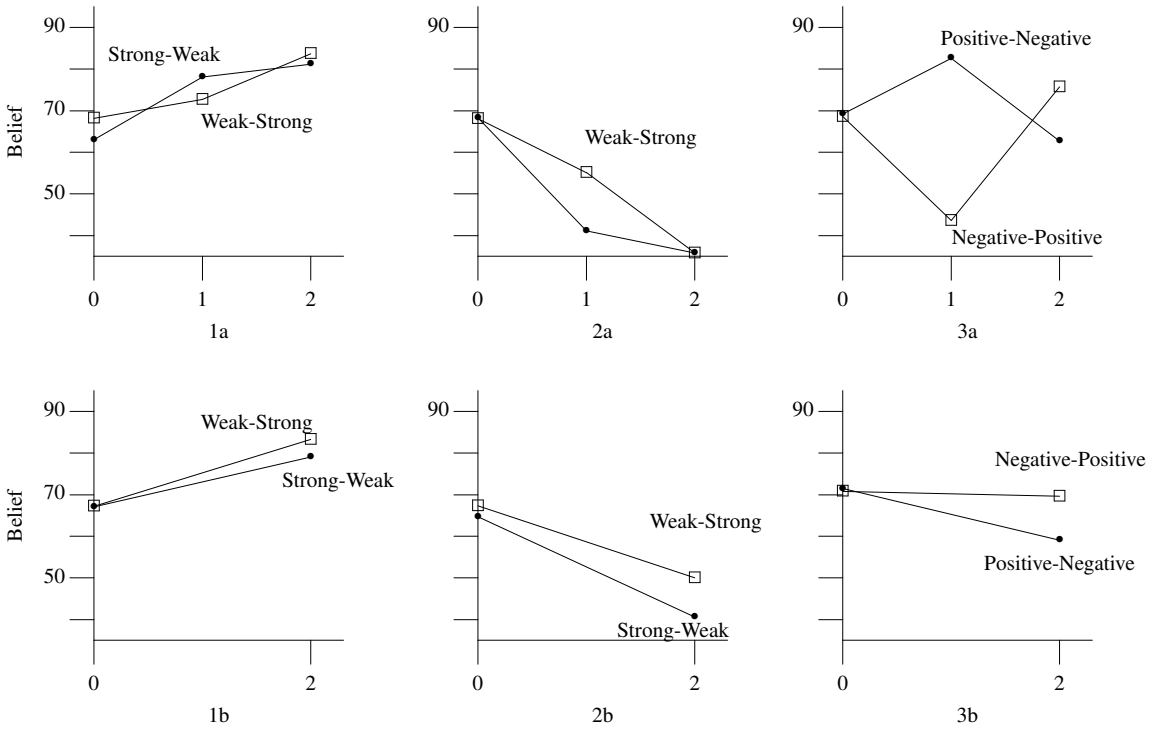

Figure 0.33: Subjects belief response curves for positive weak–strong, negative weak–strong, and positive–negative evidence; (a) Step-by-Step, (b) End-of-Sequence. Adapted from Hogarth.[581]

A *recency effect* occurs when the most recent evidence is given greater weight than earlier evidence. A *primacy effect* occurs when the initial evidence is given greater weight than later evidence.

recency effect
primacy effect

Study

A study by Hogarth and Einhorn[581] investigated order, and response mode, effects in belief updating. Subjects were presented with a variety of scenarios (e.g., a defective stereo speaker thought to have a bad connection, a baseball player whose hitting has improved dramatically after a new coaching program, an increase in sales of a supermarket product following an advertising campaign, the contracting of lung cancer by a worker in a chemical factory). Subjects read an initial description followed by two or more additional items of evidence. The additional evidence might be positive (e.g., "The other players on Sandy's team did not show an unusual increase in their batting average over the last five weeks") or negative (e.g., "The games in which Sandy showed his improvement were played against the last-place team in the league"). This positive and negative evidence was worded to create either strong or weak forms.

The evidence was presented in a variety of orders (positive or negative, weak or strong). Subjects were asked, "Now, how likely do you think X caused Y on a scale of 0 to 100?" In some cases, subjects had to respond after seeing each item of evidence: in other cases, subjects had to respond after seeing all the items.

The results (see Figure 0.33) only show a recency effect when the evidence is mixed, as predicted for the case $R = 0$.

Other studies have duplicated these results. For instance, professional auditors have been shown to display recency effects in their evaluation of the veracity of company accounts.[1062, 1368]

16.2.8.9.2 Effects of beliefs

The persistence of beliefs after the information they are based on has been discredited is an important issue in developer training.

Studies of physics undergraduates[911] found that many hours of teaching only had a small effect on their

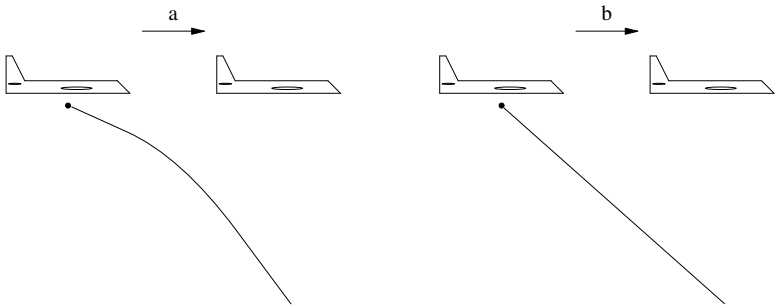

Figure 0.34: Two proposed trajectories of a ball dropped from a moving airplane. Based on McCloskey.[911]

qualitative understanding of the concepts taught. For instance, predicting the motion of a ball dropped from an airplane (see Figure 0.34). Many students predicted that the ball would take the path shown on the right (*b*). They failed to apply what they had been taught over the years to pick the path on the left (*a*).

A study by Ploetzner and VanLehn[1095] investigated subjects who were able to correctly answer these conceptual problems. They found that the students were able to learn and apply information that was implicit in the material taught. Ploetzner and VanLehn also built a knowledge base of 39 rules needed to solve the presented problems, and 85 rules needed to generate the incorrect answers seen in an earlier study.

A study by Pazzani[1066] showed how beliefs can increase, or decrease, the amount of effort needed to deduce a concept. Two groups of subjects were shown pictures of people doing something with a balloon. The balloons varied in color (yellow or purple) and size (small or large), and the people (adults or five-year-old children) were performing some operation (stretching balloons or dipping them in water). The first group of subjects had to predict whether the picture was an "example of an *alpha*", while the second group had to "predict whether the balloon will be inflated". The picture was then turned over and subjects saw the answer. The set of pictures was the same for both groups of subjects.

The conditions under which the picture was an *alpha* or *inflate* were the same, a conjunctive condition `(age == adult) || (action == stretching)` and a disjunction condition `(size == small) && (color == yellow)`.

The difference between these two tasks to predict is that the first group had no prior beliefs about *alpha* situations, while it was assumed the second group had background knowledge on inflating balloons. For instance, balloons are more likely to inflate after they have been stretched, or an adult is doing the blowing rather than a child.

conditionals 1256
conjunctive/disjunctive

The other important point to note is that people usually require more effort to learn conjunctive conditions than they do to learn disjunctive conditions.

The results (see Figure 0.35) show that, for the *inflate* concept, subjects were able to make use of their existing beliefs to improve performance on the disjunctive condition, but these beliefs caused a decrease in performance on the conjunctive condition (being small and yellow is not associated with balloons being difficult to inflate).

A study by Gilbert, Tafarodi, and Malone[490] investigated whether people could comprehend an assertion without first believing it. The results suggested that their subjects always believed an assertion presented to them, and that only once they had comprehended it were they in a position to, possibly, *unbelieve* it. The experimental setup used, involved presenting subjects with an assertion and interrupting them before they had time to *unbelieve* it. This finding has implications for program comprehension in that developers sometimes only glance at code. Ensuring that what they see does not subsequently need to be *unbelieved*, or is a partial statement that will be read the wrong way without other information being provided, can help prevent people from acquiring incorrect beliefs. The commonly heard teaching maxim of "always use correct examples, not incorrect ones" is an application of this finding.

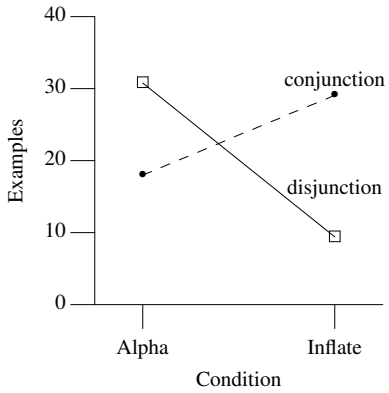

Figure 0.35: Number of examples needed before *alpha* or *inflate* condition correctly predicted in six successive pictures. Adapted from Pazzani[1066]

16.2.8.10 Confirmation bias

There are two slightly different definitions of the term *confirmation bias* used by psychologists, they are: confirmation bias

1. A person exhibits confirmation bias if they tend to interpret ambiguous evidence as (incorrectly) confirming their current beliefs about the world. For instance, developers interpreting program behavior as supporting their theory of how it operates, or using the faults exhibited by a program to conform their view that it was poorly written.
2. When asked to discover a rule that underlines some pattern (e.g., the numeric sequence 2–4–6), people nearly always apply test cases that will confirm their hypothesis. They rarely apply test cases that will falsify their hypothesis.

Rabin and Schrag[1134] built a model showing that confirmation bias leads to overconfidence (people believing in some statement, on average, more strongly than they should). Their model assumes that when a person receives evidence that is counter to their current belief, there is a positive probability that the evidence is misinterpreted as supporting this belief. They also assume that people always correctly recognize evidence that confirms their current belief. Compared to the correct statistical method, Bayesian updating, this behavior is biased toward confirming the initial belief. Rabin and Schrag showed that, in some cases, even an infinite amount of evidence would not necessarily overcome the effects of confirmatory bias; over time a person may conclude, with near certainty, that an incorrect belief is true. 0 overconfidence

The second usage of the term *confirmation bias* applies to a study performed by Wason,[1444] which became known as the *2–4–6 Task*. In this study subjects were asked to discover a rule known to the experimenter. They were given the initial hint that the sequence 2–4–6 was an instance of this rule. Subjects had to write down sequences of numbers and show them to the experimenter who would state whether they did, or did not, conform to the rule. When they believed they knew what the rule was, subjects had to write it down and declare it to the experimenter. For instance, if they wrote down the sequences 6–8–10 and 3–5–7, and were told that these conformed to the rule, they might declare that the rule was *numbers increasing by two*. However, this was not the experimenters rule, and they had to continue generating sequences. Wason found that subjects tended to generate test cases that confirmed their hypothesis of what the rule was. Few subjects generated test cases in an attempt to disconfirm the hypothesis they had. Several subjects had a tendency to declare rules that were mathematically equivalent variations on rules they had already declared.

8 10 12: two added each time; **14 16 18:** even numbers in order of magnitude; **20 22 24:** same reason; **1 3 5:** two added to preceding number.
The rule is that by starting with any number two is added each

time to form the next number.
2 6 10: middle number is the arithmetic mean of the other two;
1 50 99: same reason.
The rule is that the middle number is the arithmetic mean of the other two.
3 10 17: same number, seven, added each time; **0 3 6**;
three added each time.
The rule is that the difference between two numbers next to each other is the same.
12 8 4: the same number subtracted each time to form the next number.
The rule is adding a number, always the same one to form the next number.
1 4 9: any three numbers in order of magnitude.
The rule is any three numbers in order of magnitude.
Sample 2-4-6 subject protocol. Adapted from Wason.[1444]

The actual rule used by the experimenter was "three numbers in increasing order of magnitude".

These findings have been duplicated in other studies. In a study by Mynatt, Doherty, and Tweney,[989] subjects were divided into three groups. The subjects in one group were instructed to use a confirmatory strategy, another group to use a disconfirmatory strategy, and a control group was not told to use any strategy. Subjects had to deduce the physical characteristics of a system, composed of circles and triangles, by firing particles at it (the particles, circles and triangles, appeared on a computer screen). The subjects were initially told that "triangles deflect particles". In 71% of cases subjects selected confirmation strategies. The instructions on which strategy to use did not have any significant effect.

In a critique of the interpretation commonly given for the results from the 2–4–6 Task, Klayman and Ha[745] pointed out that it had a particular characteristic. The hypothesis that subjects commonly generate (*numbers increasing by two*) from the initial hint is completely contained within the experimenters rule, case 2 in Figure 0.36. Had the experimenters rule been *even numbers increasing by two*, the situation would have been that of case 3 in Figure 0.36.

Given the five possible relationships between hypothesis and rule, Klayman and Hu analyzed the possible strategies in an attempt to find one that was optimal for all cases. They found that the optimal strategy was a function of a variety of task variables, such as the base rates of the target phenomenon and the hypothesized conditions. They also proposed that people do not exhibit confirmation bias, rather people have a general all-purpose heuristic, the *positive test strategy*, which is applied across a broad range of hypothesis-testing tasks.

A *positive test strategy* tests a hypothesis by examining instances in which the property or event is expected to occur to see if it does occur. The analysis by Klayman and Hu showed that this strategy performs well in real-world problems. When the target phenomenon is relatively rare, it is better to test where it occurs (or where it was known to occur in the past) rather than where it is not likely to occur.

A study by Mynatt, Doherty, and Dragan[988] suggested that capacity limitations of working memory were also an issue. Subjects did not have the capacity to hold information on more than two alternatives in working memory at the same time. The results of their study also highlighted the fact that subjects process the alternatives in *action* (what to do) problems differently than in *inference* (what is) problems.

Karl Popper[1104] pointed out that scientific theories could never be shown to be logically true by generalizing from confirming instances. It was the job of scientists to try to perform experiments that attempted to falsify a theory. Popper's work on how a hypothesis should be validated has become the generally accepted way of measuring performance (even if many scientists don't appear to use this approach).

The fact that people don't follow the hypothesis-testing strategy recommended by Popper is seen, by some, as a deficiency in peoples thinking processes. The theoretical work by Klayman and Hu shows that it might

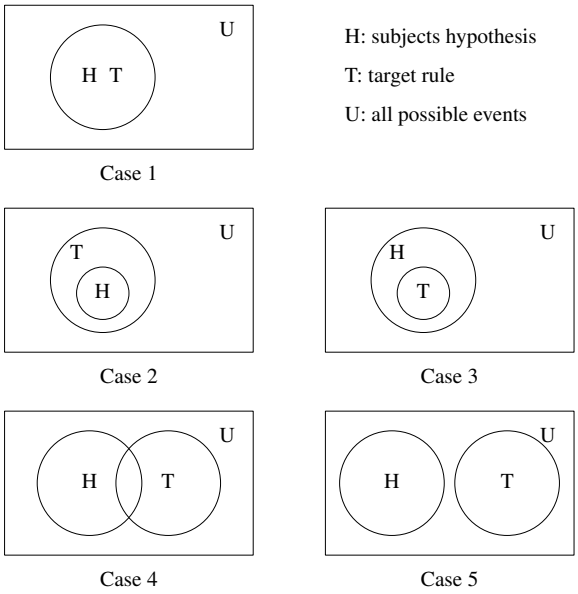

Figure 0.36: Possible relationships between hypothesis and rule. Adapted from Klayman.[745]

be Poppers theories that are deficient. There is also empirical evidence showing that using disconfirmation does not necessarily improve performance on a deduction task. A study by Tweney, Doherty, Worner, Pliske, Mynatt, Gross, and Arkkelin[1378] showed that subjects could be trained to use a disconfirmation strategy when solving the 2–4–6 Task. However, the results showed that using this approach did not improve performance (over those subjects using a confirmation strategy).

Do developers show a preference toward using positive test strategies during program comprehension? What test strategy is the best approach during program comprehension? The only experimental work that has addressed this issue used students in various stages of their academic study. A study by Teasley, Leventhal, Mynatt, and Rohlman[1334] asked student subjects to test a program (based on its specification). The results showed that the more experienced subjects created a greater number of negative tests.

16.2.8.11 Age-related reasoning ability

reasoning ability age-related

It might be thought that reasoning ability declines with age, along with the other faculties. A study by Tentori, Osherson, Hasher, and May[1336] showed the opposite effect; some kinds of reasoning ability improving with age.

Consider the case of a person who has to decide between two alternatives, A and B (e.g., vanilla and strawberry ice cream), and chooses A. Adding a third alternative, C (e.g., chocolate ice cream) might entice that person to select C. A mathematical analysis shows that adding alternative C would not cause a change of preference to B. How could adding the alternative chocolate ice cream possibly cause a person who previously selected vanilla to now choose strawberry?

So-called *irregular choices* have been demonstrated in several studies. Such irregular choices seem to occur among younger (18–25) subjects, older (60–75) subjects tending to be uninfluenced by the addition of a third alternative.

16.3 Personality

developer personality

To what extent does personality affect developers' performance, and do any personality differences need to be reflected in coding guidelines?

- A study by Turley and Bieman[1370] looked for differences in the competencies of exceptional and non-exceptional developers. They found the personal attributes that differentiated performances were:

desire to contribute, perseverance, maintenance of a *big picture* view, desire to do/bias for action, driven by a sense of mission, exhibition and articulation of strong convictions, and proactive role with management. Interesting findings in another context, but of no obvious relevance to these coding guidelines. Turley and Bieman also performed a Myers-Briggs Type Indicator (MBTI) test[987] on their subjects. The classification containing the most developers (7 out of 20) was INTJ (*Introvert*, *Intuitive*, *Thinking*, *Judging*), a type that occurs in only 10% of male college graduates. In 15 out of 20 cases, the type included *Introvert, Thinking*. There was no significance in scores between exceptional and nonexceptional performers. These findings are too broad to be of any obvious relevance to coding guidelines.

Myers-Briggs Type Indicator

- A study of the relationship between personality traits and achievement in an introductory Fortran course was made by Kagan and Douthat.[699] They found that relatively introverted students, who were hard-driving and ambitious, obtained higher grades then their more extroverted, easy-going compatriots. This difference became more pronounced as the course progressed and became more difficult. Again these findings are too broad to be of any obvious relevance to these coding guidelines.

These personality findings do not mean that to be a good developer a person has to fall within these categories, only that many of those tested did.

It might be assumed that personality could affect whether a person enjoys doing software development, and that somebody who enjoys their work is likely to do a better job (but does personal enjoyment affect quality, or quantity of work performed?). These issues are considered to be outside the scope of this book (they are discussed a little more in Staffing,).

coding 0 guidelines staffing

Developers are sometimes said to be paranoid. One study[1469] has failed to find any evidence for this claim.

Usage

17 Introduction

Usage 1 Usage introduction

This subsection provides some background on the information appearing in the Usage subsections of this book. The purpose of this usage information is two-fold:

1. To give readers a feel for the common developer usage of C language constructs. Part of the process of becoming an experienced developers involves learning about what is common and what is uncommon. However, individual experiences can be specific to one application domain, or company cultures.
2. To provide frequency-of-occurrence information that could be used as one of the inputs to cost/benefit decisions (i.e., should a guideline recommendation be made rather than what recommendation might be made). This is something of a chicken-and-egg situation in that knowing what measurements to make requires having potential guideline recommendations in mind, and the results of measurements may suggest guideline recommendations (i.e., some construct occurs frequently).

guideline 0 recommen-dations selecting

Almost all published measurements on C usage are an adjunct to a discussion of some translator optimization technique. They are intended to show that the optimization, which is the subject of the paper, is worthwhile because some constructs occurs sufficiently often for an optimization to make worthwhile savings, or that some special cases can be ignored because they rarely occur. These kinds of measurements are usually discussed in the *Common implementation* subsections. One common difference between the measurements in Common Implementation subsections and those in Usage subsections is that the former are often dynamic (instruction counts from executing programs), while the latter are often static (counts based on some representation of the source code).

There have been a few studies whose aim has been to provide a picture of the kinds of C constructs that commonly occur (e.g., preprocessor usage,[396] embedded systems[390]). These studies are quoted in the

relevant C sentences. There have also been a number of studies of source code usage for other algorithmic languages, Assembler,[292] Fortran,[750] PL/1,[387] Cobol[12, 226, 662] (measurements involving nonalgorithmic languages have very different interests[208, 240]). These are of interest in studying cross-language usage, but they are not discussed in this book. In some cases a small number of machine code instruction sequences (which might be called idioms) have been found to account for a significant percentage of the instructions executed during program execution.[1269]

The intent here is to provide a broad brush picture. On the whole, single numbers are given for the number of occurrences of a construct. In most cases there is no break down by percentage of functions, source files, programs, application domain, or developer. There is variation across all of these (e.g., application domain and individual developer). Whenever this variation might be significant, additional information is given. Those interested in more detailed information might like to make their own measurements.

0 coding guidelines applications
0 coding guidelines coding style

Many of the coding guideline recommendations made in this book apply to the visible source code as seen by the developer. For these cases any usage measurements also apply to the visible source code. The effects of any macro replacement, conditional inclusion, or **#include**d header are ignored. Each usage subsection specifies what the quoted numbers apply to (usually either visible source, or the tokens processed during translation phase 7).

macro replacement

In practice many applications do not execute in isolation; there is usually some form of operating system that is running concurrently with it. The design of processor instruction sets often takes task-switching and other program execution management tasks into account. In practice the dynamic profile of instructions executed by a processor reflects this mix of usage,[119] as does the contents of its cache.[906]

17.1 Characteristics of the source code

All source code may appear to look the same to the casual observer. An experienced developer will be aware of recurring patterns; source can be said to have a style. Several influences can affect the characteristics of source code, including the following:

source code characteristics
0 coding guidelines coding style

- *Use of extensions to the C language and differences, for prestandard C, from the standard (often known as K&R C).* Some extensions eventually may be incorporated into a revised version of the standard; for instance, **long long** was added in C99. Some extensions are specific to the processor on which the translated program is to execute.

0 common implementations language specification

- *The application domain.* For instance, scientific and engineering applications tend to make extensive use of arrays and spend a large amount of their time in loops processing information held in these arrays; screen based interactive applications often contain many calls to GUI library functions and can spend more time in these functions than the developer's code; data-mining applications can spend a significant amount of time searching large data structures.

- *How the application is structured.* Some applications consist of a single, monolithic, program, while others are built from a collection of smaller programs sharing data with one another. These kinds of organization affect how types and objects are defined and used.

- *The extent to which the source has evolved over time.* Developers often adopt the low-risk strategy of making the minimal number of changes to a program when modifying it. Often this means that functions and sequences of related statements tend to grow much larger than would be the case if they had been written from scratch, because no restructuring is performed.

0 application evolution

- *Individual or development group stylistic usage.* These differences can include the use of large or small functions, the use of enumeration constants or object-like macros, the use of the smallest integer type required rather than always using **int**, and so forth.

1931 macro object-like

17.2 What source code to measure?

This book is aimed at a particular audience and the source code they are likely to be actively working on. This audience will be working on C source that has been written by more than one developer, has existed for a year or more, and is expected to continue to be worked on over the coming years.

benchmarks 0

The benchmarks used in various application areas were written with design aims that differ from those of this book. For instance, the design aim behind the choice of programs in the SPEC CPU benchmark suite was to measure processor, memory hierarchy, and translator performance. Many of these programs were written by individuals, are relatively short, and have not changed much over time.

Although there is a plentiful supply of C source code publicly available (an estimated 20.3 million C source files on the Web[122]), this source is nonrepresentative in a number of ways, including:

- The source has had many of the original defects removed from it. The ideal time to make these measurements is while the source is being actively developed.
- Software for embedded systems is often so specialized (in the sense of being tied to custom hardware), or commercially valuable, that significant amounts of it are not usually made publicly available.

Nevertheless, a collection of programs was selected for measurement, and the results are included in this book (see Table 0.23). The programs used for this set of measurements have reached the stage that somebody has decided that they are worth releasing. This means that some defects in the source, prior to the release, will not be available to be included in these usage figures.

Table 0.23: Programs whose source code (i.e., the `.c` and `.h` files) was used as the input to measurement tools (operating on either the visible or translated forms), whose output was used to generate this book's usage figures and tables.

Name	Application Domain	Version
gcc	C compiler	2.95
idsoftware	Games programs, e.g., Doom	
linux	Operating system	2.4.20
mozilla	Web browser	1.0
openafs	File system	1.2.2a
openMotif	Window manager	2.2.2
postgresql	Database system	6.5.3

Table 0.24: Source files excluded from the Usage measurements.

Files	Reason for Exclusion
gcc-2.95/libio/tests/tfformat.c	a list of approximately 4,000 floating constants
gcc-2.95/libio/tests/tiformat.c	a list of approximately 5,000 hexadecimal constants

Table 0.25: Character sequences used to denote those operators and punctuators that perform more than one role in the syntax.

Symbol	Meaning	Symbol	Meaning
`++v`	prefix ++	`--v`	prefix --
`v++`	postfix ++	`v--`	postfix --
`-v`	unary minus	`+v`	unary plus
`*v`	indirection operator	`*p`	star in pointer declaration
`&v`	address-of		
`:b`	colon in bitfield declaration	`?:`	colon in ternary operator

17.3 How were the measurements made?

The measurements were based two possible interpretations of the source (both of them static, that is, based on the source code, not program execution):

- *The visible source.* This is the source as it might be viewed in a source code editor. The quoted results specify whether the `.c` or the `.h` files, or both, were used. The tools used to make these measurements are based on either analyzing sequences of characters or sequences of preprocessing tokens (built from the sequences of characters). The source of the tools used to make these measurements is available on this book's Web site: http://www.knosof.co.uk/cbook/cbook.html.
- *The translated source.* This is the source as processed by a translator following the syntax and semantics of the C language. Measurements based on the translated source differ from those based on the visible source in that they may not include source occurring within some arms of conditional inclusion directives, may be affected by macro replacement, may not include all source files in the distribution (because the make-file does not require them to be translated), and do not include a few files which could not be successfully translated by the tool used. (The tools used to measure the translated source were based on a C static analysis tool.[681]) Every attempt was made to exclude the contents of any **#include**d system headers (i.e., any header using the < > delimited form) from the measurements. However, the host on which the measurements were made (RedHat 9, a Linux distribution) will have some effect; for instance, use of a macro defined in an implementation's header may expand to a variety of different preprocessing tokens, depending on the implementation. Also some application code contains conditional inclusion directives that check properties of the host O/S.

conditional inclusion macro replacement

Note. The condition for inclusion in a table containing *Common token pairs involving* information was that percentage occurrence of both tokens be greater than 1% and that the sum of both token frequencies be greater than 5%. In some cases the second requirement excluded tokens pairs when the percentage occurrence of one of the tokens was relatively high. For instance, the token pair `- character-constant` does not appear in Table 866.3 because the sum of the token frequencies is 4.1 (i.e., 1.9+2.2).

The usage information often included constructs that rarely occurred. Unless stated otherwise a cut-off of 1% was used. Values for table entries such as *other-types* were created by summing the usage information below this cut-off value.

1. Scope

1 This International Standard specifies the form and establishes the interpretation of programs written in the C programming language.[1)]

standard specifies form and interpretation

Commentary

The C Standard describes the behavior of programs (not always in complete detail, an implementation is given various amounts of leeway in translating some constructs). The behavior of implementations has to be deduced from the need to implement the described behavior of programs.

The committee took the view that programs are more important than implementations. This principle was and is used during the decision-making process of the C Standard Committee. Implementors sometimes argued that what their implementation did was/is important. The particular characteristics of an implementation can influence the usage of C language in programs, as can the characteristics of the host (e.g., the width of integer types supported). The Committee preferred to consider the extent of usage in existing programs and only became involved in the characteristics of implementations when there was widespread usage of a particular construct.

Existing code is important, existing implementations are not. Rationale

C++

1.1p1 *This International Standard specifies requirements for implementations of the C++ programming language.*

The C++ Standard does not specify the behavior of programs, but of implementations. For this standard the behavior of C++ programs has to be deduced from this, implementation-oriented, specification.

In those cases where the same wording is used in both standards, there is the potential for a different interpretation. In the case of the preprocessor, an entire clause has been copied, almost verbatim, from one document into the other. Given the problems that implementors are having producing a translator that handles the complete C++ Standard, and the pressures of market forces, it might be some time before people become interested in these distinctions.

Other Languages

This exact wording appears in both the Cobol and Fortran standards (except the language name is changed and Fortran programs are "expressed" rather than "written"). Some language definitions do not explicitly specify whether they apply to programs or implementations. Pascal defines conformance requirements for both implementations and programs.

Gosling[508] *We intend that the behavior of every language construct is specified here, so that all implementations of Java will accept the same programs.*

Common Implementations

base document The C language was first described in 1975 in a Bell Labs technical report[1170] (the successor to a language called B[674]). The more commonly known book *The C Programming Language* by Brian W. Kernighan and Dennis M. Ritchie[725] was published in 1978. There was also a report published in the same year listing recent changes.[726] A second edition of this book was published after the ANSI C Standard was ratified[727] which updated its description of the language to follow that given in the newly published standard. There has been no republication since the C99 revision of the Standard.

The first edition of the Kernighan and Ritchie book describes what became known as *K&R C*. A large number of implementations were based on the original K&R book, few of them adhering exactly to the specification it contained, (because it was open to interpretation). The term K&R compiler is often applied generically to translators that do not support function prototypes (an easily spotted characteristic).

As time has passed the number of implementations, in use, based on K&R C has dropped dramatically. But there is still source code in use that was written to the K&R specification. Vendors like to keep their customers happy by translating their existing code and many have added *support K&R* options to their products.

The base document for the library clause was the *1984 /usr/group Standard* published by the /usr/group Standard's Committee, Santa Clara, California, USA.

Coding Guidelines

Coding guidelines invariably specify that ISO 9899 is the definitive document. The problem at the time of writing, and for the next few years, is that most implementations in common use follow the 1990 document, not the 1999 revision. Most of the changes involve additional functionality with very few changes to existing behavior. So most of the updates that are needed to move to C99 can be handled as new material.

Up until the mid 1990s portability considerations meant having to keep an eye on maintaining a K&R compatibility option. These days platforms that only support K&R are limited to a few niches, where there is insufficient market interest to make it worthwhile to create an ISO-conforming implementation.

Many students who are taught C++ are told that it is a superset of C. This was not always the case in C90 and is not true in C99 (where there is additional support for functionality not available in C++). Some

compiler vendors offer a *C compiler* switch on their C++ compiler. Such switches do not always have the effect of creating a conforming C compiler. The issues of C/C++ compatibility are dealt with in the C++ subsections for each sentence.

---

2 It specifies

Commentary

This list is not exhaustive in that permission is explicitly given for an implementation to have extensions.

95 implementation extensions

C++

The C++ Standard does not list the items considered to be within its scope.

Coding Guidelines

These coding guideline subsections sometimes specify recommendations to be followed by developers for the usage of C language constructs.

---

3 — the representation of C programs;

program specify representation

Commentary

The representation described is essentially the same as written text, with special meaning attributed to certain characters, singly or in sequences (e.g., end-of-line indicators). The representation also includes how the components of a C program are organized. In most cases files are used.

116 translation phase 1

108 source files

The representation of C programs occurs at many different levels. There is the representation as it appears to the developer, the bytes read from media by the operating system, and the pattern of bits held on storage media. The representation we are interested in is the one that appears, to a developer, when viewed with an editor that supports the characters required by the C Standard.

Common Implementations

The C language was first implemented on hosts that used the Ascii character set. The EBCDIC (Extended Binary-Coded-Decimal Interchange Code) character set is commonly used on mainframes and C can be represented using this character set.

EBCDIC

Use of C for embedded applications and the prominence of Japanese in this area meant that C was the first standardized language to allow the writing of programs that contained other character sets.

---

4 — the syntax and constraints of the C language;

Commentary

These two sets of specifications are set in concrete and must be implemented, as written, by every conforming implementation. These specifications appear in the Standard within clauses headed by "Syntax", or by "Constraints".

81 conformance

63 constraint

C++

The first such requirement is that they implement the language, and so this International Standard also defines C++.

1.1p1

While the specification of the C++ Standard includes syntax, it does not define and use the term *constraints*. What the C++ specification contains are *diagnosable rules*. A conforming implementation is required to check and issue a diagnostic if violated.

146 diagnostic shall produce

Common Implementations

Some implementations add additional syntax. Adding additional constraints, or relaxing the existing ones is not commonly seen in implementations, but it does occur.

Coding Guidelines

Constructs that violate C syntax or constraints are required to be diagnosed by a conforming implementation. Working programs rarely contain such constructs (unless there is a bug in the implementation; for instance, `gcc` allows semicolons to be omitted in several places). Duplicating these requirements in coding guidelines does not add value.

Implementations that provide extensions to standard C do not always fully define these extensions. In particular they often define how an extension may be used but fail to define what the constraints on its use are. The coding guideline issues relating to use of extensions is discussed elsewhere.

extensions 95.1
cost/benefit

— the semantic rules for interpreting C programs; 5

Commentary

These rules appear under the clause heading *Semantics*, or sometimes *Description*, along with definitions of conformance. The behavior arising out of these semantic rules is what developers use to write programs that have an external effect.

conformance 81
behavior 41

The standard talks about an abstract machine and how programs are to be interpreted as-if running under it. Unfortunately, the specifications given in the standard are not worded in a form that directly addresses the properties of this machine; as such, this machine is never fully defined. However, the semantic rules specified in the C Standard are not all set in stone. An implementation may be required to select among several alternatives (these form the category of unspecified behaviors), chose its own behavior (these form the category of implementation-defined behaviors), or the standard may not impose any requirements on the behavior (these form the category of undefined behaviors).

C++

The C++ Standard specifies rules for implementations, not programs.

Coding Guidelines

A good first approximation to a set of coding guidelines is to recommend against the use of constructs whose semantic rules can vary across implementations (Annex J summarizes these and the majority of the rules in the MISRA C guidelines are based on this principle). While many of these Coding guideline subsections discuss the effect of implementation differences, these are only treated as a possible contributing factor to the primary consideration (i.e., cost) and not as a rationale in their own right.

MISRA 0
guideline 0
recommen-
dations
selecting

— the representation of input data to be processed by C programs; 6

Commentary

The C language had its beginnings in solving practical problems. Ignoring the representational issues of data was not a viable option. The Committee did adopt a specification for a set of I/O concepts (e.g., streams, binary and text files) and functions for manipulating them into the C library (the base document provided the underlying models).

base doc-1
ument

The underlying unit of input is the byte. The standard does not require that any sequence of bits within any byte have a particular interpretation (the functions provided by the **<ctype.h>** header can be applied to them, just like any other numeric quantity).

Other Languages

Some language standards committees have taken the view that I/O was not an important aspect of the language and provided a minimal set of functionality in this area, saying nothing about representational issues. In other languages, for instance Cobol, I/O is a significant part of that languages' specification.

C++

The C++ Standard is silent on this issue.

Common Implementations

A form of input not explicitly dealt with in the standard is the reading/writing data from/to registers, or I/O ports. This is a common form of I/O in freestanding environments.

Many implementations that support such functionality use the **volatile** type qualifier or some extension that allows objects to be placed at known locations in storage; reading values from such objects cause input to take place. Here the representation of the input value is interpreted according to the type of object through which it is accessed.

1476 type qualifier syntax

Coding Guidelines

The issues involved in converting this input data into some internal form is an application domain issue that is outside the scope of these coding guidelines. For instance, a floating-point number presented as a sequence of characters, on an input stream, may contain more accuracy than can be represented by the host. There is a guideline recommendation dealing with the use of representation information.

569.1 representation information using

7— the representation of output data produced by C programs;

Commentary

The standard does not specify any representation in terms of bit patterns, or pixels on a display device. However, the standard does specify some ordering requirements on output data. Data written out can be read back in to produce the same value. Output written to a display device will appear in the order it is written (but nothing is said about left-to-right, right-to-left, top-to-bottom, or any other visible ordering on the device).

254 writing direction locale-specific

C supports two forms of representation on output, text and binary. Text I/O is structured into lines of characters (there can be a great deal of variability in the external representation of characters written to text streams), while binary I/O is an ordered sequence of bytes.

Other Languages

In some application domains organizing the output data is a substantial part of the problem. Some languages, for instance Cobol, have mechanisms that provide application domain related control (in the case of Cobol the formatting of numeric quantities) of the output produced by a program.

Common Implementations

In most cases, implementations use the same representation for output data as they use for input data.

Coding Guidelines

The coding guideline subsections only discuss the representation of output data to the extent that it may be used as input data to other programs written in C.

8— the restrictions and limits imposed by a conforming implementation of C.

limits specify

Commentary

The Committee recognized that all implementations impose some limits on the size of programs that can be translated. They decided to face up to this issue by specifying minimum requirements. By specifying a list of limits, the Committee is attempting to guarantee a minimal level of support, for programs, by all conforming implementations. The limits were seen as a floor that implementations should strive to exceed, not as a ceiling they could stop at.

273 environmental limits
276 translation limits

Since the C90 Standard was written, the average amount of memory available to translators, on the majority of hosts, has increased significantly. For C99 the nominal translator host memory limit was increased to 512 K.

C90

The model of the minimal host expected to be able to translate a C program was assumed to have 64 K of free memory.

C++

Annex B contains an informative list of implementation limits. However, the C++ Standard does not specify any minimum limits that a conforming implementation must meet.

Common Implementations

Few implementations document all the limits they impose. This is usually because of the use of dynamic data structures, which means that their only fixed limit is the amount of memory available during translation.

This International Standard does not specify 9

Commentary

The C committee is up front about what the C Standard is not about.

C++

The C++ Standard does not list any issues considered to be outside of its scope.

Other Languages

Some languages standards include a list of items not specified by their respective documents, while others do not. Many of the items listed in the C Standard also appear in the Fortran Standard.

Coding Guidelines

coding guidelines background to 0

A set of coding guideline recommendations cannot hope to cover every issue that occurs in source code. Delimiting the areas not covered by a set of guidelines is as important as specifying those areas covered.

---

program transformation mechanism

— the mechanism by which C programs are transformed for use by a data-processing system; 10

Commentary

The standard uses the term *translator* to disassociate itself from known implementation techniques for transforming programs, such as compilers and interpreters. There is no requirement that the transformation process use programs that have been written in C, although the library does contain many of the support functions needed in the implementation of such a translator.

All suggestions requiring some mechanism to exist for passing options to a translator, at translation-time, were turned down by the Committee.

Rationale

One proposal long entertained by the C89 Committee was to mandate that each implementation have a translation-time switch for turning off extensions and making a pure Standard-conforming implementation. It was pointed out, however, that virtually every translation-time switch setting effectively creates a different "implementation", however close may be the effect of translating with two different switch settings. Whether an implementor chooses to offer a family of conforming implementations, or to offer an assortment of non-conforming implementations along with one that conforms, was not the business of the C89 Committee to mandate. The Standard therefore confines itself to describing conformance, and merely suggests areas where extensions will not compromise conformance.

implementation single pass

Many existing translators operate in a single pass and continued support for this form of implementation a consideration for many members of WG14 when considering the specification of C syntax and semantics.

Other Languages

Some standards use the term *language processor* to define what C calls a translator.

Common Implementations

The most common transformation mechanism (implementation technique) is to compile the program's source code to some form of machine code. This machine code could represent the instructions of a real processor (in the sense of being able to hold it in one's hand), or some virtual machine whose operations are performed in software (usually called an interpreter). In a few cases processors have been designed to execute a representation of some language directly. The Bell Labs CRISP processor[362] was designed to

efficiently support the execution of translated C programs (although the extent to which its instruction set might be claimed to be *C-like* is open to debate); the Symbolics 3600 processor used Lisp as its machine language;[430] the Novix NC4016[762] used Forth as its instruction set.

The ability to execute source code on a line-by-line basis is rarely provided (the Extensible Interactive C system[156] is an exception). In such an approach the standard still requires (if a vendor wanted to claim that their product was a conforming implementation) that the entire program's source code, even the unexecuted portions, be analyzed for syntax and constraint violations. As well as providing an interactive mode, the Extensible Interactive C system also provides a batch mode.

An advantage of the virtual machine approach is that the generated code can be executed unchanged on a wide variety of different processors, given the availability of a software interpreter. This is how Java achieves its portability. Another advantage of this approach is the compactness of the generated code. In applications where code size is more important than performance, it can be the deciding factor in choosing an interpretive approach.

The performance advantage obtained from using a cache shows how the execution time characteristics of many applications is to repeatedly execute the same sequences of instructions within short time periods. It is possible to make use of this execution time characteristic to have the best of both worlds— execution performance and compact code. The less-frequently executed portions of a program exist in virtual machine code form and the frequently executed portions in host processor machine code. For a VLIW processor, Hoogerbrugge[589] was able to obtain a 50% reduction in code size for a negligible increase in execution time.

0 cache

Whatever the mechanism used to transform C programs, it will invariably support some form of `-I` and `-D` options. These two options are almost universally used by C translators for specifying search paths for **`#include`** files and for defining macros (on the command line), respectively.

1898 #include places to search for
1931 macro object-like

Some translators access environment variables, of their host operating, to obtain the values of attribute that vary between different hosts. For instance, search paths for the **`#include`** directive, or the number of processors available to a program (when generating parallelization code[1314]).

1898 #include places to search for

Mixed forms of translation are being researched. Here translation of selected portions of a program occurs during the execution of that program. The advantage of this dynamic compilation approach is that it is possible to make use of runtime information to specialize the code, enhancing performance (provided the specialized execution savings are greater than the overhead of a dynamic compilation). The DyC toolset[513,950] has achieved some interesting results.

Many so-called *number crunching* applications are written in Fortran. A variety of parallel and vector processors have been built to reduce the execution time of such programs, which has entailed producing translators capable of vectorizing and parallelizing Fortran. One way to tap into this existing technology is to translate C source to Fortran.[722]

Downloading programs onto mobile devices, where they might only be executed once, is becoming more common. In this environment, the consumption of electrical power is an important consideration. A study by Palm and Moss[1044] performed a cost/benefit analysis of translating code on the client or server, with or without optimization. The energy quantities considered were: $E_{download}$, energy consumed by the wireless card while downloading code; $E_{wait-download}$, energy consumed by the client while waiting for code to download; $E_{wait-compile}$, energy consumed while waiting for code to compile or optimize on the server; $E_{compile}$, energy for compiling or optimizing on the client; and E_{run}, energy for running the compiled application on the client.

Coding Guidelines

Providing different options to a translator effectively creates different translators. The purpose of specifying options is to change the behavior of a translator, otherwise there is no point in specifying it. Whether use of an option radically changes the behavior of a translator (e.g., by enabling language extensions, changing the alignment of objects in memory, or selecting different hosts as the execution environment) or has no noticeable effect on the external output of the generated program image (e.g., it changes the format of the listing file, or causes debug information to be generated), is outside the scope of these coding guidelines.

Selecting translation-time options is part of the configuration management for a project.

Your author has never seen a set of coding guidelines that apply to make-files (apart from layout conventions) and would suggest that work on such a set is long overdue.

— the mechanism by which C programs are invoked for use by a data-processing system; 11

Commentary

The standard specifies the behaviors of C constructs. Specifying mechanisms for executing the generated program images serves no useful purpose at the level of abstraction at which the standard operates. Whichever mechanism is used, for a hosted implementation, the standard requires that a function called `main` be called by the execution environment.

program startup 150

Common Implementations

The output generated by a translator is usually written to a file. To indicate that this file can be executed, as a program, it might be given the extension *.exe* (under Microsoft Windows), or have its execute-bit set (under a POSIX-compliant operating systems such as Linux). Existing practices for invoking a program include giving the program name on the command line, clicking on icons, and having the program automatically executed on computer startup.

freestanding environment startup 155

In a freestanding environment the program image may be stored in read-only memory at a location that the host processor jumps to when it is initialized (which usually happens by default when power is first applied). The act of switching on, or resetting, is the mechanism for invoking the program.

---

input data mechanism transformed

— the mechanism by which input data are transformed for use by a C program; 12

Commentary

The standard is not concerned with how data is represented on media (which may be held on a hard disk, paper tape, or any other media) or an interactive device. It is the implementation's responsibility to map data from the bits held on a storage device to the input values they represent to a C program.

Coding Guidelines

Programs that want to access devices at a level below that specified by the C Standard are outside the scope of these coding guidelines.

Example

Specifying that a file is to be opened in text mode will cause the input to be treated as a series of lines. How lines are represented by the host file system is outside the scope of the C Standard.

end-of-line representation 224

— the mechanism by which output data are transformed after being produced by a C program; 13

Commentary

The Committee recognized that a program image may be executing within an encompassing environment. How this environment transforms data after it has been output by a program is outside the scope of the C Standard. The standard specifies an intended external effect for operations that perform output. It does not specify a *final resting place* for this external effect. It may be characters appearing on a display device, or bits being written to a storage device, or many other possibilities.

Common Implementations

At the host environment level (operating system) the sequences of bytes output by a C program are rarely modified until they reach the lower-levels of device drivers. Bytes sent over serial links may have parity bits added to them, blocks of bytes written to media may include file system information, and so on.

Coding Guidelines

Programs that are concerned with how output data are transformed once it has been generated by a program image are outside the scope of these coding guidelines.

14 1) This International Standard is designed to promote the portability of C programs among a variety of data-processing systems. footnote 1

Commentary

The Rationale puts the case very well:

Rationale

C code can be portable. Although the C language was originally born with the UNIX operating system on the DEC PDP-11, it has since been implemented on a wide variety of computers and operating systems. It has also seen considerable use in cross-compilation of code for embedded systems to be executed in a free-standing environment. The C89 Committee attempted to specify the language and the library to be as widely implementable as possible, while recognizing that a system must meet certain minimum criteria to be considered a viable host or target for the language.

C code can be non-portable. Although it strove to give programmers the opportunity to write truly portable programs, the C89 Committee did not want to force programmers into writing portably, to preclude the use of C as a "high-level assembler:" the ability to write machine-specific code is one of the strengths of C. It is this principle which largely motivates drawing the distinction between strictly conforming program and conforming program (§4).

Avoid "quiet changes." Any change to widespread practice altering the meaning of existing code causes problems. Changes that cause code to be so ill-formed as to require diagnostic messages are at least easy to detect. As much as seemed possible consistent with its other goals, the C89 Committee avoided changes that quietly alter one valid program to another with different semantics, that cause a working program to work differently without notice. In important places where this principle is violated, both the C89 Rationale and this Rationale point out a QUIET CHANGE.

A standard is a treaty between implementor and programmer. Some numerical limits were added to the Standard to give both implementors and programmers a better understanding of what must be provided by an implementation, of what can be expected and depended on to exist. These limits were, and still are, presented as minimum maxima (that is, lower limits placed on the values of upper limits specified by an implementation) with the understanding that any implementor is at liberty to provide higher limits than the Standard mandates. Any program that takes advantage of these more tolerant limits is not strictly conforming, however, since other implementations are at liberty to enforce the mandated limits.

Keep the spirit of C. The C89 Committee kept as a major goal to preserve the traditional spirit of C. There are many facets of the spirit of C, but the essence is a community sentiment of the underlying principles on which the C language is based. Some of the facets of the spirit of C can be summarized in phrases like

- Trust the programmer.
- Don't prevent the programmer from doing what needs to be done.
- Keep the language small and simple.
- Provide only one way to do an operation.
- Make it fast, even if it is not guaranteed to be portable.

The last proverb needs a little explanation. The potential for efficient code generation is one of the most important strengths of C. To help ensure that no code explosion occurs for what appears to be a very simple operation, many operations are defined to be how the target machine's hardware does it rather than by a general abstract rule. An example of this willingness to live with what the machine does can be seen in the rules that govern the widening of char objects for use in expressions: whether the values of char objects widen to signed or unsigned quantities typically depends on which byte operation is more efficient on the target machine.

One of the goals of the C89 Committee was to avoid interfering with the ability of translators to generate compact, efficient code. In several cases the C89 Committee introduced features to improve the possible efficiency of the generated code; for instance, floating point operations may be performed in single-precision if both operands are float rather than double.

At the WG14 meeting in Tokyo, Japan, in July 1994, the original principles were re-endorsed and the following new ones were added:

Support international programming. During the initial standardization process, support for internationalization[1025] was something of an afterthought. Now that internationalization has become an important topic, it should have equal visibility. As a result, all revision proposals shall be reviewed with regard to their impact on internationalization as well as for other technical merit.

Codify existing practice to address evident deficiencies. Only those concepts that have some prior art should be accepted. (Prior art may come from implementations of languages other than C.) Unless some proposed new feature addresses an evident deficiency that is actually felt by more than a few C programmers, no new inventions should be entertained.

Minimize incompatibilities with C90 (ISO/IEC 9899:1990). It should be possible for existing C implementations to gradually migrate to future conformance, rather than requiring a replacement of the environment. It should also be possible for the vast majority of existing conforming programs to run unchanged.

Minimize incompatibilities with C++. The Committee recognizes the need for a clear and defensible plan for addressing the compatibility issue with C++. The Committee endorses the principle of maintaining the largest common subset clearly and from the outset. Such a principle should satisfy the requirement to maximize overlap of the languages while maintaining a distinction between them and allowing them to evolve separately.

The Committee is content to let C++ be the big and ambitious language. While some features of C++ may well be embraced, it is not the Committee's intention that C become C++.

Maintain conceptual simplicity. The Committee prefers an economy of concepts that do the job. Members should identify the issues and prescribe the minimal amount of machinery that will solve the problems. The Committee recognizes the importance of being able to describe and teach new concepts in a straight-forward and concise manner.

During the revision process, it was important to consider the following observations:

- Regarding the 11 principles, there is a trade-off between them-none is absolute. However, the more the Committee deviates from them, the more rationale will be needed to explain the deviation.
- There had been a very positive reception of the standard from both the user and vendor communities.
- The standard was not considered to be broken. Rather, the revision was needed to track emerging and/or changing technologies and internationalization requirements.
- Most users of C view it as a general-purpose high-level language. While higher-level constructs can be added, they should be done so only if they don't contradict the basic principles.
- There are a good number of useful suggestions to be found from the public comments and defect report processing.

Areas to which the Committee looked when revising the C Standard included:

- Incorporate AMD1.

- Incorporate all Technical Corrigenda and records of response.
- Current defect reports.
- Future directions in current standard.
- Features currently labeled obsolescent.
- Cross-language standards groups work.
- Requirements resulting from JTC 1/SC 2 (character sets).
- The evolution of C++.
- The evolution of other languages, particularly with regard to interlanguage communication issues.
- Other papers and proposals from member delegations, such as the numerical extensions Technical Report which was proposed by J11.
- Other comments from the public at large.
- Other prior art.

C++

No intended purpose is stated by the C++ Standard.

Coding Guidelines

What are coding guidelines designed to promote?

0 coding guidelines introduction

Rev 14.1 The first paragraph on page one of a coding guidelines document shall state the purpose of those guidelines and the benefits expected to accrue from adherence to them.

---

15 It is intended for use by implementors and programmers.

Commentary

One argument, used by the Committee, against the use of a formal definition language for specifying the requirements, in the standard, was that programmers would have difficulty understanding it. Given the small number of copies of the document actually sold by standards bodies, this seems to be a moot point. This situation may change with C99 thanks to a standards organization in the USA being willing to sell electronic copies at a reasonable price.

Although written using English prose, the wording of the standard is highly stylized. Readers need to become familiar with the conventions used if they are to correctly interpret its contents. The ISO directives also require that:

> *To achieve this objective, the International Standard shall*
>
> . . .
>
> — *be comprehensible to qualified persons who have not participated in its preparation.*

ISO Directives, part 3

During the initial development of the C Standard by the ANSI committee, the idea of the document being a *treaty* between implementor and developer was voiced by many members of that committee. The Rationale discusses this issue. Although many members of the ISO C committee also hold this view of a standard being a treaty, there are some members who view the document as being a specification.

14 treaty

Coding Guidelines

Who are the intended audience of these coding guidelines?

0 coding guidelines introduction

They are intended to be read by managers wanting to select a set of guideline recommendations applicable to their business model, authors of local coding guideline documents and training materials, and vendors

producing tools to enforce them. While some developers may chose to read these coding guidelines for educational purposes, there is no obvious cost/benefit justification for requiring all developers to systematically read them.

— the size or complexity of a program and its data that will exceed the capacity of any specific data-processing system or the capacity of a particular processor; 16

Commentary

The standard does not require an implementation to fail to translate and execute a program that exceeds a size or complexity (how complexity might be measured is not specified) limit. Although such a requirement could increase program portability (they would have to be rewritten to reduce their size or complexity, making it more likely that they would be able to execute on a larger range of hosts). However, restricting those programs that may be translated for these reasons is counterproductive. Some translation limits effectively specify minimum bounds on program and data size that must be translated and executed by an implementation. However, they are lower, not upper limits.

limit 285
external identifiers

Common Implementations

It is not usually the size or complexity of programs that give translators problems. Optimizers like to keep all the information associated with a given function in memory while it is being translated. Functions that are large (complexity itself is rarely a problem) run the risk of having the translator run out of memory while generating machine code for them.

During execution all programs have a limit on the memory available to them to allocate for object storage. Most implementations will allocate storage until insufficient is available; problem execution usually fails in some way at this point.

Coding Guidelines

Programs that are too large or complex to be translated are fail-safe in the sense that developer attention is needed to solve the problem. Ensuring that programs do not run out of storage during execution, or that their execution terminates within a given time frame, are issues that are outside the scope of these coding guidelines. Some coding guideline documents address the storage capacity issue by prohibiting the use of constructs that prevent a program's total storage requirements from being known at translation time.[1026]

— all minimal requirements of a data-processing system that is capable of supporting a conforming implementation. 17

Commentary

limit 285
external identifiers

This statement is not quite true. When deciding on values for the minimum translation limits, the C99 Committee had in mind a translation host with a total of 256 K of memory. The requirements needed to support a conforming implementation are considered to be a quality-of-implementation issue. Implementation vendors are left to respond to customer demands.

Common Implementations

Implementations have been created on hosts having a total memory size of 64 K.

2. Normative references

Normative references

The following normative documents contain provisions which, through reference in this text, constitute provisions of this International Standard. 18

Commentary

A normative reference is the one that carries the same weight as wording in the standard itself. An informative reference is just that, informative.

Just as the Standard proper excludes all examples, footnotes, references, and informative annexes, this Rationale is not part of the Standard. The C language is defined by the Standard alone. If any part of this Rationale is not in accord with that definition, the Committee would very much like to be so informed.

The ISO Directives do not permit the *Normative references* clause to contain

- documents that are not publicly available,
- documents to which only informative reference is made, or
- documents that have merely served as references in the preparation of the standard.

These kinds of documents may be listed in a bibliography. Other normative documents, not listed here, can be created through the mechanism of Defect Reports (DRs) raised against wording in the existing standards document. A DR can be raised by a National Body (a country who is a P, Participating, member of SC22), the Project Editor, or the convener of WG14. 0 defect report

The C committee tries to deal with DRs during the meeting immediately following their submission. The response might be to agree that there is a problem with existing wording in the standard and to provide amended wording, or to say that the issue described is not considered a problem with the standard. The committee can choose to add additional material to the standard by issuing an Amendment (such an Amendment requires a new work item, which needs the support of five P member countries before it can go ahead). There was one Amendment for C90, dealing with wide character issues.

An ISO committee can also chose to issue Technical Reports (TRs). Work has started on a TR relating to C99 (the *Embedded C* Technical Report[657]). It deals with embedded systems issues (fixed-point types, differentiating different kinds of memory, saturation arithmetic, etc.). Up-to-date information on the C Standard can be found at the official Web site, http://www.open-std.org/jtc1/sc22/wg14/. Embedded C TR

Coding Guidelines

Referencing other documents, from within coding guidelines, could mean the reader has to spend significant time obtaining a copy of that reference. In many cases readers are unlikely to invest the effort needed to locate the referenced document.

Prior to C99 the cost of obtaining a copy of the C Standard was relatively high. The introduction of electronic distribution, and support from ANSI, has made a much lower-cost copy of the standard available. It is now realistic for guidelines to assume that their readers have access to a copy of the C Standard.

Rev 18.1 A coding guidelines document shall try to minimize references to other documents; if necessary, by including the relevant information in the guidelines document, perhaps in an annex.

Understanding the issues behind most DRs requires a close reading of the wording in the standard and usually involve situations that do not occur very often. In theory most DRs will not be of interest because use of constructs should not be relying on close readings of the standard. In practice usage of particular wording in the standard may be incidental, or the developer may not have read the wording closely at all.

The DRs raised against the C90 Standard are unlikely to have had any significant impact on programs (a few implementations had to change the way they handled constructs). It is hoped that the DRs raised against C99 follow this pattern. Authors of coding guidelines documents might like to periodically check the official log of DRs on the C Standard Web site, http://www.open-std.org/jtc1/sc22/wg14/.

A coding guidelines document is likely to be referred to by higher-level documents. The extent to which such documents follow the cost/benefit aims of these coding guidelines, or are even known to be effective, is unknown (although one study[1241] that experimentally looked at the consistency of ISO/IEC 15504 Software Process Improvement found some interesting results).

19 For dated references, subsequent amendments to, or revisions of, any of these publications do not apply. Dated references

Commentary

Who knows what changes a future revision of a normative document might have. This sentence prevents revisions of some normative documents having an unintended impact on the interpretation of wording in the current version of the standard. This sentence is also explicitly stating a rule that is specified in the ISO directives.

C90

This sentence did not appear in the C90 Standard.

C++

1.2p1 *At the time of publication, the editions indicated were valid. All standards are subject to revision, and parties to agreements based on this International Standard are encouraged to investigate the possibility of applying the most recent editions of the standards indicated below.*

The C++ Standard does not explicitly state whether later versions of standards do or do not apply. In the case of the C++ library, clause 17.3.1.4 refers to "the ISO C standard,", which could be read to imply that agreements based on the C++ Standard may reference either the C90 library or the C99 library. The C++ ISO Technical Report TR 19768 (C++ Library Extensions) includes support for the wide character library functionality that is new in C99, but does not include support for some of the type generic maths functions (some of these are the subject of work on a separate TR) or extended integer types. However, the current C++ Standard document effective references the C90 library.

However, parties to agreements based on this International Standard are encouraged to investigate the possibility of applying the most recent editions of the normative documents indicated below. 20

Commentary

ISO rules require that every five years the Committee responsible for a standard investigate: should the standard be reconfirmed, should the standard be withdrawn, should the standard be revised. It typically seems to take around five years to produce and revise a language standard, creating a 10-year cycle; most other kinds of standards are either confirmed or are on a shorter cycle. Different standards can also be on different parts of their cycle. It usually takes at least 12 months for some kind of formal update to a standard to be adopted.

While parties may investigate the possibility of applying the most recent editions of standards, the timescales involved in formally adopting them are such that, unless there is a very important issue, the Committee may well decide to wait for the next revision of the standard to update the references.

C90

This sentence did not appear in the C90 Standard.

Coding Guidelines

It is unlikely that a revision of one of these standards will materially affect the C Standard. It is more likely that a revision of one of these standards will affect a developer's application domain. It is this wider issue which is outside the scope of these guidelines, that is likely to be of more importance to an application.

For undated references, the latest edition of the normative document referred to applies. 21

Commentary

The referenced standards will contain a date of publication. The C Standard requires that the most up-to-date version be applied.

C90

This sentence did not appear in the C90 Standard.

Coding Guidelines

Rev 21.1 A coding guidelines document shall specify which edition of the C Standard they refer to. They shall also state if any Addendums, Defect Reports, or Technical Reports are to be taken into account.

---

22 Members of ISO and IEC maintain registers of currently valid International Standards.

Commentary

The ISO Web site, http://www.iso.ch, is a good starting point for information.

Coding Guidelines

Putting coding guidelines documents under the same change control system as that used for source code is a good starting point for tracking revisions. However, the first priority should always be to make sure that the guideline recommendations are followed, not inventing new procedures to handle their change control.

---

23 ISO 31-11:1992, *Quantities and units— Part 11: Mathematical signs and symbols for use in the physical sciences and technology*. ISO 31-11

Commentary

This is Part 11 of a 13-part standard. Even though it is 27 pages long it is a nonexhaustive list of mathematical symbols. Part 1 of ISO 31, "Space and time", is a useful companion to ISO 8601. [27] ISO 8601

---

24 ISO/IEC 646, *Information technology— ISO 7-bit coded character set for information interchange*. ISO 646

Commentary

This standard assigns meanings to values in the range 0x0 to 0x7f. There are national variants of this standard (e.g., Ascii).

There are also 8-bit coded character set standards (i.e., ISO 8859–1 through ISO 8859–16) which assign meanings to the values 0x80 to 0xff (0x80–0x9f specify control codes and 0xa0 to 0xff additional graphics characters). ISO 8859–1 is commonly called *Latin-1* and covers all characters that occur in Danish, Dutch, English, Faeroese, Finnish, French, German, Icelandic, Italian, Norwegian, Portuguese, Spanish, and Swedish. This standard was recently replaced by ISO 8859–15, Latin-9, which added support for the Euro symbol and some forgotten French and Finnish letters. Values in the range 0x20 to 0x7e are always used to represent the invariant portion of ISO 646 (the so-called *International Reference Version*). ISO 8859

---

25 ISO/IEC 2382–1:1993, *Information technology— Vocabulary — Part 1: Fundamental terms*. ISO 2382

Commentary

This is a reference to part 1 of a 27-part standard. The other 26 parts define the vocabulary for a wide range of computer-related areas.

C++

1.2p1 *ISO/IEC 2382 (all parts), Information technology — Vocabulary*

ISO 4217, *Codes for the representation of currencies and funds.* 26

Commentary

Quoting from its scope: "This International Standard provides the structure for a three letter alphabetic code and an equivalent three-digit numeric code for the representation of currencies and funds." Apart from an example in the library section, the contents of this standard are not used within the C Standard. However, a translator vendor may need to use this standard to implement a locale. The document is shorter than its 31 pages suggest. Half of it is written in French.

C++

There is no mention of this document in the C++ Standard.

ISO 8601 ISO 8601, *Data elements and interchange formats— Information interchange— Representation of dates and times.* 27

Commentary

This standard specifies the presentation format for dates and times. It also covers issues such as whether weeks start on Sunday or Monday, and which is week-1 of a year. The definition of terms is provided by ISO 31–1, "Space and time". A translator vendor may need to use this standard to implement a locale.

ISO 31-11 23

C++

There is no mention of this document in the C++ Standard.

ISO 10646 ISO/IEC 10646 (all parts), *Information technology— Universal Multiple-Octet Coded Character Set (UCS).* 28

Commentary

The ISO/IEC 10646 Standard uses a 32-bit representation, with the code positions divided into 128 groups of 256 planes with each plane containing 256 rows of 256 cells. An industrial consortium, known as Unicode http://www.unicode.org, developed a 16-bit encoding that corresponded exactly to plane zero (known as the Basic Multilingual Plane) of the 32-bit encoding used in ISO/IEC 10646. The two groups eventually merged their efforts and at the time of this writing the Unicode encoding uses the range 0x000000 to 0x10FFFF.

The supported characters do not just include letters, numbers, and symbols denoting words or parts of words, they also include symbols for non-words. For instance, *BLACK SPADE SUIT* (U+2660) ♠, *MUSIC NATURAL SIGN* (U+266E) ♮, *BLACK TELEPHONE* (U+260E) ☎, and *WHITE SMILING FACE* (U+263A) ☺.

__STDC_ISO_10646__ 2021 macro The conditionally defined macro __STDC_ISO_10646__ may contain information on the version of ISO/IEC 10646 supported by an implementation.

Common Implementations

Support for Unicode is more commonly seen than that for the full (or subset that is larger than Unicode) ISO/IEC 10646 specification. Both specify three encoding forms, UTF (in Unicode this is an acronym for *Unicode Transformation Format*, while in ISO/IEC 10646 it is *UCS Transformation Format*), of encoding characters:

universal character name syntax 815

1. As a 32-bit value directly holding the numeric value, *UTF-32* (this is the value used in UCNs).

2. As one, or two, 16-bit values (values in the range 0x0000–0xD7FF and 0xE000–0xFFFF goes in one, 0x010000–0x10FFFF goes in two; values in the range 0xD800–0xDFFF in the first 16 bits indicate that another value, in the range 0xDC00–0xDFFF, follows), *UTF-16*. UTF-16

3. As a sequence of one or more 8-bit values, *UTF-8*. The following list shows the encoding used for various ranges of characters. For multibyte sequences, the number of leading 1's in the first octet equals the number of octets in the sequence: UTF-8

```
U+00000000–U+0000007F: 0xxxxxxx
U+00000080–U+000007FF: 110xxxxx 10xxxxxx
U+00000800–U+0000FFFF: 1110xxxx 10xxxxxx 10xxxxxx
U+00010000–U+001FFFFF: 11110xxx 10xxxxxx 10xxxxxx 10xxxxxx
U+00200000–U+03FFFFFF: 111110xx 10xxxxxx 10xxxxxx 10xxxxxx 10xxxxxx
U+04000000–U+7FFFFFFF: 1111110x 10xxxxxx 10xxxxxx 10xxxxxx 10xxxxxx 10xxxxxx
```

C++

ISO/IEC 10646–1:1993 Information technology – Universal Multiple-Octet Coded Character Set (UCS) – Part 1: Architecture and Basic Multilingual Plane 1.2p1

ISO/IEC 10646:2003 is not divided into parts and the C++ Standard encourages the possibility of applying the most recent editions of standards. [19] Dated references

---

29 IEC 60559:1989, *Binary floating-point arithmetic for microprocessor systems* (previously designated IEC 559:1989). IEC 60559

Commentary

The term *IEEE floating point* is often heard. This usage came about because the original standards on this topic were published by the IEEE. This standard for binary floating-point arithmetic is what many host processors have been providing for over a decade. However, its use is not mandated by C99. See annex F.1 for a discussion of the relationship between this standard and other related floating-point standards from which it was derived.

C90

This standard did not specify a particular floating-point format, although the values given as an example for **<float.h>** were IEEE-754 specific (which is now an International Standard, IEC 60559).

C++

There is no mention of this document in the C++ Standard.

Common Implementations

Figueroa del Cid[422] provides an extensive discussion on what the phrase *support the IEEE floating-point standard* might be interpreted to mean.

The representation for binary floating-point specified in this standard is used by the Intel x86 processor family, Sun SPARC, HP PA-RISC, IBM PowerPC, HP–was DEC– Alpha, and the majority of modern processors (some DSP processors support a subset, or make small changes, for cost/performance reasons; while others have more substantial differences e.g., TMS320C3x[1341] uses two's complement). There is also a publicly available software implementation of this standard.[552]

Other representations are still supported by processors (IBM 390 and HP–was DEC– VAX) having an existing customer base that predates the publication the documents on which this standard is based. These representations will probably continue to be supported for some time because of the existing code that relies on it (the IBM 390 and HP–was DEC– Alpha support both their companies respective older representations and the IEC 60559 requirements).

Coding Guidelines

There is a common belief that once the IEC 60559 Standard has been specified all of its required functionality will be provided by conforming implementations. It is possible that a C program's dependencies on IEC 60559 constructs, which can vary between implementations, will not be documented because of this common, incorrect belief (the person writing documentation is not always the person who is familiar with this standard).

Like the C Standard the IEC 60559 Standard does not fully specify the behavior of every construct.[700] It also provides optional behavior for some constructs, such as when underflow is raised, and has optional constructs that an implementation may or may not make use of, such as double standard. C99 does not always provide a method for finding out an implementation's behavior in these optional areas. For instance, there are no standard macros describing the various options for handling underflow.

3. Terms, definitions, and symbols

C90

The title used in the C90 Standard was "Definitions and conventions".

For the purposes of this International Standard, the following definitions apply. 30

Commentary

These definitions override any that may appear in other standards documents (including ISO 2382). In some cases terms used in the standard have a meaning that is different from their *plain* English usage. For instance, in:

```
1  int x_1,
2      x_2;
3
4  void f(void)
5  {
6  int x_1;
7  }
```

scope 415 same the objects `x_1` and `x_2`, at file scope, are said to have the same scope. However, there is a region of the program text in which one of these identifiers, `x_1`, is not visible (because of a declaration of the same name in a nested block).

C++

1.3p1 *For the purposes of this International Standard, the definitions given in ISO/IEC 2382 and the following definitions apply.*

17p9 *The following subclauses describe the definitions (17.1), and method of description (17.3) for the library. Clause 17.4 and clauses 18 through 27 specify the contents of the library, and library requirements and constraints on both well-formed C++ programs and conforming implementations.*

Coding Guidelines

Some writers of coding guidelines find the definition of terms used in the C Standard hard to understand, or at least think that their readers might. This belief then becomes the rationale for creating a *less-experienced, reader friendly* definition of terms. Your author knows of no published, or unpublished, survey of the ease, or difficulty, developers have with various technical terms. Having two sets of definitions of terms is likely to lead to confusion. There is no evidence that one set of terms is better, or worse, than any other.

Rev 30.1 The definition of terms, as defined in the C Standard and standards referenced by it, shall be used in coding guideline documents.

---

31 Other terms are defined where they appear in *italic* type or on the left side of a syntax rule. terms defined where

Commentary

In most cases the first use of a term is also where it is defined and hence where it usually appears in italic type.

C90

The fact that terms are defined when they appear "on the left side of a syntax rule" was not explicitly specified in the C90 Standard.

Coding Guidelines

A coding guidelines document cannot assume that its readers will start at the front and read each rule in turn. There are obvious advantages to collecting all terms, with a meaning specific to the guidelines, in an index or collecting them together in an annex. This is a usability issue that is outside the scope of these guidelines.

---

32 Terms explicitly defined in this International Standard are not to be presumed to refer implicitly to similar terms defined elsewhere.

Commentary

The C Standard is absolving itself of any similar terms that may be defined in any other standard.

Coding Guidelines

A coding guideline shall state that the terms defined by the C Standard are the ones that apply to itself.

---

33 Terms not defined in this International Standard are to be interpreted according to ISO/IEC 2382–1.

Commentary

Terms defined in the C Standard take precedence. If the term is not defined there, refer to ISO/IEC 2382–1 [25] ISO 2382 (Part II of ISO/IEC 2382 deals with mathematical and logical operations and is also a useful source of definitions). There has been discussion within the Committee on terms that are not defined by either document, but are technical in nature. In these cases the common dictionary usage has been claimed to be applicable. The ISO Directives specify that the two dictionaries *The Shorter Oxford English Dictionary* and *The Concise Oxford Dictionary*, provide the definitions of nontechnical words.

C++

> *For the purposes of this International Standard, the definitions given in ISO/IEC 2382 and the following definitions apply.* 1.3p1

The C++ Standard thus references all parts of the above standard. Not just the first part.

Coding Guidelines

While the above might appear to be a good sentence to include in a coding guidelines document, most developers are unlikely to have easy access to a copy of ISO/IEC 2382–1.

Rev 33.1 All technical terms used in a coding guidelines document shall be defined in that document.

Mathematical symbols not defined in this International Standard are to be interpreted according to ISO 31-11. 34

Commentary

The ISO/IEC 2382-II Standard deals with mathematical and logical operations but is not referenced by the C Standard. It is not known if there are any incompatibilities between this document and ISO 31-11.

3.1

access 35

access

⟨execution-time action⟩ to read or modify the value of an object

Commentary

While the behavior for most kinds of access are simple and easy to deduce, this innocent looking definition hides several dark corners. For instance, does an expression that multiplies an object by 1 modify that object? modify 37 includes cases Yes. Does accessing a bit-field that shares a storage unit with another bit-field also cause an access to that other bit-field? WG14 are looking into creating a more rigorous specification of what it means to access an object. A Technical Report may be published in due course (it will take at least two years). At the time of this writing WG14 has decided to wait until the various dark corners have been more fully investigated and the issues resolved and documented before making a decision on the form of publication.

reference 70 object The term *reference* is also applied to *objects*. The distinction between the two terms is that programs reference objects but access their values. An unevaluated expression may contain references to objects, but it never accesses them. The term *designate an object* is used in the standard. This term can involve a reference, an access, or both, or neither. In the following:

```
1  int *p = 0;
2  (*&*p);
```

the lvalue `(*&*p)` both accesses and references an object, namely the pointer object `p`, but it does not &* 1092 designate any object. The term *designate* also focuses attention on a particular object under discussion. For instance, in the expression `a[n]` there are the references `a`, `n`, and `a[n]`; the expression may or may not access any or all of `a`, `n`, and `a[n]`. But the discussion is likely to refer to the object designated by `a[n]`, not its component parts.

C++

In C++ the term *access* is used primarily in the sense of *accessibility*; that is, the semantic rules dealing with when identifiers declared in different classes and namespaces can be referred to. The C++ Standard has a complete clause (Clause 11, Member access control) dealing with this issue. While the C++ Standard also uses *access* in the C sense (e.g., in 1.8p1), this is not the primary usage.

Common Implementations

Many of these corner cases involve potential optimizations that translator vendors might like to perform. Some translators containing nontrivial optimizers provide options, selectable by developers, that control the degree to which optimizations are attempted. Optimizations that may change the behavior of a construct (from one choice of undefined, or unspecified behavior to another one) are usually only enabled at the higher, try harder levels of optimization.

Example

In the following:

```
1  int f(int param)
2  {
3  struct {
4          volatile unsigned int mem1:2;
5                   unsigned int mem2:4;
```

```
6           volatile unsigned int mem3:6;
7                    unsigned int mem4:1;
8          } mmap;
9
10  return mmap.mem2 += param;
11  }
```

the member mem2 may be placed in the same storage unit as mem1 and/or mem3. If the processor does not have bit-field extraction instructions, it will be necessary to generate code to load one or more bytes to obtain the value of mem2. If the member mem1 is contained in one of those bytes, does an access of mem2 also constitute an access to mem1?

Another issue is the number of accesses to a bit-field. Obtaining the value of mem3 requires a single, read, access. But how many accesses are needed to modify mem3? One to read the value, which is modified; a store back into mem3 may require another read (to obtain the value of the other members stored in the same storage unit; perhaps mem4 in the preceding example); the modified value of mem3 is inserted into the bit pattern read and the combined value written back into the storage unit. An alternative implementation may hang on to the value of mem4 so that the second read access is not needed.

36 NOTE 1 Where only one of these two actions is meant, “read” or “modify” is used.

37 NOTE 2 “Modify” includes the case where the new value being stored is the same as the previous value.

modify includes cases

Commentary

This specification only needs to be followed exactly when there is more than one access between sequence points, or for objects declared with the volatile storage class. As far as the developer is concerned, a modification occurs. As long as the implementation delivers the expected result, it is free to do whatever it likes.

Example

```
1   extern int glob;
2   extern volatile int reg;
3
4   void g(void)
5   {
6   reg *= 1; /*
7              * Value of reg looks as if it is unchanged, but because
8              * it is volatile qualified an access to the object is
9              * required.  This access may cause its value to change.
10             */
11  /*
12   * The following cannot be optimized to a single assignment.
13   */
14  reg=glob;
15  reg=glob;
16
17  glob += 0; /* Value of glob unchanged but it is still modified. */
18  /*
19   * glob modified twice between sequence points -> undefined behavior
20   */
21  glob = (glob += 0) + 4;
22  }
```

38 NOTE 3 Expressions that are not evaluated do not access objects.

Commentary

The term *not evaluated* here means *not required to be evaluated by the standard*. Implementations do not have complete freedom to decide what not to evaluate. Reasons why an expression may not be evaluated include:

- being part of a statement which is not executed,
- being part of a subexpression whose evaluation is conditional on other subexpressions within a full expression, and
- being an operand of the **`sizeof`** operator.

sizeof 1122 operand evaluated
sizeof 1123 operand not evaluated

If an implementation can deduce that the evaluation of an expression causes no side-effects, it can use the as-if rule to optimize away the generation of machine code (to evaluate the expression).

as-if rule 122

Common Implementations

The inverse of this rule is one area where translators that perform optimizations have to be careful. In:

```
1  a = b + c;
```

b and c are accessed to obtain their values for the + operator. An optimizer might, for instance, deduce that their sum had already been calculated and is still available in a register. However, using the value held in that register is only possible if it can be shown that not accessing b and c will not change the behavior of the program. If either were declared with the volatile qualifier, for instance, such an optimization could not be performed.

Coding Guidelines

Accessing an object only becomes important if there are side effects associated with that access; for instance, if the object is declared with the **`volatile`** qualifier. This issue is covered by guideline recommendations discussed elsewhere.

sequence 187.1 points all orderings give same value
code 91.1 shall affect output

Example

```
1  extern int i, j;
2  extern volatile int k;
3
4  void f(void)
5  {
6  /*
7   * Side effect of access to k occurs if the left operand
8   * of the && operator evaluates to nonzero.
9   */
10 if ((i == 2) && (j == k))
11    /* ... */ ;
12 /*
13  * In the following expression k appears to be read twice.
14  * Only one of the subexpressions will ever be evaluated.
15  * There is no unspecified or undefined behavior.
16  */
17 i = (j < 3 ? (k - j) : (j - k));
18 }
```

3.2

alignment

alignment 39

requirement that objects of a particular type be located on storage boundaries with addresses that are particular multiples of a byte address

Commentary

In an ideal world there would be no alignment requirements. In practice the designers of some processors have placed restrictions on the fetching of variously sized objects from storage. The underlying reason for these restrictions is to simplify (reduce cost) and improve the performance of the processor. Some processors do not have alignment requirements, but may access storage more quickly if the object is aligned on a particular address boundary.

The requirement that a pointer to an object behave the same as a pointer to an array of that object's type forces the requirement that `sizeof(T)` be a multiple of the alignment of `T`. If two objects, having different types, have the same alignment requirements then their addresses will be located on the same multiple of a byte address. Objects of character type have the least restrictive alignment requirements, compared to objects of other types. Alignment and padding are also behind the assumptions that need to be made for the common initial sequence concept to work.

1165 additive operators pointer to object
558 pointer to void same representation and alignment as
1038 common initial sequence

The extent to which alignment causes implementation-defined or undefined behavior is called out for each applicable construct. Various issues relating to alignment were the subject of DR #074.

C++

Object types have alignment requirements (3.9.1, 3.9.2). The alignment of a complete object type is an implementation-defined integer value representing a number of bytes; an object is allocated at an address that meets the alignment requirements of its object type. 3.9p5

There is no requirement on a C implementation to document its alignment requirements.

Other Languages

Most languages hide such details from their users.

Common Implementations

Alignment is a very important issue for implementations. Internally it usually involves trade-offs between storage and runtime efficiency. Externally it is necessary to deal with parameter passing interfaces and potentially the layout of structure members. The C language is fortunate in that many system interfaces are specified in terms of C. This means that other languages have to interface to its way of doing things, not the other way around.

1413 alignment addressable storage unit

Optimal code generation for modern processors requires implementations to consider alignment issues associated with cache lines. Techniques for finding and using the optimal memory alignment for the objects used in a program is an active research area.[812]

The Motorola 56000[970] allows its modulo arithmetic mode to be applied to pointer arithmetic operations (used to efficiently implement a circular buffer; the wraparound effectively built into the access instruction). The one requirement is that the storage be aligned on an address boundary that is a power of two greater than or equal to the buffer size. So an array of 10 characters needs to be placed on a 16-byte boundary, while an array of 100 characters would need to be on a 128-byte boundary (assuming they are to be treated as circular buffers). Translators for such processors often provide an additional type specifier to enable developers to indicate this usage.

Motorola 56000

The Intel XScale architecture[629] has data cache lines that start on a 32-byte address boundary. Arranging for aggregate objects, particularly arrays, to have such an alignment will help minimize the number of stalls while the processor waits for data, and it also enables optimal use of the prefetch instruction. The Intel x86 architecture has no alignment requirement, but can load multibyte objects more quickly if appropriately aligned. RISC processors tend to have strict alignment requirements, often requiring that scalar objects be aligned on a byte boundary that is a multiple of their size.

Does the storage class or name space of an identifier affect its alignment?

Many implementations make no attempt to save storage, for objects having static storage duration, by packing them close together. It is often simpler to give them all the same, worst-case, alignment. For hosted

implementations potential savings (e.g., storage saved, time to access) may be small; there don't tend to be significant numbers of scalar objects with static storage duration. However, in those cases where freestanding environments have limited storage availability, vendors often go to great lengths to make savings. The alignment of objects having static storage duration is sometimes controlled by the linker, which may need to consider more systemwide requirements than a C translator (e.g., handling other languages or program image restrictions). For example, the C translator may specify that all objects start on an even address boundary; objects with automatic storage duration being placed on the next available even address after the previous object, but the linker using the next eighth-byte address boundary for objects.

linkers 140

A host's parameter-passing mechanism may have a minimum alignment requirement, for instance at least the alignment of **int**, and stricter alignment for types wider than an **int**. Minimizing the padding between different objects with automatic storage duration reduces the stack overhead for the function that defines them. It also helps to ensure they all fit within any short addressing modes available within the instruction set of the host processor. Unlike objects with static storage duration, most translators attempt to use an alignment that is appropriate to the type of the object.

The `malloc` function does not know the effective type assigned to the storage it allocates. It has to make worst-case assumptions and allocate storage based on the strictest alignment requirements.

The members of a structure type are another context where alignment requirements can differ from the alignment of objects having the same type in non-member contexts.

member 1421
alignment

Most processor instructions operate on objects having a scalar type and any alignment requirements usually only apply to scalar types. However, some processors contain instructions that operate on objects that are essentially derived types and these also have alignment requirements (e.g., the Pentium streaming SIMD instructions[626]). The multiples that occur in alignment requirements are almost always a power of two. On some processors the alignment multiple of a scalar type is the same as its size, in bytes.

derived type 525

Alignment requirements are not always constant during translation. Several implementations provide **#pragma** directives that control the alignment used by translators. A common vendor extension for controlling the alignment of structure members is the **#pack** preprocessor directive. `gcc` supports several extensions for getting and setting alignment information.

- The keyword **__alignof__**, which returns the alignment requirement of its argument, for instance, `__alignof__ (double)` might return 8.
- The keyword **__attribute__** can be used to specify an object's alignment at the point of definition:

```
1  int x __attribute__((aligned(16))) = 0;
```

Coding Guidelines

Alignment is an issue that can affect program resource requirements, program interoperability, and source code portability.

Alignment can affect the size of structure types. Two adjacent members declared with different scalar types may have padding inserted between them. Ordering members such that those with the same type are adjacent to each other can eliminate this padding (because the alignment of a scalar type is often a multiple of its size). If many instances of an object having a particular structure type are created a large amount of storage may be consumed and developers may consider it to be worthwhile investigating ways of making savings; for instance, by changing the default alignment settings, or by using a vendor-supplied **#pragma**.[1314] If alignment is changed for a subset of structures there is always the danger that a declaration in one translation unit will have an alignment that differs from the others. Adhering to the guideline recommendation on having a single point of declaration reduces the possibility of this occurring.

alignment 39

identifier 422.1
declared in one file

Some applications chose to store the contents of objects having structure types, in binary form, in files as a form of data storage. This creates a dependency on an implementation and the storage layout it uses for types. Other programs that access these data files, or even the same program after retranslation, need to

ensure that the same structure types have the same storage layout. This is not usually a problem when using the same translator targeting the same host. However, a different translator, or a different host, may do things differently. The design decisions behind the choice of data file formats is outside the scope of these coding guidelines.

1354 storage layout

Programs that cast pointers to point at different scalar types are making use of alignment requirements information, or lack of them. Porting a program which makes use of such casts to a processor with stricter alignment requirements, is likely to result in some form of signal being raised (most processors raise some form of exception when an attempt is made to access objects on misaligned addresses). The cost of modifying existing code to work on such a processor is one of the factors that should have been taken into account when considering the original decision to allow a guideline deviation permitting the use of such casts.

743 pointer to void converted to/from

Developers sometimes write programs that rely on different types sharing the same alignment requirements, e.g., **int** and **long**. There are cases where the standard guarantees identical alignments, but in general there are no such guarantees. Such usage is making use of representation information and is covered by a guideline recommendation.

560 alignment pointer to structures
569.1 representation information using

Example

Do all the following objects have the same alignment?

```
1  #include <stdlib.h>
2  /*
3   * #pragma pack
4   */
5
6  struct S_1 {
7              unsigned char mem_1;
8              int mem_2;
9              float mem_3;
10            };
11
12 static unsigned char file_1;
13 static int           file_2;
14 static float         file_3;
15
16 void f(unsigned char param_1,
17        int           param_2,
18        float         param_3)
19 {
20 unsigned char        local_1, *p_uc;
21 int                  local_2, *p_i;
22 float                local_3, *p_f;
23
24 p_uc = (unsigned char *)malloc(sizeof(unsigned char));
25 p_i = (int *)malloc(sizeof(int));
26 p_f = (float *)malloc(sizeof(float));
27 }
```

No, they need not, although implementations often chose to use the same alignment requirements for each scalar type, independent of the context in which it occurs. The `malloc` function cannot know the use to which the storage it returns will be put, so it has to make worst-case assumptions.

```
1  /*
2   * Declare a union containing all basic types and pointers to them.
3   */
4  union align_u {
5          char           c, *cp;
6          short               h, *hp;
7          int            i, *ip;
8          long           l, *lp;
```

```
        long long      ll, *llp;
        float          f, *fp;
        double         d, *dp;
        long double    ld, *ldp;
        void          *vp;
/*
 * Pointer-to function.  The standard does not define any generic
 * pointer types, like it does for pointer to void.  The wording
 * only requires the ability to convert.  There is no requirement
 * to be able to call the converted function pointer.
 */
        void         (*fv)(void);
        void         (*fo)();
        void         (*fe)(int, ...);
        };
/*
 * In the following structure type, the first member has type char.
 * The second member, a union type, will be aligned at least to the
 * strictest alignment of its contained types.  Assume that there
 * is no additional padding at the end of the structure declaration
 * than in the union.  Then we can calculate the strictest alignment
 * required by any object type (well at least those used to
 * define members of the union).
 */
struct align_s {
        char           c;
        union align_u  u;
        };

#define _ALIGN_  (sizeof(struct _align_s) - sizeof(union _align_u))
```

3.3

argument

argument 40

actual argument

actual parameter (deprecated)

expression in the comma-separated list bounded by the parentheses in a function call expression, or a sequence of preprocessing tokens in the comma-separated list bounded by the parentheses in a function-like macro invocation

Commentary

The terms *argument* and *parameter* are sometimes incorrectly interchanged. One denotes an expression at the point of call, the other the identifier defined as part of a function or macro definition.

C++

The C++ definition, 1.3.1p1, does not include the terms *actual argument* and *actual parameter*.

Coding Guidelines

The term *actual parameter* is rarely used. While the standard may specify its usage as being deprecated, it cannot control the terms used by developers. This term is not used within the standard.

Example

```
#define M(a) ((a) - (1))

int f(int b) /* The object b is the parameter. */
{
```

```
5   return b + 2;
6   }
7
8   void g(int x, int y)
9   {
10  x=f(1); /* The literal 1 is the argument. */
11  y=M(x); /* The value of x is the argument. */
12  }
```

3.4

41 **behavior** behavior

external appearance or action

Commentary

Common usage of the word *behavior* would enable it to be applied to all kinds of constructs. By providing this definition, the standard is narrowing down the range of possible uses to a specific meaning.

Rationale

The terms unspecified behavior, undefined behavior, and implementation-defined behavior are used to categorize the result of writing programs whose properties the Standard does not, or cannot, completely describe. The goal of adopting this categorization is to allow a certain variety among implementations which permits quality of implementation to be an active force in the marketplace as well as to allow certain popular extensions, without removing the cachet of conformance to the standard.

External appearances can take many forms. Interactive devices may display pixels, memory-mapped devices may open and close relays, or a processor may not be as responsive (because it is executing a program whose purpose is to consume processor resources). The C Standard sometimes fully specifies the intended behavior and the ordering of actions (although this is not always unique). But in only one case does it discuss the issue of how quickly a behavior occurs.

203 interactive device intent

Coding Guidelines

Developers tend to use the word *behavior* in its general, dictionary sense and include internal changes to the program state. While this usage is not as defined by the C Standard, there is no obvious advantage in trying to change this existing practice.

3.4.1

42 **implementation-defined behavior** implementation-defined behavior

unspecified behavior where each implementation documents how the choice is made

Commentary

In choosing between making the behavior of a construct implementation-defined or unspecified, the Committee had to look at the ability of translator vendors to be able to meaningfully document their implementations behavior. For instance, for assignment the order in which the operands are evaluated may depend on a range of different conditions decided on during code optimization. The only way of documenting this behavior being to supply documentation showing the data structures and algorithms used, an impractical proposition.

49 unspecified behavior
100 implementation document
1294 assignment operand evaluation order

C90

Behavior, for a correct program construct and correct data, that depends on the characteristics of the implementation and that each implementation shall document.

The C99 wording has explicitly made the association between the terms implementation-defined and unspecified that was only implicit within the wording of the C90 Standard. It is possible to interpret the C90 definition as placing few restrictions on what an implementation-defined behavior might be. For instance, raising a signal or terminating program execution appear to be permitted. The C99 definition limits the possible behaviors to one of the possible behaviors permitted by the standard.

signed integer conversion 685
implementation-defined

C++

The C++ Standard uses the same wording, 1.3.5, as C90.

Other Languages

The C Standard is up front, and in general explicitly specifies the behavior that may vary between implementations. Other languages are not always so explicit. A major design aim for Java was to make it free of any implementation-defined behaviors. The intent is that Java programs exhibit the same behavior on all hosts. It will take time to see the extent to which this design aim can be achieved in practice.

Common Implementations

Many vendors list all of the implementation-defined behavior in an appendix of the user documentation.

Coding Guidelines

Some implementation-defined behaviors have no effect on the behavior of the abstract machine. For instance, the handling of the **`register`** storage-class specifier can affect execution time performance, but the program semantics remain unchanged. Some implementation-defined behaviors affect the execution time characteristics of a conforming program without affecting its output; for instance, the layout of structure members having a bit-field type.

bit-field 1409
addressable storage unit

The C Standard's definition of a strictly conforming program is based on the output produced by that program, not what occurs internally in the executing program image. Many coding guideline documents contain a blanket recommendation against the use of any implementation-defined behavior. This is a simplistic approach to guideline recommendations that is overly restrictive.

strictly conforming program 91
output shall not program image 141

Rev 42.1 Use of implementation-defined behavior shall be decided on a case-by-case basis. The extent to which the parameters of these cost/benefit decisions occur on a usage-by-usage based, a project-by-project basis, or a companywide-basis, is a management decision.

Coding guideline documents commonly recommend that a program's dependency on any implementation-defined behavior be documented. What purpose does such a guideline serve? Any well-written documentation would include information on implementation dependencies. The coding guidelines in this book do not aim to teach people how to write documentation. That said, the list of implementation-defined behaviors in annex J provides a good starting point.

Usage

Annex J.3 lists 97 implementation-defined behaviors.

EXAMPLE An example of implementation-defined behavior is the propagation of the high-order bit when a signed integer is shifted right. 43

EXAMPLE high-order bit propagation

3.4.2

locale-specific behavior 44

behavior that depends on local conventions of nationality, culture, and language that each implementation documents

locale-specific behavior

Commentary

The concept of locale was introduced by the C Standard. It has been picked up and extended by POSIX.[636]

Some of the execution time behavior that was implementation-defined in C90 has become locale-specific in C99. This allows programs that need to adapt to a locale to maintain a greater degree of standards conformance. Use of locale-specific behavior does not affect the conformance status of a program, while use of implementation-defined behavior means it cannot be strictly conforming (assuming that the program's output depends on it).

Rationale

While responding to a Defect Report filed against C89, the Committee came to realize that the term, "implementation-defined," was sometimes being used in the sense of "implementation must document" when dealing with locales. The term, "locale-specific behavior," already in C89, was then used extensively in C95 to distinguish those properties of locales which can appear in a strictly conforming program. Because the presence or absence of a specific locale is, with two exceptions, implementation-defined, some users of the Standard were confused as to whether locales could be used at all in strictly conforming programs.

A successful call to `setlocale` has side effects, known informally as "setting the contents of the current locale," which can alter the subsequent output of the program. A program whose output is altered only by such side effects— for example, because the decimal point character has changed— is still strictly conforming.

A program whose output is affected by the value returned by a call to `setlocale` might not be strictly conforming. If the only way in which the result affects the final output is by determining, directly or indirectly, whether to make another call to `setlocale`, then the program remains strictly conforming; but if the result affects the output in some other way, then it does not.

Common Implementations

A locale, other than `"C"`, for which there are many common implementations is Japanese.

The POSIX locale registry is slowly beginning to accumulate information on the locales of planet Earth. Both the Unix and Microsoft Windows host environments provide some form of interface to locale databases. It is these locales that C implementations usually provide a means of accessing.

Coding Guidelines

There are two locale issues that relate to these coding guidelines:

1. *The locale in which source code is translated.* Many coding guidelines relate to how developers extract information from source code. Having the source code written in the locale of the reader is likely to make this process easier. The issues involved in using identifiers that contain characters other than those in the basic execution character set are discussed elsewhere.
2. *The locale in which translated programs are executed.* Users want programs that adapt to their locales. The priority given to ensuring that software satisfies user's requirements is invariably much higher than that given to satisfying coding guidelines.

815 universal character name syntax
796 identifier UCN

Writing programs that depend on locale-specific behavior obviously reduces their portability to other locales. There is also the possibility that expected behaviors will not be available if the locale is changed. However, the issues involved in deciding when to use locale-specific behavior are outside the scope of these coding guideline subsections.

Implementations do not always fully document their handling of locale-specific behavior. Locales are a concept that is still evolving. To gain confidence in the behavior of an implementation, test programs need to be written to verify the behavior is as documented. Dealing with partial documentation is outside the scope of these coding guidelines.

45 EXAMPLE An example of locale-specific behavior is whether the **`islower`** function returns true for characters other than the 26 lowercase Latin letters.

EXAMPLE locale-specific behavior

Example

The character e-acute is a lowercase letter in a Latin-1 locale, but not the "C" locale.

3.4.3

undefined behavior

undefined behavior 46

behavior, upon use of a nonportable or erroneous program construct or of erroneous data, for which this International Standard imposes no requirements

Commentary

conforming programs may depend on 103

EXAMPLE constraint violation and undefined behavior 148

The term *nonportable* is discussed elsewhere.

Although a sequence of source code may be an erroneous program construct, a translator is only required to issue a diagnostic message for a syntax violation or a constraint violation. The erroneous data can occur during translation, or during execution. For instance, division by zero within a constant expression or a division operator whose right operand had been assigned a zero value during the execution of a previous statement.

The C Standard does not contain any requirements for issuing diagnostics at execution time.

C90

Behavior, upon use of a nonportable or erroneous program construct or of erroneous data, or of indeterminately valued objects, for which this International Standard imposes no requirements.

indeterminate value 75

trap representation 579

reading indeterminate value undefined behavior

unsigned char 571

pure binary

Use of an indeterminate value need not result in undefined behavior. If the value is read from an object that has **`unsigned char`** type, the behavior is unspecified. This is because objects of type **`unsigned char`** are required to represent values using a notation that does not support a trap representation.

Common Implementations

While the C Standard may specify that use of a construct causes undefined behavior, developers may have expectations of behavior or be unaware of what the C Standard has to say. Implementation vendors face customer pressure to successfully translate existing code. For this reason diagnostic messages are not usually generated at translation time when a construct causing undefined behavior is encountered.

The following are some of the results commonly seen when executing constructs exhibiting undefined behavior:

- *A signal is raised.* For instance, `SIGFPE` on divide by zero, or `SIGSEGV` when dereferencing a pointer that does not refer to an object.
- *The defined behavior of the processor occurs.* For instance, two's complement modulo rules for signed integer overflow.
- *The machine code generated as a result of a translation time decision is executed.* For instance, `i = i++;` may have been translated to the machine code `LOAD i; STORE i; INC i;` (instead of `INC i; LOAD i; STORE i;`, or some other combination of instructions).

Coding Guidelines

Developers are often surprised to learn that some construct, which they believed to have well-defined behavior, actually has undefined behavior. They often have clear ideas in their own heads of what the implementation behavior is in these cases and consider that to be the behavior mandated by the standard. This is an issue of developers' education and is outside the scope of these coding guidelines (although vendors of static analysis tools may consider it worthwhile issuing a diagnostic for uses of such constructs).

Usage

Annex J.2 lists 190 undefined behaviors.

---

47 NOTE Possible undefined behavior ranges from ignoring the situation completely with unpredictable results, to behaving during translation or program execution in a documented manner characteristic of the environment (with or without the issuance of a diagnostic message), to terminating a translation or execution (with the issuance of a diagnostic message).

undefined behavior possible

Commentary

This is only a list of possible behaviors; it is not intended to be a complete list. Behaving in a documented manner, plus issuing a diagnostic, is often considered to be the ideal case.

Common Implementations

The two most common ways of handling a construct, whose behavior is undefined, are to issue a diagnostic and to ignore it completely (the translator continuing to translate, or the execution environment delivering whatever result happens to occur). Some translators provide options that allow the developer to select the extent to which a translator will attempt to diagnose these constructs (e.g., the *-Wall* option of `gcc`). Very few implementations document any of their handling of undefined behaviors.

Some undefined behaviors often give consistent results, e.g., signed integer overflow, while in other cases the behavior is understood but the results are completely unpredictable. For instance, when accessing an object after its lifetime has ended, the common behavior is to access the storage previously assigned to that object, but the value held in that location is unpredictable.

Most diagnostics issued during program execution (most implementations issue a few during translation) are as a result of the program violating some host requirement in some way (for instance, a misaligned access to storage) and the host issuing a diagnostic prior to terminating program execution.

Coding Guidelines

There are a some undefined behaviors that give consistent results on many processors, for instance, the result of a signed integer overflow. Making use of such behavior is equivalent to making use of representation information, which is covered by a guideline recommendation.

569.1 representation information using

---

48 EXAMPLE An example of undefined behavior is the behavior on integer overflow.

EXAMPLE undefined behavior

3.4.4

---

49 **unspecified behavior**

use of an unspecified value, or other behavior where this International Standard provides two or more possibilities and imposes no further requirements on which is chosen in any instance

unspecified behavior

Commentary

The difference between unspecified (implementation-defined) and undefined is that the former applies to a correct program construct and correct data while the latter applies to an erroneous program construct or erroneous data. Are there any restrictions on possible translator behaviors? The following expresses the Committee's intent:

42 implementation-defined behavior

88 correct program

> This latitude does not extend as far as failing to translate the program.

Rationale

The wording was changed by the response to DR #247.

C90

Behavior, for a correct program construct and correct data, for which this International Standard imposes no requirements.

The C99 wording more clearly describes the intended meaning of the term *unspecified behavior*, given the contexts in which it is used.

C++

1.3.13 *behavior, for a well-formed program construct and correct data, that depends on the implementation. The implementation is not required to document which behavior occurs. [Note: usually, the range of possible behaviors is delineated by this International Standard.]*

This specification suggests that there exist possible unspecified behaviors that are not delineated by the standard, while the wording in the C Standard suggests that all possible unspecified behaviors are mentioned.

Common Implementations

Because there is no requirement to document the behavior in these cases, and the frequent difficulty of being able to say anything specific, most vendors say nothing.

Coding Guidelines

For implementation-defined behaviors, it is possible to read the documented behavior. For unspecified behaviors vendors do not usually document possible behaviors.

All nontrivial programs contain unspecified behavior; for instance, in the expression `b+c`, it is unspecified whether the object `b` is accessed before or after the object `c`. But, unless both objects are defined using the **`volatile`** qualifier, the order has no affect on a program's output.

type qualifier 1476 syntax

A blanket guideline recommendation prohibiting the use of any construct whose behavior is unspecified would be counterproductive. If the behavior of a construct is unspecified, but the behavior of the program containing it is identical for all of the different possibilities, the usage should be regarded as acceptable. How possible, different unspecified behaviors might be enumerated and the effects these behaviors have on the output of a program is left to developers to deduce. This issue is also covered by a guideline recommendation discussed elsewhere.

sequence 187.1 points all orderings give same value

Example

In an optimizing compiler the order of evaluation of expressions is likely to depend on context: What registers are free to store intermediate values; What registers contain previously calculated values that can be reused in the current expression? Documenting the behavior would entail describing all of the flow analysis, expression tree structure, and code optimization algorithms. In theory the order of evaluation, for each expression, could be deduced from this information. However, it would be impractical to carry out.

```
1  #include <stdio.h>
2
3  static int glob_1, glob_2;
4
5  int main(void)
6  {
7  if ((glob_1++, (glob_1+glob_2)) == (glob_2++, (glob_1+glob_2)))
8     printf("We may print this\n");
9  else
10    printf("or we may print this\n");
11 }
```

Usage

Annex J.1 lists 50 unspecified behaviors.

50 EXAMPLE An example of unspecified behavior is the order in which the arguments to a function are evaluated.

3.5

51 **bit** bit

unit of data storage in the execution environment large enough to hold an object that may have one of two values

Commentary

Although it is the most commonly used representation in silicon-based processors, two-valued logic is not the most efficient form of representation. The most efficient radix, in terms of representation space (number of digits times number of possible values of each digit), is, e[555] (i.e., 2.718 . . .). The closest integral value to e is 3. While using a ternary representation maximizes the efficiency of representation, there are practical problems associated with its implementation.

The two states needed for binary representation can be implemented using a silicon transistor in its off (very low-voltage, high-current) and saturated (high-voltage, very low-current) states. Transistors in these two states consume very little power (voltage times current). Using transistors to implement a ternary representation would require the use of a third voltage (for instance, midway between low and high). At such a midpoint voltage, the current would also be mid-way between very low and high and the corresponding power consumption would be significantly higher than the off and saturated states. Power consumption, or rather the heat generated by it, is a significant limiting factor in processors built using transistors.

Vendors have chosen to trade-off efficiency of representation for the lower power consumption needed to prevent chips melting. Processors based on a binary representation are overwhelmingly used today. The definition of the C language reflects this fact.

C++

The C++ Standard does not explicitly define this term. The definition given in ISO 2382 is “Either of the digits 0 or 1 when used in the binary numeration system.”. 25 ISO 2382

Other Languages

The concept of a bit is a low-level one, intimately connected to the processor architecture. Many languages do not get explicitly involved in this level of detail. The language of Carbon-based processors (at least on planet Earth), DNA, uses a unit of storage that has one of four possible values (a *quyte*[41]): *A*, *C*, *G*, or *T*.

Common Implementations

Processors rarely provide a mechanism for referencing a particular bit in storage. The smallest unit of addressable storage is usually the byte. There are a few applications where the data is not byte-aligned and processors supporting some form of bit-level addressing are available.[1012] Automatic mapping of C source that performs its own manipulation of sequences of bits (using the bitwise operators) to use these processor instructions is not yet available. However, at least one research compiler[1432] provides support via what, to the developer, looks like a function-call interface. 53 byte addressable unit

52 NOTE It need not be possible to express the address of each individual bit of an object. bit address of

Commentary

The smallest object that is required to be addressable is one having character type. The number of bits in such an object is defined by the `CHAR_BIT` macro, which must have a value greater than or equal to 8. 515 character types 307 CHAR_BIT macro

Common Implementations

Processors rarely support bit addressing, although a few of them have instructions for extracting a sequence of bits (that is not a multiple of a byte) from a storage location.

3.6

byte
addressable unit

byte 53

addressable unit of data storage large enough to hold any member of the basic character set of the execution environment

Commentary

octet

A byte is traditionally thought of as occupying 8 bits. The technical term for a sequence of 8 bits is *octet*. POSIX[636] defines a byte as being an octet (i.e., 8 bits). These standards also define the terms *byte* and *character* independently of each other.

character 59 single-byte
CHAR_BIT 307 macro
char 477 hold any member of execution character set

There is something of a circularity in the C Standard's definition of byte and character. The macro `CHAR_BIT` defines the number of bits in a character type and is required to have a minimum value of 8. The definition of byte deals with data storage, while that for the **char** type deals with type.

This term first appeared in print in 1959.[176]

Other Languages

The DNA encoding used in Carbon based processors uses three *quytes*[41] (each of which has one of the four possible values *A*, *C*, *G*, or *T*) to form a *codon*. The 64 possible codons are used to represent different amino acids, which are used to make proteins, plus a representation for *stop*.

byte
address unique

NOTE 1 It is possible to express the address of each individual byte of an object uniquely. 54

Commentary

banked 559 storage

What is an address? In most cases it is taken to be the value representation held in a pointer object. In some cases a pointer object may not contain all the information needed to calculate an address. For instance, the IAR PICmicro compiler[612] provides access to more than 10 different kinds of banked storage. Pointers to this storage can be 1, 2, or 3 bytes in size. On such a host the address of an object is the combination of the pointer value and information on the bank being referred to (which is encoded either in the instruction accessing the byte or a status register).

There is no requirement that the *addressable unit* be the address returned by the address-of operator, with the object as its operand. An implementation may choose to indirectly reference the actual storage used to hold an object's value representation via a lookup table, indexed by the value returned by the address-of, **&**, operator. This index value is then the *address* seen by programs.

object 570 contiguous sequence of bytes
object 765 point at each bytes of
value 573 copied using unsigned char
structure 1206 members later compare later
lifetime 451 of object
union type 531 overlapping members

Objects are made up of one or more bytes and it is possible to calculate values that point at any of them. The standard is therefore requiring that the individual bytes making up an object are uniquely identifiable. An implementation cannot hide the internal bits of an object. The ordering of bytes within an object and their relative addresses is not defined by the standard (although the relative order of structure members and array elements is defined). This requirement does not prevent more than one object from sharing the same address (i.e., their lifetimes may be different, or they may be members of a union type).

Common Implementations

word addressing

So-called *word addressed* processors only assign unique addresses to units of storage larger than 8 bits (for instance, 32-bit quantities, the word). Implementations for such processors have two choices: (1) define a byte to be the word size (e.g., the Motorola DSP56300 which has a 24 bit word[967] and the Analog Devices SHARC has a 32-bit word[30]), or (2) addresses of types smaller than a word use a different representation. Unless there is hardware support, the choice is usually to select the first option. With hardware support, some vendors chose option 2 (or to be exact they did not like option 1 and added support for a different representation, the offset of the byte within a word being encoded in additional representation bits). For instance, the Cray PVP[515] uses a 64-bit representation for pointers to character and **void** types and a 32-bit value representation for pointers to other types (a 64-bit object representation is used); a version of PR1ME Computers C compiler used 48-bit and 32-bit representations, respectively.

For the HP 3000 architecture, it was necessary to be extremely careful of conversions from byte addresses to word addresses and vice versa because of negative stack addressing, which makes byte addresses ambiguous.

The original Hewlett-Packard MPE processor (not the later models based on PA-RISC) was word addressed, using 16-bit words (128 K bytes). Byte addresses were signed from -64 K to +64 K, the sign depending on the current setting of the DL and Z registers. This scheme made it possible to access all the storage using byte addresses, but it created an ambiguity in the interpretation of a byte address value (this could only be resolved by knowing the settings of two processor registers).

Some processors are *word addressed* and don't use all the available representation bits. For instance, the Data General Nova[319] used only 15 of a possible 16 bits to address storage. The convention of using the additional bit to represent one of the two 8-bit quantities within a 16-bit word was adopted as a software solution to a hardware limitation (i.e., two software routines were provided to read and write individual bytes in storage, using addresses constructed using this convention).

The C Standard recognizes that not all pointer types have the same representation requirements.

562 alignment pointers

Coding Guidelines

Developers often assume more about the properties of the addresses of bytes than the C Standard requires of an implementation support; for instance, the extent to which bytes are allocated at similar addresses (an important consideration if performing relational operations on those addresses). The extent to which it is possible to make assumptions about the addresses of bytes is discussed elsewhere.

570 object contiguous sequence of bytes

Example

```
#include <stdio.h>

extern short glob;

void f(void)
{
int working_g = glob;
/*
 * Write out bytes, starting from least significant byte.
 */
for (int g_index=0; g_index < sizeof(glob); g_index++)
   {
   unsigned char uc = (working_g & UCHAR_MAX);
   fwrite(&uc, 1, 1, stdout);
   working_g >>= CHAR_BIT;
   }

/*
 * Will the following generate least or most significant
 * byte orderings?  Could be same or different from above.
 */
fwrite(&glob, sizeof(glob), 1, stdout);
}
```

---

55 NOTE 2 A byte is composed of a contiguous sequence of bits, the number of which is implementation-defined.

Commentary

Implementations where, for instance, the first four bits of a byte are separated from the second four bits by a single bit that is not part of that byte are not permitted. The type **`unsigned char`** is specified to use all the bits in its representation. The representational issues of this contiguous sequence of bits are discussed elsewhere.

573 value copied using unsigned char
595 value representation
574 object representation

The number of bits must be at least 8, the minimum value of the `CHAR_BIT` macro.

307 CHAR_BIT macro

Common Implementations

At the hardware level, storage can use one or more parity bits for error detection and correction (more than one bit is required for this). These additional bits are not visible through the conventional storage access mechanisms. Some hardware platforms do provide methods for accessing the bits in storage at the chip level.

---

low-order bit

The least significant bit is called the *low-order bit*; 56

Commentary

This defines the term *low-order bit*.

---

high-order bit

the most significant bit is called the *high-order bit*. 57

Commentary

This defines the term *high-order bit*.

3.7

---

character <abstract>

character 58

⟨abstract⟩ member of a set of elements used for the organization, control, or representation of data

Commentary

This is the abstract definition of the term *character* (it is a very minor rewording of the definition given in ISO/IEC 2382–1:1993). The C-specific sense of the term *character* is given in the following (standard) sentence.

Characters are not created as stand-alone entities. Each is part of a larger whole, a character set. There are a large number of character sets (see Fischer[425] for the history until 1968), one for almost ever human language in the world. A character set provides another means of interpreting sequences of bits.

glyph

Characters are the smallest components of written languages that can have semantic value. The visible appearance of a character when it is displayed is called a *glyph* (there are often many different possible glyphs that can be used to represent the same character). A single character may be representable in a single byte (usually an alphabetic character) or may require several bytes (a multibyte character, often representing what English speakers would call a symbol). A repertoire (set) of glyphs is called a font (see Figure 792.17).

character 59
single-byte
multibyte 60
character
basic source 221
character set

The C Standard defines the basic character set that it requires an implementation to support.

C++

The C++ Standard does not define the term *character*; however, it does reference ISO/IEC 2382. Part 1, Clause 01.02.11, defines *character* using very similar wording to that given in the C Standard. The following might also be considered applicable.

17.1.2 *in clauses 21, 22, and 27, means any object which, when treated sequentially, can represent text. The term does not only mean* **`char`** *and* **`wchar_t`** *objects, but any value that can be represented by a type that provides the definitions provided in these clauses.*

3.7.1

---

character single-byte

character 59

single-byte character ⟨C⟩ bit representation that fits in a byte

Commentary

byte 53
addressable unit

This is the C-specific definition of the term *character*. It is a little circular in that byte is defined in terms of a character. The definition of the term *character*, referring to it in the abstract sense, is given in the previous sentence. Members of the basic source character set are required to fit in a byte. By definition any other character that fits in a byte is a single-byte character.

basic source 221
character set

C++

The C++ Standard does not define the term *character*. This term has different meanings in different application contexts and human cultures. In a language that supports overloading, it makes no sense to restrict the usage of this term to a particular instance.

Coding Guidelines

The terms character and byte are often used interchangeably by C developers. Changing developers' existing terminological habits may be very difficult, but this is not a reason why coding guideline documents should be sloppy in their use of terminology. Separating the two concepts can be helpful in highlighting potential problems associated with assuming particular representations for members of character sets (usually Ascii).

3.7.2

60 **multibyte character** multibyte character

sequence of one or more bytes representing a member of the extended character set of either the source or the execution environment

Commentary

Multibyte characters are a means of representing characters from those character sets that contain more members than can be represented in a byte.[875] Somewhat confusingly the term *extended character set* is used by the C Standard to denote all supported characters, not just the extended characters. 216 extended character set 215 extended characters

A multibyte character is usually made up of a sequence of bytes that can be generated by pressing keys on the commonly available keyboards. There is not usually an obvious correspondence between the sequence of byte values and the numeric value of a member of the execution character set (such a correspondence does exist for a wide character), but there is an algorithm (often specified using a finite state machine) for converting them to this execution character set value. 243 multibyte character state-dependent encoding

Note: The use of the term *character* in the C Standard excludes multibyte characters, unless explicitly stated otherwise. This convention is also followed in the non-C Standard material in this book.

Common Implementations

The sequence of bytes in a multibyte character often has no relationship to what a developer types on a keyboard. For instance, at one end of the scale UTF-8 is unrelated to keystrokes. At the other end, many European keyboards have *dead keys* so that the single-byte characters *a-grave* or *i-circumflex* might be typed as *grave* followed by *a* or *circumflex* followed by *i*.

The most commonly used encoding methods include ISO 2022, EUC (Extended Unix Code), Big Five, Shift-JIS, and ISO 10646. Lunde[875,876] covers East Asian characters and their representations and encodings in great detail. 243 ISO 2022

61 NOTE The extended character set is a superset of the basic character set.

Commentary

The definition of the terms *basic character set* and *extended character set* implies that they are disjoint sets. 215 basic character set 216 extended character set

3.7.3

62 **wide character** wide character

bit representation that fits in an object of type **`wchar_t`**, capable of representing any character in the current locale

Commentary

A wide character can be thought of as the execution-time representation of a multibyte character. It is a pattern of bits held in an object, of type `wchar_t`, much like a character is a pattern of bits. The `wchar_t` type 60 multibyte character

often contains more than one byte, so it is capable of representing many more values. The bit representation of a particular character, held in an object of `wchar_t` type, can vary between locales.

Wide characters are best suited to be used when the numeric values of the characters are of importance, or when a fixed-size object is needed to manipulate character data.

C++

The C++ Standard uses the term *wide-character literal* and *wide-character sequences*, 17.3.2.1.3.3, but does not define the term *wide character*.

2.13.2p2 *A character literal that begins with the letter L, such as `L'x'`, is a wide-character literal.*

Common Implementations

On many implementations the `wchar_t` type usually occupies 16 bits. So, up until recently, it was capable of ISO 10646 28 being used to hold the values assigned to characters by the Unicode Consortium.

3.8

constraint

constraint 63

restriction, either syntactic or semantic, by which the exposition of language elements is to be interpreted

Commentary

These are the constructs that a conforming translator must detect and issue a diagnostic for, if encountered during translation of the source. Constraint and syntax violations are the only kinds of construct, defined by the standard, for which an implementation is required to issue a diagnostic.

In C, constraints only appear in subclauses that have the heading Constraints. These appear in Clause 6, shall 82 Language, but not Clause 7, Library. These language constraints are specified by use of the word *shall* within one of these subclauses. Violating a requirement specified using the word *shall* that appears within another shall 84 outside constraint kind of subclause causes undefined behavior.

C++

The C++ Standard does not contain any constraints; it contains diagnosable rules.

1.3.14 well-formed program *a C++ program constructed according to the syntax rules, diagnosable semantics rules, and the One Definition Rule (3.2).*

However, the library does use the term constraints.

17.4.3 Constraints on programs *This subclause describes restrictions on C++ programs that use the facilities of the C++ Standard Library.*

17.4.4p1 *This subclause describes the constraints upon, and latitude of, implementations of the C++ Standard library.*

But they are not constraints in the C sense of requiring a diagnostic to be issued if they are violated. Like C, the C++ Standard does not require any diagnostics to be issued during program execution.

Coding Guidelines

There is a common, incorrectly, held belief that diagnostics are issued for violations of any requirement contained within the C Standard. Diagnostics need only be issued for violations of requirements contained within a Constraints clause. Educating developers of the differences between constraints and the other forms of behavior described in the standard is an issue that is outside the scope of these coding guidelines.

Usage

There are 134 instances of the word *shall* in a Constraints clause (out of 588 in the complete standard). This places a lower bound on the number of constraints that can be violated (some uses of *shall* describe more than one kind of construct).

3.9

---

64 **correctly rounded result** correctly rounded result

representation in the result format that is nearest in value, subject to the ~~effective~~current rounding mode, to what the result would be given unlimited range and precision

Commentary

In Figure 64.1 the value b is midway between the representable values x and y. The representable value it will round to depends on the sign of its value, whether the rounding mode is round-to-even (least significant bit not set), round-to-zero, or round-to ±infinity. The values a and c have a *nearest* value to round to, if that rounding mode is in effect. [352] FLT_ROUNDS

`DBL_MAX*(1+DBL_EPSILON)` is *nearest* to `DBL_MAX` (in the Euclidean sense) but it is rounded to infinity.

The result referred to here is the result of a single arithmetic operation, not the result of an expression containing more than one operation. For instance, the expression `a+b-c` consists of the operation `a+b`, whose result then has `c` subtracted from it. If `a=1`, `b=1E-25`, and `c=1`, the correctly rounded result (assuming IEC 60559 single-precision) of `a+b` is `1`, and after the subtraction operation the final result of the complete expression is `0` (the expression can be rewritten to return the result `1E-25`).

The notation used to indicate rounded arithmetic operations is to place a circle around the operator; for instance:

$$x \oplus y = round(x + y) \tag{64.1}$$

where $x + y$ denotes the exact mathematical result. Based on the preceding example it is obvious that, in general:

$$a \oplus b \ominus c \neq a \ominus c \oplus b \tag{64.2}$$

The issue of correctly rounded results for some of the functions defined in the header **`<math.h>`** is discussed by Lefèvre and Muller.[827]

The wording was changed by the response to DR #286.

C++

This term is not defined in the C++ Standard (the term *rounded* only appears once, when discussing rounding toward zero).

Common Implementations

Implementations that don't always round correctly include some Cray processors and the IBM S/360 (truncates).

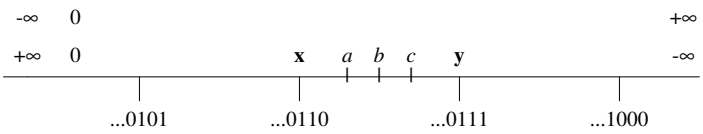

Figure 64.1: Some exactly representable values and three values (a, b, and c) that are not exactly representable.

Some implementations use a different rounding process when performing I/O than when performing floating-point operations. For instance, should the call `printf("%.0f", 2.5)` produce the same correctly rounded result (as output on `stdout`) as the value stored in an equivalent assignment expression?

Parks[1058] discusses methods for generating test cases that stress various boundary conditions that occur when rounding floating-point values.

Coding Guidelines

The fact that the term *correctly rounded result* can denote different values under different circumstances is something that should be included in the training of developers' who write code that uses floating-point types.

Obtaining the correctly rounded result of an addition or subtraction operation requires an additional bit in the significand (as provided by the IEC 60559 guard bit) to hold the intermediate result.[500] When multiplying two p bit numbers the complete $2p$ bits of the intermediate result need to be generated, before producing the final correctly rounded, p bit, result. A floating-point calculation that frequently occurs, for instance, in the evaluation of the determinant of a matrix is:

```
1  float d, w, x, y, z;
2
3  /* Use casts in case the minimum evaluation format is float. */
4
5  d = ((double)w) * x - ((double)y) * z;
```

If the relative precision of the type **`double`** is at least twice that of the type **`float`**, then the result will be correctly rounded (implementations where the types **`float`** and **`double`** have the same precision are not uncommon).

3.10

diagnostic message

diagnostic message

message belonging to an implementation-defined subset of the implementation's message output

Commentary

There is no requirement that the diagnostic message say anything of consequence. An implementation could choose to play a tune. Market forces usually dictate that the quality of most implementation diagnostic messages be more informative.

Common Implementations

Most implementations attempt to localize the construct being diagnosed. Localization usually occurs to the extent of giving a line number in the source code and an offset within that line. In some cases, for instance during macro expansion, the exact line number or character offset within a line may not be clear-cut.

macro replacement

All vendors like to think that their diagnostic messages are meaningful to developers. Diagnostic messages sometimes include a reference to what is considered to be the appropriate section of the C Standard.

Example

```
1  void f(int valu)
2  {
3  int log;
4
5  /* ... */
6  if (valu == 99)
7     {
8     int loc;
9     /* ... */
10    }
```

```
11
12  valu = loc;
13  /*
14   * What diagnostic is applicable to the previous statement:
15   *
16   *    o loc not declared,
17   *    o statement valu=loc should occur before prior closing brace,
18   *    o Previous closing brace should appear after this statement,
19   *    o Identifier log misspelled as loc.
20   */
21  }
```

3.11

66 **forward reference** forward reference

reference to a later subclause of this International Standard that contains additional information relevant to this subclause

Commentary

The references contained within a forward reference are not always exhaustive, neither are all applicable forward references always cited.

C++

C++ does not contain any forward reference clauses. However, the other text in the other clauses contain significantly more references than C99 does.

3.12

67 **implementation** implementation

particular set of software, running in a particular translation environment under particular control options, that performs translation of programs for, and supports execution of functions in, a particular execution environment

Commentary

The Committee tried to be as general as possible. They did not want to tie down how C programs might be processed to obtain the output required by the abstract machine.

It is not necessary to move to a different O/S or processor to use a different implementation. Each new release of a translator is a different implementation, even each invocation of a translator with different options enabled, or use of a different set of libraries, is a different implementation.

C++

The C++ Standard does not provide a definition of what an implementation might be.

Common Implementations

The software running in the translation environment is usually called a compiler. The software running in the execution environment is usually called the runtime system; it may also include an interpreter for the code generated by the compiler.

3.13

68 **implementation limit** implementation limit

restriction imposed upon programs by the implementation

Commentary

The Committee recognized that there are limits in the real world. The intent of calling them out is to highlight to the developer where they might occur and, by specifying values to give a base to work from. 273 environmental limits

Common Implementations

translation limits 276

All implementations have limits of various kinds. Even if very large amounts of memory and swap space are available, given a sufficiently large program, it will not be sufficient. Implementations also place limits on the range and precision of representable values. In this case there are efficiency issues; it would be possible to provide arbitrary ranges and precision. The greater the range and precision that must be handled, the longer it takes to perform an operation.

Coding Guidelines

Having a program keep within all implementation limits increases its portability. However, the extent to which portability to hosts is likely to impose limits, that a program exceeds, is an issue that needs to be decided by management. Specific implementation issues are discussed, in these coding guidelines, where they occur in the C Standard.

3.14

object

object

region of data storage in the execution environment, the contents of which can represent values

Commentary

object 570
contiguous sequence of bytes
value representation 595
object representation 574

Objects are created by definitions and calls to the library memory-allocation functions. The region of data storage for objects is a contiguous sequence of bytes. Representation of values within the region of data storage allocated to objects is discussed in great detail later in the standard.

C++

While an *object* is also defined, 1.8p1, to be a region of storage in C++, the term has many other connotations in an object-oriented language.

Other Languages

What C calls objects are often called variables in other languages.

Coding Guidelines

Many developers use the term *variable* to refer to what the C Standard calls an object. The introduction of the term *object-oriented* has meant that few developers use the term *object* in the C sense. Trying to change developer terminology in this case is liable to lead to confusion, and to be of little use (apart from being technically correct).

Example

```
#include <stdlib.h>

extern int glob;    /* Declaration of a named object. */

void f(long param)  /* A parameter is also an object. */
{
typedef short S_17; /* No storage created, not an object. */

float * p_f = (float *)malloc(sizeof(float)); /* Create an unnamed object. */
}
```

The response to DR #042 (question 2) specified that the bytes from which an object is composed need not correspond to any type declared in the program. For instance, a contiguous sequence of elements within an array can be regarded as an object in its own right. Nonoverlapping portions of an array can be regarded as objects in their own right.

```
#include <stdlib.h>
#include <string.h>
```

```
3
4   extern int N;
5
6   void DR_042(void)
7   {
8   void *p = malloc(2*N); /* Allocate an object. */
9
10     {
11     char (*q)[N] = p; /*
12                        * The object pointed to by p may be interpreted
13                        * as having type (char [2][N]) when referenced
14                        * through q.
15                        */
16     memcpy(q[1], q[0], N);
17     }
18     {
19     char *r = p; /*
20                   * The object pointed to by p may be interpreted as
21                   * having type (char [2*N]) when referenced through r.
22                   */
23     memcpy(r+N, r, N);
24     }
25  }
```

70 NOTE When referenced, an object may be interpreted as having a particular type; see 6.3.2.1.

reference object

Commentary

A reference that is also an access requires the bits making up an object to be interpreted as a value. This requires that it be interpreted as having a particular type. A reference that does not interpret the contents of an object, for instance an argument to the `memcpy` library function, does not need to interpret it as having a particular type. The issue of the type of an object, when it is referenced, is dealt with in detail elsewhere.

35 access
723 particular type
948 effective type

C++

The properties of an object are determined when the object is created. 1.8p1

This referenced/creation difference, compared to C, is possible in C++ because it contains the **`new`** and **`delete`** operators (as language keywords) for dynamic-storage allocation. The type of the object being created is known at the point of creation, which is not the case when the `malloc` library function is used (one of the reasons for the introduction of the concept of effective type in C99).

948 effective type

Coding Guidelines

A guideline recommendation dealing with the types that may be used to reference a given object is discussed elsewhere.

949.1 object effective type shall stay the same

Example

```
1   static int glob;
2
3   void f(void)
4   {
5   unsigned char *p_uc = (unsigned char *)&glob;
6
7   glob = 3;  /* Object glob interpreted to have type int. */
8
```

```
9   *p_uc = 3; /* Same object interpreted as an array of unsigned char. */
10  }
```

3.15

parameter

parameter 71

formal parameter

formal argument (deprecated)

object declared as part of a function declaration or definition that acquires a value on entry to the function, or an identifier from the comma-separated list bounded by the parentheses immediately following the macro name in a function-like macro definition

Commentary

The term *formal argument* is rarely used. The term *formal parameter* is sometimes seen in documents written by people with a mathematically oriented computer science education.

Coding Guidelines

argument 40

The terms *argument* and *parameter* are sometimes incorrectly interchanged in discussions between developers. The context can often be used by the listener to deduce the intended meaning.

Example

```
1   #define FUNC_MACRO(x, y) /* Two parameters. */
2
3   void f(int param_1)      /* One parameter.  */
4   { /* ... */ }
5
6   int g(param_2)           /* One parameter.  */
7   int param_2;
8   { /* ... */ }
```

3.16

recommended practice

recommended practice 72

specification that is strongly recommended as being in keeping with the intent of the standard, but that may be impractical for some implementations

Commentary

The Recommended practice subsections have no more status than any other statement in the C Standard that is not mandatory.

C90

The *Recommended practice* subsections are new in C99.

C++

C++ gives some recommendations inside "[Note: . . .]", but does not explicitly define their status (from reading C++ Committee discussions it would appear to be non-normative).

Other Languages

Implementation Advice

Optional advice given to the implementer. The word "should" is used to indicate that the advice is a recommendation, not a requirement. It is implementation defined whether or not a given recommendation is obeyed.

Common Implementations

The C99 Standard is still too new to have any experience with how closely the new concept of recommended practice is followed.

Coding Guidelines

The extent to which *recommended practice*s will be followed by implementations is unknown. The specific instances are discussed when they occur.

3.17

---

73 **value** value

precise meaning of the contents of an object when interpreted as having a specific type

Commentary

For instance, the bits making up an object could be interpreted as an integer value, a pointer value, or a floating-point value. The definition of the type determines how the contents are to be interpreted. 1352 declaration interpretation of identifier

A literal also has a value. Its type is determined by both the lexical form of the token and its numeric value. 835 integer constant type first in list

C++

The value representation of an object is the set of bits that hold the value of type T. 3.9p4

Coding Guidelines

This definition separates the ideas of representation and value. A general principle behind many guidelines is that making use of representation information is not cost effective. The C Standard does not provide many guarantees that any representation is fixed (in places it specifies that two representations are the same). 569.1 representation information using

Example

```
1  #include <stdio.h>
2
3  union {
4        float mem_1;
5        int mem_2;
6        char *mem_3;
7        } x = {1.234567};
8
9  int main(void)
10 {
11 /*
12  * Interpret the same bit pattern using various types.
13  * The values output might be: 1.234567, 1067320907, 0x3f9e064b
14  */
15 printf("%f, %d, %p\n", x.mem_1, x.mem_2, x.mem_3);
16 }
```

3.17.1

implementation-defined value

implementation-defined value 74

unspecified value where each implementation documents how the choice is made

Commentary

unspecified value 76

Implementations are not required to document any unspecified value unless it has been specified as being implementation-defined. The semantic attribute denoted by an implementation-defined value might be applicable during translation (e.g., `FLT_EVAL_METHOD`), or only during program execution (e.g., the values assigned to `argv` on program startup).

FLT_EVAL_METHOD 354
argv 171
values

C90

Although C90 specifies that implementation-defined values occur in some situations, it never formally defines the term.

C++

The C++ Standard follows C90 in not explicitly defining this term.

Coding Guidelines

symbolic name 822

Implementation-defined values can vary between implementations. In some cases the C Standard defines a symbol (usually a macro name) to have certain properties. The key to using symbolic names is to make use of the property they denote, not the representation used (which includes the particular numerical value, as well as the bit pattern used to represent that value). For instance, a comparison against `UCHAR_MAX` should not be thought of as a comparison against the value `255` (or whatever its value happens to be), but as a comparison against the maximum value an object having **`unsigned char`** type can have. In some cases the result of an expression containing a symbolic name can still be considered to have a property. For instance, `UCHAR_MAX-3` might be said to represent the symbolic value having the property of being three less than the maximum value of the type **`unsigned char`**.

Example

```
#include <limits.h>

int int_max_div_10 = INT_MAX / 10;    /* 1/10th of the maximum representable int. */
int int_max_is_even = INT_MAX & 0x01; /* Testing for a property using representation information. */
```

3.17.2

indeterminate value

indeterminate value 75

either an unspecified value or a trap representation

Commentary

object 461
initial value indeterminate

This is the value objects have prior to being assigned one by an executing program. In practice it is a conceptual value because, in most implementations, an object's value representation makes use of all bit patterns available in its object representation (there are no spare bit patterns left to represent the indeterminate value).

unspecified value 76
trap representation 579
reading is undefined behavior

Accessing an object that has an unspecified value results in unspecified behavior. However, accessing an object having a trap representation can result in undefined behavior.

C++

Objects may have an indeterminate value. However, the standard does not explicitly say anything about the properties of this value.

4.1p1

. . . , or if the object is uninitialized, a program that necessitates this conversion has undefined behavior.

Common Implementations

A few execution time debugging environments tag storage that has not had a value stored into it so that read accesses to it cause a diagnostic to be issued.

Coding Guidelines

Many coding guideline documents contain wording to the effect that "indeterminate value shall not be used by a program." Developers do not intend to use such values and such usage is a fault. These coding guidelines are not intended to recommend against the use of constructs that are obviously faults.

0 guidelines not faults

Example

```
1  extern int glob;
2
3  void f(void)
4  {
5  int int_loc;     /* Initial value indeterminate. */
6  unsigned char uc_loc;
7
8  /*
9   * The reasons behind the different status of the following
10  * two assignments is discussed elsewhere.
11  */
12 glob = int_loc; /* Indeterminate value, a trap representation. */
13 glob = uc_loc;  /* Indeterminate value, an unspecified value.  */
14 }
```

3.17.3

76 **unspecified value** unspecified value

valid value of the relevant type where this International Standard imposes no requirements on which value is chosen in any instance

Commentary

Like unspecified behavior, unspecified values can be created by strictly conforming programs. Making use of such a value is by definition dependent on unspecified behavior.

49 unspecified behavior

Coding Guidelines

In itself the generation of an unspecified value is usually harmless. However, a coding guideline's issue occurs if program output changes when different unspecified values, chosen from the set of values possible in a given implementation, are generated. In practice it can be difficult to calculate the affect that possible unspecified values have on program output. Simplifications include showing that program output does not change when different unspecified values are generated, or a guideline recommendation that the construct generating an unspecified value not be used. A subexpression that generates an unspecified value having no affect on program output is dead code.

49 unspecified behavior

190 dead code

Example

```
1  extern int ex_f(void);
2
3  void f(void)
4  {
```

```
5   int loc;
6   /*
7    * If a call to the function ex_f returns a different value each
8    * time it is invoked, then the evaluation of the following can
9    * yield a number of different possible results.
10   */
11  loc = ex_f() - ex_f();
12  }
```

NOTE An unspecified value cannot be a trap representation. 77

Commentary

correct program 88 Unspecified values can occur for correct program constructs and correct data. A trap representation is likely to raise an exception and change the behavior of a correct program.

3.18

$\lceil x \rceil$ 78

ceiling of *x*: the least integer greater than or equal to *x*

Commentary

ISO 31-11 23 The definition of a mathematical term that is not defined in ISO 31-11.

EXAMPLE $\lceil 2.4 \rceil$ is 3, $\lceil -2.4 \rceil$ is -2. 79

3.19

floor $\lfloor x \rfloor$ 80

floor of *x*: the greatest integer less than or equal to *x*

Commentary

ISO 31-11 23 The definition of a mathematical term that is not defined in ISO 31-11.

EXAMPLE $\lfloor 2.4 \rfloor$ is 2, $\lfloor -2.4 \rfloor$ is -3. 81

conformance

4. Conformance

Commentary

In the C90 Standard this header was titled *Compliance*. Since this standard talks about conforming and strictly conforming programs it makes sense to change this title. Also, from existing practice, the term *Conformance* is used by voluntary standards, such as International Standards, while the term *Compliance* is used by involuntary standards, such as regulations and laws.

SC22 had a Working Group responsible for conformity and validation issues, WG12. This WG was formed in 1983 and disbanded in 1989. It produced two documents: *ISO/IEC TR 9547:1988— Test methods for programming language processors – guidelines for their development and procedures for their approval* and *ISO/IEC TR 10034:1990— Guidelines for the preparation of conformity clauses in programming language standards*.

shall In this International Standard, “shall” is to be interpreted as a requirement on an implementation or on a program; 82

Commentary

How do we know which is which? In many cases the context in which the *shall* occurs provides the necessary information. Most usages of *shall* apply to programs and these commentary clauses only point out those cases where it applies to implementations.

The extent to which implementations are required to follow the requirements specified using *shall* is affected by the kind of subclause the word appears in. Violating a *shall* requirement that appears inside a subsection headed *Constraint* clause is a constraint violation. A conforming implementation is required to issue a diagnostic when it encounters a violation of these constraints.

84 shall outside constraint
63 constraint

The term *should* is not defined by the standard. This word only appears in footnotes, examples, recommended practices, and in a few places in the library. The term *must* is not defined by the standard and only occurs once in it as a word.

1622 EXAMPLE compatible function prototypes

C++

The C++ Standard does not provide an explicit definition for the term *shall*. However, since the C++ Standard was developed under ISO rules from the beginning, the default ISO rules should apply.

84 ISO shall rules

Coding Guidelines

Coding guidelines are best phrased using "shall" and by not using the words "should", "must", or "may".

Usage

The word *shall* occurs 537 times (excluding occurrences of *shall not*) in the C Standard.

---

83 conversely, "shall not" is to be interpreted as a prohibition.

Commentary

In some cases this prohibition requires a diagnostic to be issued and in others it results in undefined behavior. An occurrence of a construct that is the subject of a *shall not* requirement that appears inside a subsection headed *Constraint* clause is a constraint violation. A conforming implementation is required to issue a diagnostic when it encounters a violation of these constraints.

84 shall outside constraint
63 constraint

Coding Guidelines

Coding guidelines are best phrased using *shall not* and by not using the words *should not*, *must not*, or *may not*.

Usage

The phrase *shall not* occurs 51 times (this includes two occurrences in footnotes) in the C Standard.

---

84 If a "shall" or "shall not" requirement that appears outside of a constraint is violated, the behavior is undefined.

shall outside constraint

Commentary

This C sentence brings us onto the use of ISO terminology and the history of the C Standard. ISO use of terminology requires that the word *shall* implies a constraint, irrespective of the subclause it appears in. So under ISO rules, all sentences that use the word *shall* represent constraints. But the C Standard was first published as an ANSI standard, ANSI X3.159-1989. It was adopted by ISO, as ISO/IEC 9899:1990, the following year with minor changes (e.g., the term Standard was replaced by International Standard and there was a slight renumbering of the major clauses; there is a `sed` script that can convert the ANSI text to the ISO text), but the *shall*s remained unchanged.

ISO shall rules

If you, dear reader, are familiar with the ISO rules on *shall*, you need to forget them when reading the C Standard. This standard defines its own concept of constraints and meaning of *shall*.

C++

This specification for the usage of *shall* does not appear in the C++ Standard. The ISO rules specify that the meaning of these terms does not depend on the kind of normative context in which they appear. One implication of this C specification is that the definition of the preprocessor is different in C++. It was essentially copied verbatim from C90, which operated under different *shall* rules :-O.

84 ISO shall rules

Coding Guidelines

Many developers are not aware that the C Standard's meaning of the term *shall* is context-dependent. If developers have access to a copy of the C Standard, it is important that this difference be brought to their attention; otherwise, there is the danger that they will gain false confidence in thinking that a translator will issue a diagnostic for all violations of the stated requirements. In a broader sense educating developers about the usage of this term is part of their general education on conformance issues.

Usage

The word *shall* appears 454 times outside of a Constraint clause; however, annex J.2 only lists 190 undefined behaviors. The other uses of the word *shall* apply to requirements on implementations, not programs.

---

undefined behavior indicated by

Undefined behavior is otherwise indicated in this International Standard by the words "undefined behavior" or by the omission of any explicit definition of behavior. 85

Commentary

Failure to find an explicit definition of behavior could, of course, be because the reader did not look hard enough. Or it could be because there was nothing to find, implicitly undefined behavior. On the whole the Committee does not seem to have made any obvious omissions of definitions of behavior. Those DRs that have been submitted to WG14, which have later turned out to be implicitly undefined behavior, have involved rather convoluted constructions. This specification for the omissions of an explicit definition is more of a catch-all rather than an intent to minimize wording in the standard (although your author has heard some Committee members express the view that it was never the intent to specify every detail).

shall 84 outside constraint

The term *shall* can also mean undefined behavior.

C++

The C++ Standard does not define the status of any omission of explicit definition of behavior.

Coding Guidelines

Is it worth highlighting omissions of explicit definitions of behavior in coding guidelines (the DRs in the record of response log kept by WG14 provides a confirmed source of such information)? Pointing out that the C Standard does not always fully define a construct may undermine developers' confidence in it, resulting in them claiming that a behavior was undefined because they could find no mention of it in the standard when a more thorough search would have located the necessary information.

Example

The following quote is from Defect Report #017, Question 19 (raised against C90).

DR #017

X3J11 previously said, "The behavior in this case could have been specified, but the Committee has decided more than once not to do so. [They] do not wish to promote this sort of macro replacement usage." I interpret this as saying, in other words, "If we don't define the behavior nobody will use it." Does anybody think this position is unusual?

Response

If a fully expanded macro replacement list contains a function-like macro name as its last preprocessing token, it is unspecified whether this macro name may be subsequently replaced. If the behavior of the program depends upon this unspecified behavior, then the behavior is undefined.

For example, given the definitions:

```
#define f(a) a*g

#define g(a) f(a)
```

the invocation:

```
f(2)(9)
```

results in undefined behavior. Among the possible behaviors are the generation of the preprocessing tokens:

```
2*f(9)
```

and

```
2*9*g
```

```
Correction
Add to subclause G.2, page 202:
-- A fully expanded macro replacement list contains a
function-like macro name as its last preprocessing token (6.8.3).
```

Subclause G.2 was the C90 annex listing undefined behavior. Different wording, same meaning, appears in annex J.2 of C99.

---

86 There is no difference in emphasis among these three;

Commentary

It is not possible to write a construct whose behavior is more undefined than another construct, simply because of the wording used, or not used, in the standard.

Coding Guidelines

There is nothing to be gained by having coding guideline documents distinguish between the different ways undefined behavior is indicated in the C Standard.

---

87 they all describe "behavior that is undefined".

---

88 A program that is correct in all other aspects, operating on correct data, containing unspecified behavior shall be a correct program and act in accordance with 5.1.2.3.

correct program

Commentary

As pointed out elsewhere, any nontrivial program will contain unspecified behavior.

49 unspecified behavior

A wide variety of terms are used by developers to refer to programs that are not correct. The C Standard does not define any term for this kind of program.

Terms, such as *fault* and *defect*, are defined by various standards:

defect. See fault.

error. (1) A discrepancy between a computed, observed, or measured value or condition and the true, specified, or theoretical correct value or condition.

(2) Human action that results in software containing a fault. Examples include omission or misinterpretation of user requirements in a software specification, incorrect translation or omission of a requirement in the design specification. This is not the preferred usage.

fault. (1) An accidental condition that causes a functional unit to fail to perform its required function.

(2) A manifestation of an error(2) in software. A fault, if encountered, may cause a failure. Synonymous with bug.

ANSI/IEEE Std 729–1983, IEEE Standard Glossary of Software Engineering Terminology

Error (1) A discrepancy between a computed, observed or measured value or condition and the true, specified or theoretically correct value or condition. (2) Human action that results in software containing a fault. Examples

ANSI/AIAA R–013-1992, Recommended Practice for Software Reliability

include omission or misinterpretation of user requirements in a software specification, and incorrect translation or omission of a requirement in the design specification. This is not a preferred usage.

Failure (1) The inability of a system or system component to perform a required function with specified limits. A failure may be produced when a fault is encountered and a loss of the expected service to the user results. (2) The termination of the ability of a functional unit to perform its required function. (3) A departure of program operation from program requirements.

Failure Rate (1) The ratio of the number of failures of a given category or severity to a given period of time; for example, failures per month. Synonymous with failure intensity. (2) The ratio of the number of failures to a given unit of measure; for example, failures per unit of time, failures per number of transactions, failures per number of computer runs.

Fault (1) A defect in the code that can be the cause of one or more failures. (2) An accidental condition that causes a functional unit to fail to perform its required function. Synonymous with bug.

Quality The totality of features and characteristics of a product or service that bears on its ability to satisfy given needs.

Software Quality (1) The totality of features and characteristics of a software product that bear on its ability to satisfy given needs; for example, to conform to specifications. (2) The degree to which software possesses a desired combination of attributes. (3) The degree to which a customer or user perceives that software meets his or her composite expectations. (4) The composite characteristics of software that determine the degree to which the software in use will meet the expectations of the customer.

Software Reliability (1) The probability that software will not cause the failure of a system for a specified time under specified conditions. The probability is a function of the inputs to and use of the system, as well as a function of the existence of faults in the software. The inputs to the system determine whether existing faults, if any, are encountered. (2) The ability of a program to perform a required function under stated conditions for a stated period of time.

C90

This statement did not appear in the C90 Standard. It was added in C99 to make it clear that a strictly conforming program can contain constructs whose behavior is unspecified, provided the output is not affected by the behavior chosen by an implementation.

C++

1.4p2 *Although this International Standard states only requirements on C++ implementations, those requirements are often easier to understand if they are phrased as requirements on programs, parts of programs, or execution of programs. Such requirements have the following meaning:*

— If a program contains no violations of the rules of this International Standard, a conforming implementation shall, within its resource limits, accept and correctly execute that program.

footnote 3 *"Correct execution" can include undefined behavior, depending on the data being processed; see 1.3 and 1.9.*

Programs which have the status, according to the C Standard, of being *strictly conforming* or *conforming* have no equivalent status in C++.

Common Implementations

A program's source code may look correct when mentally executed by a developer. The standard assumes that C programs are correctly translated. Translators are programs like any other, they contain faults. Until the 1990s, the idea of proving the correctness of a translator for a commercially used language was not taken seriously. The complexity of a translator and the volume of source it contained meant that the resources

required would be uneconomical. Proofs that were created applied to toy languages, or languages that were so heavily subseted as to be unusable in commercial applications.

Having translators generate correct machine code continues to be very important. Processors continue to become more powerful and support gigabytes of main storage. Researchers continue to increase the size of the language subsets for which translators have been proved correct.[836, 1003, 1496] They have also looked at proving some of the components of an existing translator, `gcc`, correct.[1002]

Coding Guidelines

The phrase *the program is correct* is used by developers in a number of different contexts, for instance, to designate intended program behavior, or a program that does not contain faults. When describing adherence to the requirements of the C Standard, the appropriate term to use is *conformance*.

Adhering to coding guidelines does not guarantee that a program is correct. The phase *correct program* does not really belong in a coding guidelines document. These coding guidelines are silent on the issue of what constitutes correct data.

---

89 The implementation shall not successfully translate a preprocessing translation unit containing a **`#error`** preprocessing directive unless it is part of a group skipped by conditional inclusion.

#error terminate translation

Commentary

The intent is to provide a mechanism to unconditionally cause translation to fail. Prior to this explicit requirement, it was not guaranteed that a **`#error`** directive would cause translation to fail, if encountered, 1993 #error
although in most cases it did.

C90

C90 required that a diagnostic be issued when a **`#error`** preprocessing directive was encountered, but the translator was allowed to continue (in the sense that there was no explicit specification saying otherwise) translation of the rest of the source code and signal *successful translation* on completion.

C++

. . . , and renders the program ill-formed. 16.5

It is possible that a C++ translator will continue to translate a program after it has encountered a **`#error`** directive (the situation is as ambiguous as it was in C90).

Common Implementations

Most, but not all, C90 implementations do not successfully translate a preprocessing translation unit containing this directive (unless skipping an arm of a conditional inclusion). Some K&R implementations failed to translate any source file containing this directive, no matter where it occurred. One solution to this problem is to write the source as `??=error`, because a K&R compiler would not recognize the trigraph.

Some implementations include support for a `#warning` preprocessor directive, which causes a diagnostic 1993 #warning
to be issued without causing translation to fail.

Example

```
#if CHAR_BIT != 8
#error Networking code requires byte == octet
#endif
```

---

90 A *strictly conforming program* shall use only those features of the language and library specified in this International Standard.[2)]

strictly conforming program
use features of language/library

Commentary

In other words, a strictly conforming program cannot use extensions, either to the language or the library. A strictly conforming program is intended to be maximally portable and can be translated and executed by any conforming implementation. Nothing is said about using libraries specified by other standards. As far as the translator is concerned, these are translation units processed in translation phase 8. There is no way of telling apart user-written translation units and those written by third parties to conform to another API standard.

translation phase 8 139

Rationale

The Standard does not forbid extensions provided that they do not invalidate strictly conforming programs, and the translator must allow extensions to be disabled as discussed in Rationale §4. Otherwise, extensions to a conforming implementation lie in such realms as defining semantics for syntax to which no semantics is ascribed by the Standard, or giving meaning to undefined behavior.

C++

1.3.14 well-formed program

a C++ program constructed according to the syntax rules, diagnosable semantic rules, and the One Definition Rule (3.2).

The C++ term *well-formed* is not as strong as the C term *strictly conforming*. This is partly as a result of the former language being defined in terms of requirements on an implementation, not in terms of requirements on a program, as in C's case. There is also, perhaps, the thinking behind the C++ term of being able to check statically for a program being well-formed. The concept does not include any execution-time behavior (which strictly conforming does include). The C++ Standard does not define a term stronger than *well-formed*.

standard 1 specifies form and interpretation

The C requirement to use only those library functions specified in the standard is not so clear-cut for freestanding C++ implementations.

1.4p7

For a hosted implementation, this International Standard defines the set of available libraries. A freestanding implementation is one in which execution may take place without the benefit of an operating system, and has an implementation-defined set of libraries that includes certain language-support libraries (17.4.1.3).

Other Languages

Most language specifications do not have as sophisticated a conformance model as C.

Common Implementations

All implementations known to your author will successfully translate some programs that are not strictly conforming.

Coding Guidelines

extensions 95.1 cost/benefit

This part of the definition of strict conformance mirrors the guideline recommendation on using extensions. Translating a program using several different translators, targeting different host operating systems and processors, is often a good approximation to *all implementations* (this is a tip, not a guideline recommendation).

---

strictly conforming program output shall not

It shall not produce output dependent on any unspecified, undefined, or implementation-defined behavior, and shall not exceed any minimum implementation limit. 91

Commentary

The key phrase here is *output*. Constructs that do not affect the output of a program do not affect its conformance status (although a program whose source contains violations of constraint or syntax will never get to the stage of being able to produce any output). A translator is not required to deduce whether a construct affects the output while performing a translation. Violations of syntax and constraints must be diagnosed independent of whether the construct is ever executed, at execution time, or affects program output. These are extremely tough requirements to meet. Even the source code of some C validation suites did not meet these requirements in some cases.[682]

implementation validation 92

Coding Guidelines

Many coding guideline documents take a strong line on insisting that programs not contain any occurrence of unspecified, undefined, or implementation-defined behaviors. As previously discussed, this is completely unrealistic for unspecified behavior. For some constructs exhibiting implementation-defined behavior, a strong case can be made for allowing their use. The issues involved in the use of constructs whose behavior is implementation-defined is discussed in the relevant sentences.

49 unspecified behavior
42 implementation-defined behavior

The issue of programs exceeding minimum implementation limits is rarely considered as being important. This is partly based on developers' lack of experience of having programs fail to translate because they exceed the kinds of limits specified in the C Standard. Program termination at execution time because of a lack of some resource is often considered to be an application domain, or program implementation issue. These coding guidelines are not intended to cover this kind of situation, although some higher-level, application-specific guidelines might.

The issue of code that does not affect program output is discussed elsewhere.

190 redundant code

Cg 91.1 All of a programs translated source code shall be assumed to affect its output, when determining its conformance status.

---

92 The two forms of *conforming implementation* are hosted and freestanding.

implementation two forms

Commentary

Not all hardware containing a processor can support a C translator. For instance, a coffee machine. In these cases programs are translated on one host and executed on a completely different one. Desktop and minicomputer-based developers are not usually aware of this distinction. Their programs are usually designed to execute on hosts similar to those that translate them (same processor family and same kind of operating system).

A freestanding environment is often referred to as the *target* environment; the thinking being that source code is translated in one environment with the aim of executing it on another, the target. This terminology is only used for a hosted environment, where the program executes in a different environment from the one in which it was translated.

The concept of implementation-conformance to the standard is widely discussed by developers. In practice implementations are not perfect (i.e., they contain bugs) and so can never be said to be conforming. The testing of products for conformance to International Standards is a job carried out by various national testing

implementation validation

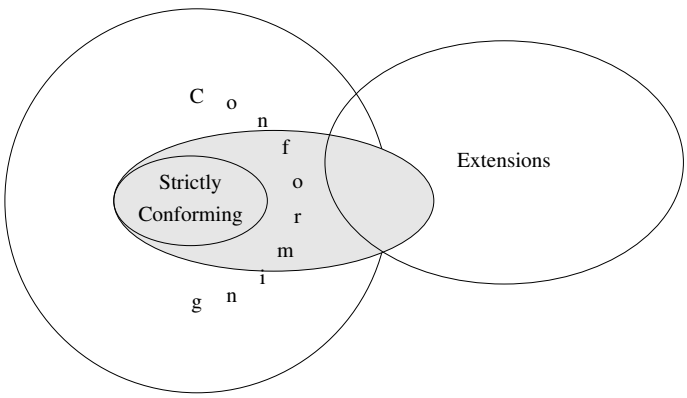

Figure 92.1: A conforming implementation (gray area) correctly handles all strictly conforming programs, may successfully translate and execute some of the possible conforming programs, and may include some of the possible extensions.

laboratories. Several of these testing laboratories used to be involved in testing software, including the C90 language standard (language implementation validation did not prove commercially viable and there are no longer any national testing laboratories offering this service). A suite of test programs was used to measure an implementation's handling of various constructs. An implementation that successfully processed the tests was not certified to be a conforming implementation but rather (in BSI's case): "This is to certify that the language processor identified below has been found to contain no errors when tested with the identified validation suite, and is therefore deemed to conform to the language standard."

Ideally, a validation suite should have the following properties:

- Check all the requirements of the standard.
- Tests should give the same results across all implementations (they should be strictly conforming programs).
- Should not contain coding bugs.
- Should contain a test harness that enables the entire suite to be compiled/linked/executed and a pass/fail result obtained.
- Should contain a document that explains the process by which the above requirements were checked for correctness.

There are two validation suites that are widely used commercially: Perennial CVSA (version 8.1) consists of approximately 61,000 test cases in 1,430,000 lines of source code, and Plum Hall validation suite (CV-Suite 2003a) for C contains 84,546 test cases in 157,000 lines of source. A study by Jones[682] investigated the completeness and correctness of the ACVS. Ciechanowicz[236] did the same for the Pascal validation suite.

Most formal validation concentrates on language syntax and semantics. Some vendors also offer automated expression generators for checking the correctness of the generated machine code (by generating various combinations of operators and operands whose evaluation delivers a known result, which is checked by translating and executing the generated program). Wichmann[1457] describes experiences using one such generator.

Other Languages

Most other standardized languages are targeted at a hosted environment.

Some language specifications support different levels of conformance to the standard. For instance, Cobol has three implementation levels, as does SQL (Entry, Intermediate, and Full). In the case of Cobol and Fortran, this approach was needed because of the technical problems associated with implementing the full language on the hosts of the day (which often had less memory and processing power than modern hand calculators).

The Ada language committee took the validation of translators seriously enough to produce a standard: ISO/IEC 18009:1999 *Information technology— Programming languages – Ada: Conformity assessment of a language processor*. This standard defines terms, and specifies the procedures and processes that should be followed. An Ada Conformity Assessment Test suite is assumed to exist, but nothing is said about the attributes of such a suite.

The POSIX Committee, SC22/WG15, also defined a standard for measuring conformance to its specifications. In this case they[620] attempted to provide a detailed top-level specification of the tests that needed to be performed. Work on this conformance standard was hampered by the small number of people, with sufficient expertise, willing to spend time writing it. Experience also showed that vendors producing POSIX test suites tended to write to the requirements in the conformance standard, not the POSIX standard. Lack of resources needed to update the conformance standard has meant that POSIX testing has become fossilized.

Java was originally designed to run in what is essentially a freestanding environment.

Common Implementations

The extensive common ground that exists between different hosted implementations does not generally exist within freestanding implementations. In many cases programs intended to be executed in a hosted environment are also translated in that environment. Programs intended for a freestanding environment are rarely translated in that environment.

---

93 A *conforming hosted implementation* shall accept any strictly conforming program.

conforming hosted implementation

Commentary

This is a requirement on the implementation. Another requirement on the implementation deals with limits. This requirement does not prohibit an implementation from accepting programs that are not strictly conforming.

276 translation limits
95 implementation extensions
90 strictly conforming program use features of language/library

A strictly conforming program can use any feature of the language or library. This requirement is stating that a conforming hosted implementation shall implement the entire language and library, as defined by the standard (modulo those constructs that are conditional).

C++

No such requirement is explicitly specified in the C++ Standard.

Example

Is a conforming hosted implementation required to translate the following translation unit?

```
1  int array1[5];
2  int array2[5];
3  int *p1 = &array1[0];
4  int *p2 = &array2[0];
5
6  int DR_109()
7  {
8  return (p1 > p2);
9  }
```

1209 relational pointer comparison undefined if not same object

It would appear that the pointers `p1` and `p2` do not point into the same object, and that their appearance as operands of a relational operator results in undefined behavior. However, a translator would need to be certain that the function `f_1` is called, that `p1` and `p2` do not point into the same object, and that the output of any program that calls it is dependent on it. Even in the case:

```
1  int f_2(void)
2  {
3  return 1/0;
4  }
```

a translator cannot fail to translate the translation unit unless it is certain that the function `f_2` is called.

---

94 A *conforming freestanding implementation* shall accept any strictly conforming program that does not use complex types and in which the use of the features specified in the library clause (clause 7) is confined to the contents of the standard headers **<float.h>**, **<iso646.h>**, **<limits.h>**, **<stdarg.h>**, **<stdbool.h>**, **<stddef.h>**, and **<stdint.h>**.

conforming freestanding implementation

Commentary

This is a requirement on the implementation. There is nothing to prevent a conforming implementation supporting additional standard headers, that are not listed here.

Complex types were added to help the Fortran supercomputing community migrate to C. They are very unlikely to be needed in a freestanding environment.

The standard headers that are required to be supported define macros, typedefs, and objects only. The runtime library support needed for them is therefore minimal. The header **<stdarg.h>** is the only one that may need runtime support.

C90

The header **<iso646.h>** was added in Amendment 1 to C90. Support for the complex types, the headers **<stdbool.h>** and **<stdint.h>**, are new in C99.

C++

1.4p7 *A freestanding implementation is one in which execution may take place without the benefit of an operating system, and has an implementation-defined set of libraries that include certain language-support libraries (17.4.1.3).*

17.4.1.3p2 *A freestanding implementation has an implementation-defined set of headers. This set shall include at least the following headers, as shown in Table 13:*

. . .

Table 13 C++ Headers for Freestanding Implementations

Subclause	Header(s)
18.1 Types	**<cstddef>**
18.2 Implementation properties	**<limits>**
18.3 Start and termination	**<cstdlib>**
18.4 Dynamic memory management	**<new>**
18.5 Type identification	**<typeinfo>**
18.6 Exception handling	**<exception>**
18.7 Other runtime support	**<cstdarg>**

The supplied version of the header ***<cstdlib>*** *shall declare at least the functions* `abort()`*,* `atexit()`*, and* `exit()` *(18.3).*

The C++ Standard does not include support for the headers **<stdbool.h>** or **<stdint.h>**, which are new in C99.

Common Implementations

String handling is a common requirement at all application levels. Some freestanding implementations include support for many of the functions in the header **<string.h>**.

Coding Guidelines

Issues of which headers must be provided by an implementation are outside the scope of coding guidelines. This is an application build configuration management issue.

---

implementation extensions

A conforming implementation may have extensions (including additional library functions), provided they do not alter the behavior of any strictly conforming program.[3)] 95

Commentary

The C committee did not want to ban extensions. Common extensions were a source of material for both C90 and C99 documents. But the Committee does insist that any extensions do not alter the behavior of other constructs it defines. Extensions that do not change the behavior of any strictly conforming program are sometimes called *pure extensions*.

An implementation may provide additional library functions. It is a moot point whether they are actual extensions, since it is not suggested that libraries supplied by third parties have this status. The case for calling them extensions is particularly weak if the functionality they provide could have been implemented by the developer, using the same implementation but without those functions. However, there is an established practice of calling anything provided by the implementation that is not part of the standard an extension.

Common Implementations

One of the most common extensions is support for inline assembler code. This is sometimes implemented by making the assembler code look like a function call, the name of the function being `asm`, e.g., `asm("ld r1, r2");`.

In the Microsoft/Intel world, the identifiers **`NEAR`**, **`FAR`**, and **`HUGE`** are commonly used as pointer type modifiers.

Implementations targeted at embedded systems (i.e., freestanding environments) sometimes use the `^` operator to select a bit from an object of a specified type. This is an example of a nonpure extension.

Coding Guidelines

These days vendors do not try to tie customers into their products by doing things different from what the C Standard specifies. Rather, they include additional functionality; providing extensions to the language that many developers find useful. Source code containing many uses of a particular vendor's extensions is likely to be more costly to port to a different vendor's implementation than source code that does not contain these constructs.

Many developers accumulated most of their experience using a single implementation; this leads them into the trap of thinking that what their implementation does is what is supported by the standard. They may not be aware of using an extension. Using an extension through ignorance is poor practice.

Use of extensions is not in itself poor practice; it depends on why the extension is being used. An extension providing functionality that is not available through any other convenient means can be very attractive. Use of a construct, an extension or otherwise, after considering all other possibilities is good engineering practice.

A commonly experienced problem with vendor extensions is that they are not fully specified in the associated documentation. Every construct in the C Standard has been looked at by many vendors and its consequences can be claimed to have been very well thought through. The same can rarely be said to apply to a vendor's extensions. In many cases the only way to find out how an extension behaves, in a given situation, is to write test cases.

Some extensions interact with constructs already defined in the C Standard. For instance, some implementations[20] define a type, using the identifier **`bit`** to indicate a 1-bit representation, or using the punctuator `^` as a binary operator that extracts the value of a bit from its left operand (whose position is indicated by the right operand).[717] This can be a source of confusion for readers of the source code who have usually not been trained to expect this usage.

Experience shows that a common problem with the use of extensions is that it is not possible to quantify the amount of usage in source code. If use is made of extensions, providing some form of documentation for the usage can be a useful aid in estimating the cost of future ports to new platforms.

Rev 95.1 The cost/benefit of any extensions that are used shall be evaluated and documented.

Dev 95.1 Use is made of extensions and:

- their use has been isolated within a small number of functions, or translation units,
- all functions containing an occurrence of an extension contain a comment at the head of the function definition listing the extensions used,
- test cases have to be written to verify that the extension operates as specified in the vendor's documentation. Test cases shall also be written to verify that use of the extension outside of the context in which it is defined is flagged by the implementation.

Some of the functions in the C library have the same name as functions defined by POSIX. POSIX, being an API-based standard (essentially a complete operating system) vendors have shown more interest in implementing the POSIX functionality.

Example

The following is an example of an extension, provided the VENDOR_X implementation is being used and the call to `f` is followed by a call to a trigonometric function, that affects the behavior of a strictly conforming program.

```
#include <math.h>

#if defined(VENDOR_X)
#include "vmath.h"
#endif

void f(void)
{
/*
 * The following function call causes all subsequent calls
 * to functions defined in <math.h> to treat their argument
 *  values as denoting degrees, not radians.
 */
#if defined(VENDOR_X)
switch_trig_to_degrees();
#endif
}
```

The following examples are pure extensions. Where might the coding guideline comments be placed?

```
/*
 * This function contains assembler.
 */
void f(void)
/*
 * This function contains assembler.
 */
{
/*
 * This function contains assembler.
 */
asm("make the, coffee"); /* How do we know this is an extension? */
} /* At least we can agree this is the end of the function. */

void no_special_comment(void)
{
asm("open the, biscuits");
}

void what_syntax_error(void)
{
asm wash up, afterwards
}

void not_isolated(void)
{
/*
 * Enough standard C code to mean the following is not isolated.
 */
asm wait for, lunch
}
```

footnote 2

2) A strictly conforming program can use conditional features (such as those in annex F) provided the use is guarded by a **`#ifdef`** directive with the appropriate macro.

Commentary

The definition of a macro, or lack of one, can be used to indicate the availability of certain functionality. The **#ifdef** directive providing a natural, language, based mechanism for checking whether an implementation supports a particular optional construct. The POSIX standard[636] calls macros, used to check for the availability (i.e., an implementations' support) of an optional construct, *feature test* macros.

feature test macro

C90

The C90 Standard did not contain any conditional constructs.

C++

The C++ Standard also contains optional constructs. However, testing for the availability of any optional constructs involves checking the values of certain class members. For instance, an implementation's support for the IEC 60559 Standard is indicated by the value of the member `is_iec559` (18.2.1.2).

29 IEC 60559

Other Languages

There is a philosophy of language standardization that says there should only be one language defined by a standard (i.e., no optional constructs). The Pascal and C90 Standard committees took this approach. Other language committees explicitly specify a multilevel standard; for instance, Cobol and SQL both define three levels of conformance.

C (and C++) are the only commonly used languages that contain a preprocessor, so this type of optional construct-handling functionality is not available in most other languages.

Common Implementations

If an implementation does not support an optional construct appearing in source code, a translator often fails to translate it. This failure invariably occurs because identifiers are not defined. In the case of optional functions, which a translator running in a C90 mode to support implicit function declarations may not diagnose, there will be a link-time failure.

Coding Guidelines

Use of a feature test macro highlights the fact that support for a construct is optional. The extent to which this information is likely to be already known to the reader of the source will depend on the extent to which a program makes use of the optional constructs. For instance, repeated tests of the `__STDC_IEC_559__` macro in the source code of a program that extensively manipulates IEC 60559 format floating-point values complicates the visible source and conveys little information. However, testing this macro in a small number of places in the source of a program that has a few dependencies on the IEC 60559 format is likely to provide useful information to readers.

2015 __STDC_IEC_ macro

Use of a feature test macro does not guarantee that a program correctly performs the intended operations; it simply provides a visual reminder of the status of a construct. Whether an **#else** arm should always be provided (either to handle the case when the construct is not available, or to cause a diagnostic to be generated during translation) is a program design issue.

Example

```
#include <fenv.h>

void f(void)
{
#ifdef __STDC_IEC_559__
   fesetround(FE_UPWARD);
#endif /* The case of macro not being defined is ignored. */

#ifdef __STDC_IEC_559__
   fesetround(FE_UPWARD);
#else
   #error Support for IEC 60559 is required
```

```
13  #endif
14
15  #ifdef __STDC_IEC_559__
16     fesetround(FE_UPWARD);
17  #else
18     /*
19      * An else arm that does nothing.
20      * Does this count as handling the alternative?
21      */
22  #endif
23  }
```

example __STDC_IEC_559__

For example: 97

```
#ifdef __STDC_IEC_559__ /* FE_UPWARD defined */
   /* ... */
   fesetround(FE_UPWARD);
   /* ... */
#endif
```

footnote 3

3) This implies that a conforming implementation reserves no identifiers other than those explicitly reserved in this International Standard. 98

Commentary

If an implementation did reserve such an identifier, then its declaration could clash with one appearing in a strictly conforming program (probably leading to a diagnostic message being generated). The issue of reserved identifiers is discussed in more detail in the library section.

C++

The clauses 17.4.3.1, 17.4.4, and their associated subclauses list identifier spellings that are reserved, but do not specify that a conforming C++ implementation must not reserve identifiers having other spellings.

Common Implementations

In practice most implementation's system headers do define (and therefore could be said to reserve) identifiers whose spelling is not explicitly reserved for implementation use (see Table 1897.1). Many implementations that define additional keywords are careful to use the double underscore, `__`, prefix on their spelling. Such an identifier spelling is not always seen as being as readable as one without the double underscore. A commonly adopted renaming technique is to use a predefined macro name that maps to the double underscore name. The developer can always **`#undef`** this macro if its name clashes with identifiers declared in the source.

It is very common for an implementation to predefine several macros. These macros are either defined within the program image of the translator, or come into existence whenever one of the standard-defined headers is included. The names of the macros usually denote properties of the implementation, such as `SYSTYPE_BSD`, `WIN32`, `unix`, `hp9000s800`, and so on.

Identifiers defined by an implementation are visible via headers, which need to be included, and via libraries linked in during the final phase of translation. Most linkers have an *only extract the symbols needed* mode of working, which enables the same identifier name to be externally visible in the developers' translation unit and an implementation's library. The developers' translation unit is linked first, resolving any references to its symbol before the implementation's library is linked.

Coding Guidelines

Coding guidelines cannot mandate what vendors (translator, third-party library, or systems integrator) put in the system headers they distribute. Coding guideline documents need to accept the fact that almost no commercial implementations meet this requirement.

Requiring that all identifiers declared in a program first be **#undef**'ed, on the basis that they may also be declared in a system header, would be overkill (and would only remove previously defined macro names). Most developers use a suck-it-and-see approach, changing the names of any identifiers that do clash.

Identifier name clashes between included header contents and developer written file scope declarations are likely to result in a diagnostic being issued during translation. Name usage clashes between header contents and block scope identifier definitions may sometimes result in a diagnostic; for instance, the macro replacement of an identifier in a block scope definition resulting in a syntax or constraint violation.

Measurements of code show (see Table 98.1) that most existing code often contains many declarations of identifiers whose spellings are reserved for use by implementations. Vendors are aware of this usage and often link against the translated output of developer written code before finally linking against implementation libraries (on the basis that resolving name clashes in favour of developer defined identifiers is more likely to produce the intended behavior).

Whether the cost of removing so many identifier spellings potentially having informative semantics, to readers of the source, associated with them is less than the benefit of avoiding possible name clash problems with implementation provided libraries is not known. No guideline recommendation is given here.

Table 98.1: Number of developer declared identifiers (the contents of any header was only counted once) whose spelling (the notation *[a-z]* denotes a regular expression, i.e., a character between *a* and *z*) is reserved for use by the implementation or future revisions of the C Standard. Based on the translated form of this book's benchmark programs.

Reserved spelling	Occurrences
Identifier, starting with __, declared to have any form	3,071
Identifier, starting with *_[A-Z]*, declared to have any form	10,255
Identifier, starting with *wcs[a-z]*, declared to have any form	1
Identifier, with external linkage, defined in C99	12
File scope identifier or tag	6,832
File scope identifier	2
Macro name reserved when appropriate header is **#include**d	6
Possible macro covered identifier	144
Macro name starting with *E[A-Z]*	339
Macro name starting with *SIG[A-Z]*	2
Identifier, starting with *is[a-z]*, with external linkage (possibly macro covered)	47
Identifier, starting with *mem[a-z]*, with external linkage (possibly macro covered)	108
Identifier, starting with *str[a-z]*, with external linkage (possibly macro covered)	904

99 A *conforming program* is one that is acceptable to a conforming implementation.[4)]

conforming program

Commentary

Does the conforming implementation that accepts a particular program have to exist? Probably not. When discussing conformance issues, it is a useful simplification to deal with possible implementations, not having to worry if they actually exist. Locating an actual implementation that exhibits the desired behavior adds nothing to a discussion on conformance, but the existence of actual implementations can be a useful indicator for quality-of-implementation issues and the likelihood of certain constructions being used in real programs (the majority of real programs being translated by an extant implementation at some point).

C++

The C++ conformance model is based on the conformance of the implementation, not a program (1.4p2). However, it does define the term *well-formed program*:

1.3.14 well-formed program

a C++ program constructed according to the syntax rules, diagnosable semantic rules, and the One Definition Rule (3.2).

Coding Guidelines

strictly conforming program
use features of language/library
Just because a program is translated without any diagnostics being issued does not mean that another translator, or even the same translator with a different set of options enabled, will behave the same way. A conforming program is acceptable to a conforming implementation. A strictly conforming program is acceptable to all conforming implementations.

The cost of migrating a program from one implementation to all implementations may not be worth the benefits. In practice there is a lot of similarity between implementations targeting similar environments (e.g., the desktop, DSP, embedded controllers, supercomputers, etc.). Aiming to write software that will run within one of these specific environments is a much smaller task and can produce benefits at an acceptable cost.

---

implementation document
An implementation shall be accompanied by a document that defines all implementation-defined and locale-specific characteristics and all extensions. 100

Commentary

The formal validation process carried out by BSI (in the UK) and NIST (in the USA), when they were in the language-implementation validation business, checked that the implementation-defined behavior was documented. However, neither organization checked the accuracy of the documented behavior.

C90

locale-specific behavior
Support for locale-specific characteristics is new in C99. The equivalent C90 constructs were defined to be implementation-defined, and hence were also required to be documented.

Common Implementations

Many vendors include an appendix in their documentation where all implementation-defined behavior is collected together.

Of necessity a vendor will need to document extensions if their customers are to make use of them. Whether they document all extensions is another matter. One method of phasing out a superseded extension is to cease documenting it, but to continue to support it in the implementation. This enables programs that use the extension to continue being translated, but developers new to that implementation will be unlikely to make use of the extension (not having any documentation describing it).

Coding Guidelines

For those cases where use of implementation-defined behavior is being considered, the vendor implementation-provided document will obviously need to be read. The commercially available compiler validation suites do not check implementation-defined behavior. It is recommended that small test programs be written to verify that an implementation's behavior is as documented.

Forward references: conditional inclusion (6.10.1), error directive (6.10.5), characteristics of floating types <float.h> (7.7), alternative spellings <iso646.h> (7.9), sizes of integer types <limits.h> (7.10), variable arguments <stdarg.h> (7.15), boolean type and values <stdbool.h> (7.16), common definitions <stddef.h> (7.17), integer types <stdint.h> (7.18). 101

---

footnote 4
4) Strictly conforming programs are intended to be maximally portable among conforming implementations. 102

Commentary

strictly conforming program
use features of language/library
A strictly conforming program is acceptable to all conforming implementations.

C++

The word *portable* does not occur in the C++ Standard. This may be a consequence of the conformance model which is based on implementations, not programs.

Example

It is possible for a strictly conforming program to produce different output with different implementations, or even every time it is compiled:

```
#include <limits.h>
#include <stdio.h>

int main(void)
{
printf("INT_MAX=%d\n", INT_MAX);
printf("Translated date is %s\n", __DATE__);
}
```

---

103 Conforming programs may depend upon nonportable features of a conforming implementation.

conforming programs may depend on

Commentary

What might such *nonportable* features be? The standard does not specify any construct as being nonportable. The only other instance of this term occurs in the definition of undefined behavior. One commonly used meaning of the term *nonportable* is a construct that is not likely to be available in another vendor's implementation. For instance, support for some form of inline assembler code is available in many implementations. Use of such a construct might not be considered as a significant portability issue.

46 undefined behavior

C++

While a conforming implementation of C++ may have extensions, 1.4p8, the C++ conformance model does not deal with programs.

Coding Guidelines

There are a wide range of constructs and environment assumptions that a program can make to render it nonportable. Many nonportable constructs tend to fall into the category of undefined and implementation-defined behaviors. Avoiding these could be viewed, in some cases, as being the same as avoiding nonportable constructs.

Example

Relying on `INT_MAX` being larger than 32,767 is a dependence on a nonportable feature of a conforming implementation.

```
#include <limits.h>

_Bool f(void)
{
return (32767 < INT_MAX);
}
```

5. Environment

---

104 An implementation translates C source files and executes C programs in two data-processing-system environments, which will be called the *translation environment* and the *execution environment* in this International Standard.

environment execution

Commentary

For a hosted implementation the two environments are often the same. In some cases application developers do cross-translate from one hosted environment to another hosted environment. In a freestanding environment,

93 conforming hosted implementation
155 freestanding environment startup

the two environments are very unlikely to be the same.

A commonly used term for the execution environment is *runtime system*. In some cases this terminology refers to a more restricted set of functionality than a complete execution environment.

diagnostic 146 shall produce

The requirement on when a diagnostic message must be produced prevents a program from being translated from the source code, on the fly, as statements to execute are encountered.

Rationale

Because C has seen widespread use as a cross-compiled cross-compilation language, a clear distinction must be made between translation and execution environments. The C89 preprocessor, for instance, is permitted to evaluate the expression in a `#if` directive using the long integer or unsigned long integer arithmetic native to the translation environment: these integers must comprise at least 32 bits, but need not match the number of bits in the execution environment. In C99, this arithmetic must be done in `intmax_t` or `uintmax_t`, which must comprise at least 64 bits and must match the execution environment. Other translation time arithmetic, however, such as type casting and floating point arithmetic, must more closely model the execution environment regardless of translation environment.

C++

The C++ Standard says nothing about the environment in which C++ programs are translated.

Other Languages

JIT

Java defines an execution environment. It says nothing about the translation environment. But its philosophy, *write once run anywhere* means that there should not be any implementation-defined characteristics to worry about. There are implementations that perform Just-in-time (JIT) translation on an as needed basis during execution (implementations differ in the granularity of source that is JIT translated).

Coding Guidelines

Coding guidelines often relate to the translation environment; that is, what appears in the visible source code. In some cases the behavior of a program may vary because of characteristics that only become known when a program is executed. The coding guidelines in this book are aimed at both environments. It is management's responsibility to select the ones (or remove the ones) appropriate to their development environment.

Their characteristics define and constrain the results of executing conforming C programs constructed according to the syntactic and semantic rules for conforming implementations. 105

Commentary

The translation environment need not have any effect on the translated program, subject to sufficient memory being available to perform a translation. It is not even necessary that the translation environment be a superset of the execution environment. For instance, a translator targeting a 64-bit execution environment, but running in a 32-bit translation environment, could support its own 64-bit arithmetic package (for constant folding).

translation phase 4 129

In theory each stage of translation could be carried out in a separate translation environment. In some development environments, the code is distributed in preprocessed (i.e., after translation phase 4) form. Header files will have been included and any conditional compilation directives executed.

In those cases where a translator performs operations defined to occur during program execution, it must follow the execution time behavior. For instance, a translator may be able to evaluate parts of an expression, that are not defined to be a constant expression. In this case any undefined behavior associated with a signed arithmetic overflow could be defined to be the diagnostic generated by the translator.

C++

The C++ Standard makes no such observation.

Coding Guidelines

The characteristics of the execution environment are usually thought of as being part of the requirements of the application (i.e., that the application is capable of execution in this environment). The characteristics of the translation environment are of interest to these coding guidelines if they may affect the behavior of a translator.

106 **Forward references:** In this clause, only a few of many possible forward references have been noted.

Commentary

This statement could be said to be true for all of the Forward references appearing in the C Standard.

5.1 Conceptual models

5.1.1 Translation environment

5.1.1.1 Program structure

107 A C program need not all be translated at the same time.

program not translated at same time

Commentary

C's separate compilation model is one of independently translated source files that are merged together by a linker to form a program image. There is no concept of program library built into the language. Neither is there any requirement to perform cross-translation unit checking, although there are cross-translation unit compatibility rules for derived types.

1810 translation unit syntax
113 translation unit linked
141 program image
633 compatible separate translation units

There is no requirement that all source files making up a C program be translated prior to invoking the function `main`. An implementation could perform a JIT translation of each source file when an object or function in an untranslated source file is first referenced (a translator is required to issue a diagnostic if a translation unit contains any syntax and constraint violations).

104 JIT

Linkage is the property used to associate the same identifier, declared in different translation units, with the same object or function.

420 linkage

Other Languages

Some languages enforce strict dependency and type checks between separately translated source files. Others have a very laid-back approach. Some execution environments for the Basic language delay translation of a declaration or statement until it is reached in the flow of control during program execution. A few languages require that a program be completely translated at the same time (Cobol and the original Pascal standard).

Java defines a process called resolution which, " . . . is optional at the time of initial linkage."; and "An implementation may instead choose to resolve a symbolic reference only when it is actively used; . . . ".

Common Implementations

Most implementations translate individual source files into object code files, sometimes also called object modules. To create a program image, most implementations require all referenced identifiers to be defined and externally visible in one of these object files.

Coding Guidelines

The C model could be described as one of *it's up to you to build it correctly or the behavior is undefined.*. Having all of the source code of a program in a single file represents poor practice for all but the smallest of programs. The issue of how to divide up source code into different sources files, and how to select what definitions go in what files, is discussed elsewhere. There is also a guideline recommendation dealing with the uniqueness and visibility of declarations that appear at file scope.

1810 external declaration syntax
422.1 identifier declared in one file

Example

The following is an example of objects declared in different translation units with different types.

file_1.c

```
1  extern int glob;
```

file_2.c

```
1  float glob = 1.0;
```

Usage

A study by Linton and Quong[858] used an instrumented `make` program to investigate the characteristics of programs (written in a variety of languages, including C) built over a six-month period at Stanford University. The results (see Figure 107.1) showed that approximately 40% of programs consisted of three or fewer translation units.

---

source files
preprocessing files

The text of the program is kept in units called *source files*, (or *preprocessing files*) in this International Standard. 108

Commentary

This defines the terms *source files* and *preprocessing files*. The term *source files* is commonly used by developers, while the term *preprocessing files* is an invention of the Committee.

C90

The term *preprocessing files* is new in C99.

C++

The C++ Standard follows the wording in C90 and does not define the term *preprocessing files*.

Other Languages

The Java language specification[508] strongly recommends that certain naming conventions be followed for package names and class files. The names mimic the form of Web addresses and RFCs 920 and 1032 are cited.

Common Implementations

A well-established convention is to suffix source files that contain the object and function definitions with the `.c` extension. Header files usually being given a `.h` suffix. This convention is encoded in the `make` tool, which has default rules for processing file names that end in `.c`.

Coding Guidelines

file name abbreviations

Restrictions on the number of characters in a filename are usually more severe than for identifiers (MS-DOS 8.3, POSIX 14). These restrictions can lead to the use of abbreviations in the naming of files. An automated tool developed by Anquetil and Lethbridge[48] was able to extract abbreviations from file names with better than 85% accuracy. A comparison of automated file clustering,[49] against the clustering of files in a large application, by a human expert, showed nearly 90% accuracy for both precision (files grouped into subsystems to which they do not belong) and recall (files grouped into subsystems to which they do belong).

Development groups often adopt naming conventions for source file names. Source files associated with implementing particular functionality have related names, for instance:

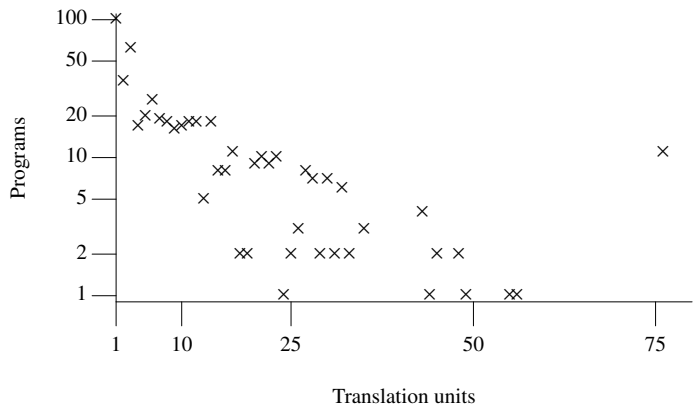

Figure 107.1: Number of programs built from a given number of translation units. Adapted from Linton.[858]

1. Data manipulation: *db* (database), *str* (string), or *queue*.
2. Algorithms or processes performed: *mon* (monitor), *write*, *free*, *select*, *cnv* (conversion), or *chk* (checking).
3. Program control implemented: *svr* (server), or *mgr* (manager).
4. The time period during which processing occurs: *boot*, *ini* (initialization), *rt* (runtime), *pre* (before some other task), or *post* (after some other task).
5. I/O devices, services or external systems interacted with: *k2*, *sx2000*, (a particular product), *sw* (switch), *f* (fiber), *alarm*.
6. Features implemented: *abrvdial* (abbreviated dialing), *mtce* (maintenance), or *edit* (editor).
7. Names of other applications from where code has been reused.
8. Names of companies, departments, groups or individuals who developed the code.
9. Versions of the files or software (e.g., the number 2 or the word *new* may be added, or the name of target hardware), different versions of a product sold in different countries (e.g., *na* for North America, and *ma* for Malaysia).
10. Miscellaneous abbreviations, for instance: *utl* (utilities), or *lib* (library).

792 identifier selecting spelling

The standard has no concept of directory structure. The majority of hosts support a file system having a directory structure and larger, multisource file projects often store related source files within individual directories. In some cases the source file directory structure may be similar to the structure of the major components of the program, or the directory structure mirrors the layered structure of an application.[790] The issues involved in organizing names into the appropriate hierarchy are discussed later.

530 structure type sequentially allocated objects

Files are not the only entities having names that can be collected into related groups. The issues associated with naming conventions, the selection of appropriate names and the use of abbreviations. are discussed elsewhere.

517 enumeration set of named constants
792 abbreviating identifier
792 identifier introduction

Source files are not the only kind of file discussed by the C Standard. The **#include** preprocessing directive causes the contents of a file to be included at that point. The standard specifies a minimum set of requirements for mapping these header files. The coding guideline issues associated with the names used for these headers is discussed elsewhere.

1896 source file inclusion
422 header name same as .c file

---

109 A source file together with all the headers and source files included via the preprocessing directive **#include** is known as a *preprocessing translation unit*.

preprocessing translation unit known as

Commentary

This defines the term *preprocessing translation unit*, which is not generally used outside of the C Standard Committee. A preprocessing translation unit contains all of the possible combinations of translation units that could appear after preprocessing. A preprocessing translation unit is parsed according to the syntax for preprocessing directives.

1854 preprocessor directives syntax

C90

The term *preprocessing translation unit* is new in C99.

C++

Like C90, the C++ Standard does not define the term *preprocessing translation unit*.

Other Languages

Java defines the term *compilation unit*. Other terms used by languages include *module*, *program unit*, and *package*.

Coding Guidelines

Use of this term by developers is almost unknown. The term *source file* is usually taken to mean a single file, not including the contents of any files that may be **#include**d. Although a slightly long-winded term, *preprocessing translation unit* is the technically correct one. As such its use should be preferred in coding guideline documents.

---

translation unit known as

After preprocessing, a preprocessing translation unit is called a *translation unit.* 110

Commentary

This defines the term *translation unit*. A translation unit is the sequence of tokens that are the output of translation phase 4. The syntax for translation units is given elsewhere.

translation phase 4 129
translation unit syntax 1810

C90

A source file together with all the headers and source files included via the preprocessing directive ***#include****, less any source lines skipped by any of the conditional inclusion preprocessing directives, is called a translation unit.*

This definition differs from C99 in that it does not specify whether macro definitions are part of a translation unit.

C++

The C++ Standard, 2p1, contains the same wording as C90.

Common Implementations

In many translators the task of turning a preprocessing translation unit into a translation unit is the job of a single program .

footnote 5 120

Coding Guidelines

Although the term *translation unit* is defined by the standard to refer to the sequence of tokens *after preprocessing*; the term is not commonly used by developers. The term *after preprocessing* is commonly used by developers to refer to what the standard calls a translation unit. There seems to be little to be gained in trying to change this common usage term.

translation phase 7 136

Some of these coding guidelines apply to the sequence of tokens input to translation phase 7 (semantic analysis). There is rarely any difference between what goes into phase 5 and what goes into phase 7, and the term *after preprocessing* is commonly used by developers. For simplicity all phrases of translation after preprocessing are lumped together as a single whole. The guidelines in this book apply either to the visible source, before preprocessing, or after preprocessing.

---

translation units preserved

Previously translated translation units may be preserved individually or in libraries. 111

Commentary

The standard does not specify what information is preserved in these translated translation units. It could be a high-level representation, even some tokenized form, of the original source. It is most commonly relocatable machine code and an associated symbol table.

The standard says nothing about the properties of libraries, except what is stated here.

Other Languages

Some languages specify the information available from, or the properties of, their separately translated translation units. Many languages, for instance Fortran, do not even specify as much as the C Standard.

Java defines several requirements for how packages are to be preserved and suggests several possibilities; for instance, class files in a hierarchical file system with a specified naming convention.

Common Implementations

In the Microsoft Windows environment, translated files are usually given the suffix `.obj` and libraries the suffix `.lib` or `.dll`. In a Unix environment, the suffix `.o` is used for object files and the suffix `.a` for library files, or `.so` for dynamically linked libraries.

Coding Guidelines

Coding guidelines, on the whole, do not apply to the translated output. Use of tools, such as `make`, for ensuring consistency between libraries and the translated translation unit they were built from, and the source code that they were built from, are outside the scope of this book.

---

112 The separate translation units of a program communicate by (for example) calls to functions whose identifiers have external linkage, manipulation of objects whose identifiers have external linkage, or manipulation of data files.

translation units communication between

Commentary

Translation phase 8 is responsible for ensuring that all references to external objects and functions refer to the same entity. The technical details of how an object or function referenced in one translation unit accesses the appropriate definition in another translation unit is a level of detail that the standard leaves to the implementation. The issues of the types of these objects agreeing with each other, or not, is discussed elsewhere.

139 translation phase 8
1810 translation unit syntax
633 compatible separate translation units

Data read from a binary file is always guaranteed to compare equal to the data that was earlier written to the same file, during the same execution of a program. Separate translation units can also communicate by manipulating objects through pointers to those objects. These objects are not restricted to having external linkage. Similarly, functions can also be called via pointers to them. Visible identifiers denoting object or function definitions are not necessary.

Common Implementations

Information on the source file in which a particular function or object was defined is not usually available to the executing program. However, hosts that support dynamic linking provide a mechanism for implementations to locate functions that are referenced during program execution (most implementations require objects to have storage allocated to them during program startup).

150 program startup

Coding Guidelines

The issue of deciding which translation unit should contain which definition is discussed elsewhere, as is the issue of keeping identifiers declared in different translation units synchronized with each other.

1810 declarations in which source file
422.1 identifier declared in one file

---

113 Translation units may be separately translated and then later linked to produce an executable program.

translation unit linked

Commentary

This is all there is to the C model of separate compilation. The C Standard places no requirements on the linking process, other than producing a program image. How the translation units making up a complete program are identified is not specified by the standard. The input to translation phase 8 requires, under a hosted implementation, at least a translation unit that contains a function called `main` to create a program image.

107 program not translated at same time
162 hosted environment startup

Common Implementations

Most translators have an option that specifies whether the source file being translated should be linked to produce a program image (translation phase 8), or the output from the translator should be written to an object file (with no linking performed). In a Unix environment, the convention is for the default name of the file containing the executable program to be `a.out`.

---

114 **Forward references:** linkages of identifiers (6.2.2), external definitions (6.9), preprocessing directives (6.10).

5.1.1.2 Translation phases

translation phases of

The precedence among the syntax rules of translation is specified by the following phases.[5)]

Commentary

These phases were introduced by the C committee to answer translation ordering issues that differed among early C implementations.

If one or more source files is **#include**d, the phases are applied, in sequence, to each file. So it is not possible for constructs created prior to phase 4 (which handles **#include**) to span more than one source file. For instance, it is not possible to open a comment in one file and close it in another file. Constructs that occur after phase 4 can span multiple files. For instance, a string literal as the last token in one file can be concatenated to a string literal which is the first token in an immediately **#include**d file.

universal character name syntax 815

The following quote from the Rationale does not belong within any specific phrase of translation, so it is provided here. UCNs are discussed elsewhere.

UCN models of

Rationale

> . . . , how to specify UCNs in the Standard. Both the C and C++ Committees studied this situation and the available solutions, and drafted three models:
>
> A. Convert everything to UCNs in basic source characters as soon as possible, that is, in translation phase 1.
>
> B. Use native encodings where possible, UCNs otherwise.
>
> C. Convert everything to wide characters as soon as possible using an internal encoding that encompasses the entire source character set and all UCNs.
>
> Furthermore, in any place where a program could tell which model was being used, the standard should try to label those corner cases as undefined behavior.

C++

C++ has nine translation phases. An extra phase has been inserted between what are called phases 7 and 8 in C. This additional phase is needed to handle templates, which are not supported in C. The C++ Standard specifies what the C Rationale calls model A.

C++ model A 116

Other Languages

Most languages do not contain a preprocessor, and do not need to go to the trouble of explicitly calling out phases of translation. The C Standard might not have had to do this either, had it not been for the differing interpretations of the base document made by some translators.

base document 1

Java has three lexical translation steps (the first two are needed to handle Unicode).

Coding Guidelines

Few developers have any detailed knowledge of the phases of translation. It can be argued that use of constructs whose understanding requires a detailed knowledge of the phases of translation should be avoided. The problem is how to quantify *detailed knowledge*. Coding guidelines apply in all phases of translation, unless stated otherwise.

The distinction between preprocessor and subsequent phases is a reasonably well-known and understood division. The processes used by developers for extracting information from source code is likely to be affected by their knowledge of how a translator operates. Thinking in terms of the full eight phases is often unnecessary and overly complicated. The following phases are more representative of how developers view the translation process:

1. Preprocessing.
2. Syntax, semantics, and machine code generation.
3. Linking.

Example

```
1  #include <stdio.h>
2
3  int main(void)
4  {
5  printf("\\" "101");
6  }
```

---

116 1. Physical source file multibyte characters are mapped, in an implementation-defined manner, to the source character set (introducing new-line characters for end-of-line indicators) if necessary. translation phase 1

Commentary

This phase maps the bits held on some storage device onto members of the source character set (which is defined elsewhere). C requires that sequences of source file characters be grouped into units called lines (actually there are two kinds of lines). There is a lot of variability between hosts on how end-of-line is indicated. This specification requires that whatever method is used at the physical level, it be mapped to a single new-line indicator. 214 source character set 118 translation phase 2 224 end-of-line representation

The source file being translated may reside on host A, with the implementation doing the translation may be executing on host B, and the translated program may be intended to run on host C. All three hosts could be using different character set representations. During this phase of translation, we are only interested in host A and host B. The character set used by host C is of no consequence, to the translator, until translation phase 5. 133 translation phase 5

C90

In C90 the source file contains characters (the 8-bit kind), not multibyte characters.

C++

1. Physical source file characters are mapped, in an implementation-defined manner, to the basic source character set (introducing new-line characters for end-of-line indicators) if necessary. . . . Any source file character not in the basic source character set (2.2) is replaced by the universal-character-name that designates that character. 2.1p1

```
1  #define mkstr(s) #s
2
3  char *dollar = mkstr($); // The string "\u0024" is assigned
4                           /* The string "$", if that character is supported */
```

C++ model A

The C++ Committee defined its Standard in terms of model A, just because that was the clearest to specify (used the fewest hypothetical constructs) because the basic source character set is a well-defined finite set. Rationale

The situation is not the same for C given the already existing text for the standard, which allows multibyte characters to appear almost anywhere (the most notable exception being in identifiers), and given the more low-level (or *close to the metal*) nature of some uses of the language.

Therefore, the C committee agreed in general that model B, keeping UCNs and native characters until as late as possible, is more in the “spirit of C” and, while probably more difficult to specify, is more able to encompass

the existing diversity. The advantage of model B is also that it might encompass more programs and users' intents than the two others, particularly if shift states are significant in the source text as is often the case in East Asia.

In any case, translation phase 1 begins with an implementation-defined mapping; and such mapping can choose to implement model A or C (but the implementation must document it). As a by-product, a strictly conforming program cannot rely on the specifics handled differently by the three models: examples of non-strict conformance include handling of shift states inside strings and calls like `fopen("\\ubeda\\file.txt","r")` and `#include "sys\udefault.h"`. Shift states are guaranteed to be handled correctly, however, as long as the implementation performs no mapping at the beginning of phase 1; and the two specific examples given above can be made much more portable by rewriting these as `fopen("\\" "ubeda\\file.txt", "r")` and `#include "sys/udefault.h"`.

Other Languages

Java 3.2 *A translation of the Unicode escapes (3.3) in the raw stream of Unicode characters to the corresponding Unicode character . . .*

ISO 646 24 Which means that characters other than those appearing in ISO/IEC 646 can appear in identifiers, strings and character constants, etc.

Common Implementations

This phase is where a translator interfaces with the host to read sequences of bytes from a source file. A source file is usually represented as a text file. There are a few hosts that have no concept of a text file. Some translators use relatively high-level system routines and rely on the host to return a line of characters; others perform block reads of binary data and perform their own character mappings. The choice will depend on the facilities offered by the host and the extent to which a translator wants to get involved in unpicking the format used to store characters in a source file. Some hosts treat text files (the usual method for storing source files) differently from binary files (lines are terminated and end-of-file may be indicated by a special character or trailing null characters).

There is no requirement that the file containing C source code have any particular form. Known forms include the following:

- *Stream of bytes.* Both text and binary files are treated as a linear sequence of bytes— the Unix model.
- *Text files have special end-of-line markers and end-of-file is indicated by a special character.* Binary files are treated as a sequence of bytes.
- *Fixed-length records.* These records can be either fixed-line length (a line cannot contain more than a given, usually 72 or 80, number of characters; dating back to when punch cards were the primary form of input to computers), or fixed-block length (i.e., lines do not extend over block boundaries and null characters are used to pad the last line in a block).

A translator that reads a block of characters at a time has to be responsible for knowing the representation of source files and may, or may not, have to perform some conversion to create an end-of-line indicator.[447]

Source files are usually represented in storage using the same set of byte values that are used by the translator to represent the source character set, so there is no actual mapping involved in many cases. The physical representation used to represent source files will be chosen by the tools used to create the source file, usually an editor.

The Unisys A Series[1390] uses fixed-length records. Each record contains 72 characters and is padded on the right with spaces (no new-line character is stored). To represent logical lines that are longer than 72

characters, a backslash is placed in column 72 of the physical line, folding characters after the 71 onto the next physical line. A logical line that does end in a backslash character is represented in the physical line by two backslash characters.

The Digital Mars C[356] compiler performs special processing if the input file name ends in `.htm` or `.html`. In this case only those characters bracketed between the HTML tags <code> and </code> are considered significant. All other characters in the input file are ignored.

The IBM ILE C development environment[617] associates a Coded Character Set Identifier (CCSID) with a source physical file. This identifier denotes the encoding used, the character set identifiers, and other information. Files that are **#include**d may have different CCSID values. A set of rules is defined for how the contents of these include files is mapped in relation to CCSID of the source files that **#include**d them. A **#pragma** preprocessing directive is provided to switch between CCSIDs within a single source file; for instance:

```
1  char EBCDIC_hello[] = "Hello World";
2
3  /* Switch to ASCII character set. */
4  #pragma convert(850)
5  char ASCII_hello[] = "Hello World";
6
7  /* Switch back. */
8  #pragma convert(0)
```

Example

WG14/N770

If the source contains:

$??)

and the translator is operating in a locale where $ and the immediately following character represent a single multibyte character. Then the input stream consists of the multibyte characters: $? ?)

In another locale the input stream might consist of the multibyte characters: $? ?) with the ??) being treated as a trigraph sequence and replaced by].

Table 116.1: Total number of characters and new-lines in the visible form of the `.c` and `.h` files.

	`.c` files	`.h` files
total characters	192,165,594	64,429,463
total new-lines	6,976,266	1,811,790
non-comment characters	144,568,262	43,485,916
non-comment new-lines	6,113,075	1,491,192

117 Trigraph sequences are replaced by corresponding single-character internal representations.

trigraph sequences phase 1

Commentary

The replacement of trigraphs by their corresponding single-character occurs before preprocessing tokens are created. This means that the replacement happens for all character sequences, not just those outside of string literals and character constants.

233 trigraph sequences mappings
895 string literal syntax
867 integer character constant

Other Languages

Many languages are designed with an Ascii character set in mind, or do not contain a sufficient number of punctuators and operators that all characters not in a commonly available subset need to be used. Pascal specifies what it calls lexical alternatives for some lexical tokens.

Common Implementations

Studies of translator performance have shown that a significant amount of time is consumed by lexing characters to form preprocessing tokens.[1436] In order to improve performance for the average case (trigraphs are not frequently used), one vendor (Borland) wrote a special program to handle trigraphs. A source file that contained trigraphs first had to be processed by this program; the resulting output file was then fed into the program that implemented the rest of the translator.

Coding Guidelines

Because the replacement occurs in translation phase 1, trigraphs can have unexpected effects in string literals and character constants. Banning the use of trigraphs will not prevent a translator from replacing them if encountered in the source. Also, in string literal contexts the developers mind-set is probably not thinking of trigraphs, so such sequences are unlikely to be noticed anyway.

Sequences of ? characters may be needed within literals by the application. One solution is to replace the second of the ? characters by the escape sequence \?, unless a trigraph is what was intended.

Some guidelines suggest running translators in a nonstandard mode (some translators provide an option that causes trigraph sequences to be left unreplaced), if one exists, as a way of preventing trigraph replacement from occurring. Running a translator in a nonstandard mode is rarely a good idea; what of those developers who are aware of trigraphs and intentionally use them?

The use of trigraphs may overcome the problem of entering certain characters on keyboards. But visually they are not easily processed, or to be exact very few developers get sufficient practice reading trigraphs to be able to recognize them effortlessly. Digraphs were intended as a more readable alternative (the characters used are more effective memory prompts for recalling the actual character they represent; they are discussed elsewhere).

digraphs 916

Example

```
#include <stdio.h>

void f(void)
{
printf("??=");     /* Prints # */
printf("?" "?=");  /* Prints ??= */
printf("?\?=");    /* Prints ??= */
}
```

Usage

The visible form of the `.c` files contain 8 trigraphs (`.h` 0).

---

translation phase 2
physical source line
logical source line
line splicing

2. Each instance of a backslash character (\) immediately followed by a new-line character is deleted, splicing physical source lines to form logical source lines. 118

Commentary

This process is commonly known as *line splicing*. The preprocessor grammar requires that a directive exists on a single logical source line. The purpose of this rule is to allow multiple physical source lines to be spliced to form a single logical source line so that preprocessor directives can span more than one line. Prior to the introduction of string concatenation, in C90, this functionality was also used to create string literals that may have been longer than the physical line length, or could not be displayed easily by an editor.

Emailing source code is now common. Some email programs limit the number of characters on a line and will insert line breaks if this limit is exceeded. Human-written source might not form very long lines, but automatically generated source can sometimes contain very long identifier names.

C++

The first sentence of 2.1p2 is the same as C90.

The following sentence is not in the C Standard: 2.1p2

If, as a result, a character sequence that matches the syntax of a universal-character-name is produced, the behavior is undefined.

```
#include <stdio.h>

int \u1F\
5F;          // undefined behavior
             /* defined behavior */
void f(void)
{
printf("\\u0123"); /* No UCNs. */
printf("\\u\
0123"); /* same as above, no UCNs */
        // undefined, character sequence that matches a UCN created
}
```

Common Implementations

Some implementations use a fixed-length buffer to store logical source lines. This does not necessarily imply that there is a fixed limit on the maximum number of characters on a line. But encountering a line longer than the input buffer can complicate the generation of log files and displaying the input line with any associated diagnostics. Both quality-of-implementation issues are outside the scope of the standard.

Coding Guidelines

A white-space character is sometimes accidentally placed after a backslash. This can occur when source files are ported, unconverted between environments that use different end-of-line conventions; for instance, reading MS-DOS files under Linux. The effect is to prevent line splicing from occurring and invariably causes a translator diagnostic to be issued (often syntax-related). This is an instance of unintended behavior and no guideline recommendation is made.

The limit on the number of characters on a logical source line is very unlikely to be reached in practice and line splicing is rarely used outside of preprocessing directives. Existing source sometimes uses line splicing to create a string literal spanning more than one source code line. The reason for this usage often is originally based on having to use a translator that did not support string literal concatenation.

292 limit characters on line

Example

```
#include <stdio.h>

#define X          ??/
           (1+1) /* ??/ -> \ */

extern int g\
l\
o\
b
;

void f(void)
{
if (glob)
   {
   printf("Something so verbose we need\
 to split it over more than one line\n");
   printf ("Something equally verbose but at"
```

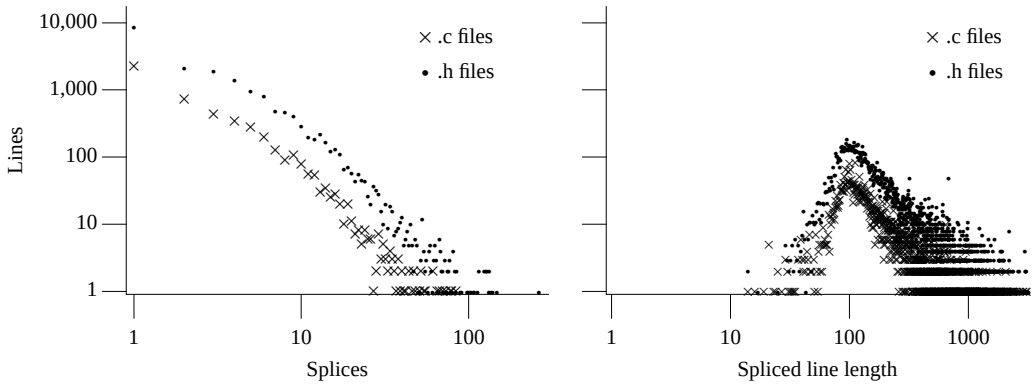

Figure 118.1: Number of physical lines spliced together to form one logical line and the number of logical lines, of a given length, after splicing. Based on the visible form of the `.c` and `.h` files.

```
            " least we have some semblance of visual layout\n");
    }

printf("\\u0123"); /* No UCNs. */
printf("\\
\u0123");          /* Same as above, no UCNs. */

printf("\\
\n");              /* No new-line output. */
}
```

Usage

In the visible form of the `.c` files 0.21% (`.h` 4.7%) of all physical lines are spliced. Of these line splices 33% (`.h` 7.8%) did not occur within preprocessing directives (mostly in string literals).

Only the last backslash on any physical source line shall be eligible for being part of such a splice. 119

Commentary

A series of backslash characters at the end of a line does not get consumed (assuming there are sufficient empty following lines). This is a requirement that causes no code to be written in the translator, as opposed to a requirement that needs code to be written to implement it.

C90

This fact was not explicitly specified in the C90 Standard.

C++

The C++ Standard uses the wording from C90.

Example

```
#include <stdio.h>

void f(void)
{
/*
 * In the following the two backslash characters do not cause two
 * line splices.  There is a single line splice.  This results in
 * a single double-quote character, causing undefined behavior.
 */
printf("\\
```

```
11
12  n");
13  /*
14   * The above is not equivalent to printf("n");
15   */
16
17  /*
18   * Below the backslash characters are on different lines.
19   */
20  printf("\
21  \
22  n");
23  }
```

120 5) Implementations shall behave as if these separate phases occur, even though many are typically folded together in practice. footnote 5

Commentary

The phases of translation describe an intended effect, not an implementation strategy. It is not expected that implementations implement the different phases via different programs.

Common Implementations

Many translators do split up the job of translation between a number of programs. Typically one program performs preprocessing (translation phases 1–4), while another performs syntax, semantic analysis, and code generation (the last operation is not directly mentioned in the standard). The usual method of communicating between the two programs is via intermediate files. If the original source file has the name `f.c` and translator options are used to save the output of various translation phases, the file holding the preprocessed output is normally given the name `f.i` and the file holding any generated assembler code is given the name `f.s`. Phase 8 is nearly always performed by a separate program (that can usually also handle languages other than C), a linker. [0] translation technology

A compiler sold by Borland included a separate program to handle trigraphs (the programs handling other phases of translation did not include code to process trigraphs).

At least one program, `lcc`,[448] effectively only performs phase 7. It requires a third-party program to perform the earlier and later phases. The method of communication between phases is a file containing a sequence of characters that look remarkably like a preprocessed file (so `lcc` has to retokenize its input).

source file representation

121 Source files, translation units and translated translation units need not necessarily be stored as files, nor need there be any one-to-one correspondence between these entities and any external representation.

Commentary

The term *file* has a common usage within computing and the term *source file* could be interpreted to imply that source code had to be stored in such files. While source files are commonly represented using a text file within a host file system there is no requirement to use such a representation.

A translator may chose to internally maintain information about the effect of including a system header (e.g., an internal symbol table of declared identifiers) that is accessed when the corresponding **`#include`** is encountered. In such an implementation there is no external representation of the system header.

This sentence was added by the response to DR #308.

Other Languages

Languages which are defined by a written specification do not usually require that a particular external representation be used for source files. Languages defined by a particular implementation (e.g., PERL) require a source file representation that can be handled by that implementation.

Common Implementations

header precompiled

Some implementations support what are known as *precompiled headers*.[755, 860] The contents of such headers have a form that has been partially processed through some phases of translation. The benefit of using precompiled headers is a, sometimes dramatic, improvement in rate of translation (figures of 20–70% have been reported).

IDE

Some software development environments (often called *IDE*s', Integrated Development Environments) hold the source code within some form of database. This database often includes version-control information, translator options, and other support information.

The description is conceptual only, and does not specify any particular implementation. 122

Commentary

as-if rule

The term *as-if rule* (or sometimes *as-if principle*) occurs frequently in discussions involving the C Standard. This term is not defined in the C Standard, but is mentioned in the Rationale:

Rationale

> The as if principle is invoked repeatedly in this Rationale. The C89 Committee found that describing various aspects of the C language, library, and environment in terms of concrete models best serves discussion and presentation. Every attempt has been made to craft the models so that implementors are constrained only insofar as they must bring about the same result, as if they had implemented the presentation model; often enough the clearest model would make for the worst implementation.
>
> A question sometimes asked regarding optimization is, "Is the rearrangement still conforming if the precomputed expression might raise a signal (such as division by zero)?" Fortunately for optimizers, the answer is "Yes," because any evaluation that raises a computational signal has fallen into an undefined behavior (§6.5), for which any action is allowable.

Essentially, a translator is free to do what it likes as long as the final program behaves, in terms of visible output and effects, as-if the semantics of the abstract machine were being followed. In some instances the standard calls out cases based on the as-if rule.

expression 190 need not evaluate part of

This sentence was added by the response to DR #308.

C++

1.9p1

> *In particular, they need not copy or emulate the structure of the abstract machine. Rather, conforming implementations are required to emulate (only) the observable behavior of the abstract machine as explained below.5)*

Footnote 5

> *This provision is sometimes called the "as-if" rule, because an implementation is free to disregard any requirement of this International Standard as long as the result is as if the requirement had been obeyed, as far as can be determined from the observable behavior of the program. For instance, an actual implementation need not evaluate part of an expression if it can deduce that its value is not used and that no side effects affecting the observable behavior of the program are produced.*

---

source file end in new-line

A source file that is not empty shall end in a new-line character, which shall not be immediately preceded by a backslash character before any such splicing takes place. 123

Commentary

What should the behavior be if the last line of an included file did not end in a new-line? Should the characters at the start of the line following the **#include** directive be considered to be part of any preceding preprocessing token (from the last line of the included file)? Or perhaps source files should be treated as containing an implicit new-line at their end. This requirement simplifies the situation by rendering the behavior undefined.

125 source file partial preprocessing token

Lines are important in preprocessor directives, although they are not important after translation phase 4. Treating two apparently separate lines, in two different source files, as a single line opens the door to a great deal of confusion for little utility.

C90

The wording, " . . . before any such splicing takes place.", is new in C99.

Coding Guidelines

While undefined behavior will occur for this usage, instances of it occurring are so rare that it is not worth creating a coding guideline recommending against its use.

Example

```
1  /*
2   * If this source file is #include'd by another source file, might
3   * some implementation splice its first line onto the last line?
4   */
5  void f(void)
6  {
7  }\
```

---

124 3. The source file is decomposed into preprocessing tokens[6)] and sequences of white-space characters (including comments). translation phase 3

Commentary

Preprocessing tokens are created before any macro substitutions take place. The C preprocessor is thus a token preprocessor, not a character preprocessor. The base document was not clear on this subject and some implementors interpreted it as defining a character preprocessor. The difference can be seen in:

925 EXAMPLE tokenization
1 base document

```
1  #define a(b) printf("b=%d\n", b);
2
3  a(var);
```

The C preprocessor expands the above to:

```
1  printf("b=%d\n", var);
```

while a character preprocessor would expand it to:

```
1  printf("var=%d\n", var);
```

Linguists used the term *lexical analysis* to describe the process of collecting characters to form a word before computers were invented. This term is used to describe the process of building preprocessing tokens and in C's case would normally be thought to include translation phases 1–3. The part of the translator that performs this role is usually called a *lexer*. As well as the term *lexing*, the term *tokenizing* is also used.

Common Implementations

Decomposing a source file into preprocessing tokens is straight-forward when starting from the first character. However, in order to provide a responsive interface to developers, integrated development environments often perform incremental lexical analysis[1433] (e.g., only performing lexical analysis on those characters in the source that have changed, or characters that are affected by the change).

Coding Guidelines

The term *preprocessing token* is rarely used by developers. The term *token* is often used generically to apply to such entities in all phases of translation.

Usage

The visible form of the `.c` files contain 30,901,028 (`.h` 8,338,968) preprocessing tokens (new-line not included); 531,677 (`.h` 248,877) `/* */` comments, and 52,531 (`.h` 27,393) `//` comments.

preprocessing tokens 777
white space separation

Usage information on white space is given elsewhere.

---

source file partial preprocessing token

A source file shall not end in a partial preprocessing token or in a partial comment. 125

Commentary

What is a partial preprocessing token? Presumably it is a sequence of characters that do not form a preprocessing token unless additional characters are appended. However, it is always possible for the individual characters of a multiple-character preprocessing token to be interpreted as some other preprocessing token (at worst the category "each non-white-space character that cannot be one of the above" applies). For instance, the two characters `..` (where an additional period character is needed to create an ellipsis preprocessing token) represents two separate preprocessing tokens (e.g., two periods). The character sequence `%:%` represents the two preprocessing tokens `#` and `%` (rather than `##`, had a `:` followed).

preprocessing token 770
syntax

The intent is to make it possible to be able perform low-level lexical processing on a per source file basis. That is, an **`#include`**d file can be lexically analyzed separately from the file from which it was included. This means that developers only need to look at a single source file to know what preprocessing tokens it contains. It can also simplify the implementation.

source file 123
end in new-line

The requirement that source files end in a new-line character means that the behavior is undefined if a line (physical or logical) starts in one source file and is continued into another source file.

In this phase a comment is an indivisible unit. A source file cannot contain part of such a unit, only a whole comment. That is, it is not possible to start a comment in one source file and end it in another source file.

Coding Guidelines

Translators are not required to diagnose a comment that starts in one source file and ends in another. However, this usage is very rare and consequently a guideline recommendation is not cost effective.

---

comment replaced by space

Each comment is replaced by one space character. 126

Commentary

The C committee had to choose how many space characters a comment was converted into, including zero. The zero case had the disadvantage of causing some surprising effects, although some existing implementations had gone down this route. They finally decided that specifying more than a single space character was of dubious utility. Replacing a comment by one space character minimizes the interaction between it and the adjacent preprocessing tokens (space characters are not usually significant).

white space 780
significant

Other Languages

Java supports the `/* */` form of comments. The specification does not say what they get converted into.

Common Implementations

base document 1

The base document replaced a comment by nothing (some implementations continue to support this functionality for compatibility with existing code[600, 1314]). This had the effect of treating:

```
1  int a/* comment */b;
```

as a declaration of the identifier ab. The C Committee introduced the ## operator to explicitly provide this functionality. 1958 ## operator

Example

```
1  #define mkstr(a) #a
2
3  char *p = mkstr(x/* a comment*/y); /* p points at the string literal "x y" */
```

---

127 New-line characters are retained.

Commentary

New-line is a token in the preprocessor grammar. It is used to delimit the end of preprocessor directives.

Other Languages

New-line is important in several languages. Some older languages, and a few modern ones, have given meaning to new-line. Fortran (prior to Fortran 90) was not free format; the end of a line is the end of a statement or declaration, unless a line-continuation character appears in column 5 of the following line.

---

128 Whether each nonempty sequence of white-space characters other than new-line is retained or replaced by one space character is implementation-defined.

white-space sequence replaced by one

Commentary

In this phase the only remaining white-space characters that need to be considered are those that occur between preprocessing tokens. All other white-space characters will have been subsumed into preprocessing tokens. White-space characters only have significance now when preprocessing tokens are glued together, or as a possible constraint violation (i.e., vertical-tab or form-feed within a preprocessing directive). 1952 white space between macro argument tokens 1864 white-space within preprocessing directive

Other Languages

Some languages treat the amount of white space at the start of a line as being significant (make requires a horizontal tab at the beginning of a line in some contexts[1329]). In Fortran (prior to Fortran 90) statements were preceded by six space characters (five if a line continuation was being used, or a comment). In Occam statement indentation is used to indicate the nesting of blocks.

Common Implementations

Most implementations replace multiple white-space characters by one space character. The existence, or not, of white-space separation can be indicated by a flag associated with each preprocessing token, preceded by space.

Integrated development environments vary in their handling of white-space. Some only allow multiple white-space characters, between tokens, at the start of a line, while others allow them in any context. White-space characters introduce complexity for tools' vendors[1434] that is not visible to the developer.

Coding Guidelines

Sequences of more than one white-space character often occur at the start of a line. They also occur between tokens forming a declaration when developers are trying to achieve a particular visual layout. However, white-space can only make a difference to the behavior of a program, outside of the contents of a character constant or string literal, when they appear in conjunction with the stringize operator. 1950 # operator

Example

```
#define mkstr(a) #a

char *p = mkstr(2  []; /* p may point at the string "2  [", or "2 [" */
char *q = mkstr(2[];   /* q points at the string "2[" */
```

translation phase 4

4. Preprocessing directives are executed, macro invocations are expanded, and **_Pragma** unary operator expressions are executed. 129

Commentary

This phase is commonly referred to as *preprocessing*. The various special cases in previous translation phases do not occur often, so they tend to be overlooked.

Although the standard uses the phrase *executed*, the evaluation of preprocessor directives is not dynamic in the sense that any form of iteration, or recursion, takes place. There is a special rule to prevent recursion from occurring. The details of macro expansion and the **_Pragma** unary operator are discussed elsewhere.

macro being replaced found during rescan 1970
macro replacement _Pragma operator 2030

C90

Support for the **_Pragma** unary operator is new in C99.

C++

Support for the **_Pragma** unary operator is new in C99 and is not available in C++.

Other Languages

PL/1 contained a sophisticated preprocessor that supported a subset of the expressions and statements of the full language. For the PL/1 preprocessor, *executed* really did mean executed.

Common Implementations

The output of this phase is sometimes written to a temporary source file to be read in by the program that implements the next phrase of translation.

If a character sequence that matches the syntax of a universal character name is produced by token concatenation (6.10.3.3), the behavior is undefined. 130

Commentary

The C Standard allows UCNs to be interpreted and converted into internal character form either in translation phase 1 or translation phase 5 (the C committee could not reach consensus on specifying only one of these). If an implementation chooses to convert UCNs in translation phase 1, it makes no sense to require them to perform another conversion in translation phase 4. This behavior is different from that for other forms of preprocessing tokens. For instance, the behavior of concatenating two integer constants is well defined, as is concatenating the two preprocessing tokens whose character sequences are `0x` and `123` to create a hexadecimal constant.

universal character name syntax 815

The intent is that universal character names be used to create a readable representation of the source in the native language of the developer. Once this phase of translation has been reached, the sequence of characters in the source code needed to form that representation are not intended to be manipulated in smaller units than the universal character name (which may have already been converted to some other internal form).

C90

Support for universal character names is new in C99.

C++

translation phase 1 116

In C++ universal character names are only processed during translation phase 1. Character sequences created during subsequent phases of translation, which might be interpreted as a universal character name, are not interpreted as such by a translator.

Coding Guidelines

Support for universal character names is new and little experience has been gained in the kinds of mistakes developers make in its usage. It is still too early to know whether a guideline recommending "A character sequence that matches the syntax of a universal character name shall not be produced by token concatenation." is worthwhile.

Example

```
#define glue(a, b) a ## b

int glue(\u1, 234);
```

131 A **#include** preprocessing directive causes the named header or source file to be processed from phase 1 through phase 4, recursively.

Commentary

The **#include** preprocessing directives are processed in-depth first order. Once an **#include** has been fully processed, translation continues in the file that **#include**d it. There is a limit on how deeply **#include**s can be nested. Just prior to starting to process the **#include**, the macros __FILE__ and __LINE__ are set (and they are reset when processing resumes in the file containing the **#include**).

295 limit #include nesting
2007 __FILE__ macro
2008 __LINE__ macro

The effect of this processing is that phase 5 sees a continuous sequence of preprocessing tokens. These preprocessing tokens do not need to maintain any information about the source file that they originated from.

132 All preprocessing directives are then deleted.

preprocessing directives deleted

Commentary

This requirement was not explicitly specified in C90. In practice it is what all known implementations did. Also, macro definitions have no significance after translation phase 4.

1975 macro definition no significance after

Preprocessing directives have their own syntax, which does not connect to the syntax of the C language proper. The preprocessing directives are used to control the creation of preprocessing tokens. These are handed on to subsequent phases; they don't get past phase 4.

1854 preprocessor directives syntax

C++

This explicit requirement was added in C99 and is not stated in the C++ Standard.

Common Implementations

Many implementations write the output of the preprocessor to a file to be read back in by the next phase. Ensuring that declarations and statements retain the same line number as they had in the source file allows more specific diagnostic messages to be produced. To achieve this effect, some implementations convert preprocessing directives to blank lines, while others insert **#line** directives.

133 5. Each source character set member and escape sequence in character constants and string literals is converted to the corresponding member of the execution character set;

translation phase 5

Commentary

The execution character set is used by the host on which the translated program will execute. Up until this phase characters have been represented using the physical-to-source character set mapping that occurred in translation phase 1.

218 execution character set represented by
116 translation phase 1

The translation and execution environments may, or may not, use the same values for character set members. This conversion relies on implementation-defined behavior. In the case of escape sequences, an implementation is required to use the value specified (provided this value is representable in the type **char**).

870 character constant mapped
873 escape sequence octal digits
875 escape sequence hexadecimal digits

For instance, the equality `'\07'==7` is true, independent of whether any member of the basic execution character set maps to the value seven. This issue is discussed in DR #040q8.

Common Implementations

Probably the most commonly used conversion uses the values specified in the Ascii character set. Some mainframe hosted implementations continue to use EBCDIC.

Coding Guidelines

Differences between the values of character set members in the translation and execution environments become visible if a relationship exists between two expressions, one appearing in a **`#if`** preprocessing directive and the other as a controlling expression. This issue is discussed elsewhere.

footnote 1874 141

Example

In the following:

```
1  void f(void)
2  {
3  char ch = 'a';
4  char dollar = '$';
5  }
```

the integer character constant `'a'` is converted to its execution time value. It may have an Ascii value in the source character set and an EBCDIC value in the execution character set. The $ character will have been mapped to the source character set in translation phase 1. In the following example it can be mapped back to the $ character if the implementation so chooses.

```
1  #if ('a' == 97) && ('Z' == 90)
2  #define PREPROCESSOR_USES_ASCII 1
3  #else
4  #define PREPROCESSOR_USES_ASCII 0
5  #endif
6
7  _Bool ascii_execution_character_set(void)
8  {
9  return ('a' == 97) && ('Z' == 90);
10 }
```

---

corresponding member if no

if there is no corresponding member, it is converted to an implementation-defined member other than the null (wide) character.[7)] 134

Commentary

All source character set members and escape sequences, which have no corresponding execution character set member, may be converted to the same member, or they may be converted to different members. The behavior is required to be documented.

The null character is special in that it is used to terminate string literals. It is possible for a string literal to contain a null character through the use of an escape sequence, but such an occurrence has to be explicitly created by the developer. It is never added by the implementation.

C90

The C90 Standard did not contain this statement. It was added in C99 to handle the fact that the UCN notation supports the specification of numeric values that may not represent any specified (by ISO 10646) character.

ISO 10646 28

C++

The values of the members of the execution character sets are implementation-defined, and any additional members are locale-specific.

116 translation phase 1

C++ handles implementation-defined character members during translation phase 1.

Common Implementations

Most implementations simply convert escape sequences to their numerical value. There is no check that the value maps to a character in the execution character set. Characters in the source character set, which are not in the execution character set, are often mapped to the value used to represent that value in the translation environment.

Coding Guidelines

Why would source code contain an instance of a source character or escape sequence that did not have a corresponding member in the execution character set? The usage could be because of a fault in the program (and therefore outside the scope of these coding guidelines), or existing source is being ported to a new environment that does not support it.

Use of members of an extended character set is by its very nature dependent on particular environments. Porting source that contains such character usage does not fall within the scope of these guidelines.

216 extended character set

Example

```
1  char g_c = '$';
2  char my_address = "derek@99.C.ISO.Earth";
3
4  char e_c = '\007';
5
6  #if '@' == 64
7  char *char_set = "ASCII";
8  #else
9  char *char_set = "EBCDIC ;-)";
10 #endif
```

---

135 6. Adjacent string literal tokens are concatenated.

translation phase 6

Commentary

This concatenation only applies to string literals. It is not a general operation on objects having an array of **char**. String literal preprocessing tokens do not have a terminating null character. That is added in the next translation phase.

C90

6. Adjacent character string literal tokens are concatenated and adjacent wide string literal tokens are concatenated.

It was a constraint violation to concatenate the two types of string literals together in C90. Character and wide string literals are treated on the same footing in C99.

The introduction of the macros for I/O format specifiers in C99 created the potential need to support the concatenation of character string literals with wide string literals. These macros are required to expand to character string literals. A program that wanted to use them in a format specifier, containing wide character string literals, would be unable to do so without this change of specification.

Other Languages

Most languages that support string concatenation require that the appropriate operator be used to specify an operation to be performed. For instance, Ada uses the character **&**.

Coding Guidelines

There is the possibility, in an initializer or argument list, that a missing comma causes two unrelated string literals to be concatenated. However, this is a fault and considered to be outside the scope of these coding guidelines.

guidelines 0 not faults

Example

```
#include <stdio.h>

/*
 * Assign the same value, L"ab", to three different objects.
 */
wchar_t *w_p1 = L"a" L"b",
        *w_p2 = L"a"  "b",
        *w_p3 = "a" L"b";

void f(void)
{
printf("\\" "066"); /* Output \066, escape sequences were processed earlier. */
}
```

Usage

In the visible form of the `.c` files 4.9% (`.h` 15.6%) of string literals are concatenated.

---

translation phase 7

7. White-space characters separating tokens are no longer significant. 136

Commentary

White-space is not part of the syntax of the C language. It is only significant in separating characters in the lexical grammar and in some contexts in the preprocessor. This statement could have equally occurred in translation phase 5.

replacement list 1918 identical if

Other Languages

Fortran 777 spaces not significant

In Fortran white space is never significant.

Example

```
#define mkstr(x) #x

char *a_space_plus_b = mkstr(a +b);
char *a_plus_b = mkstr(a+b);
```

---

preprocessing token converted to token

Each preprocessing token is converted into a token. 137

Commentary

These are the tokens seen by the C language parser (the same conversion also occurs within **#if** preprocessing directives). It is possible for a preprocessing token to not be convertible to a token. For instance, in:

#if 1878 identifier replaced by 0

```
float f = 1.2.3.4.5;
```

`1.2.3.4.5` is a valid preprocessing token; it is a pp-number. However, it is not a valid token. 927 pp-number syntax

Preprocessing tokens that are skipped as part of conditional compilation need never be converted to tokens (because they never make it out of translation phase 4).

```
#if 0
float f = 1.2.3.4.5; /* Never converted. */
#endif
```

A preprocessing token that cannot be converted to a token is likely to cause a diagnostic to be issued. At the very least, there will be a syntax violation. It is a quality-of-implementation issue as to whether the translator issues a diagnostic for the failed conversion.

Other Languages

Few other language contain a preprocessor. Any problems associated with creating a token are directly caused by the sequence of input characters.

---

138 The resulting tokens are syntactically and semantically analyzed and translated as a translation unit. syntactically analyzed

Commentary

This is what the bulk of the standard's language clause is concerned with.

Common Implementations

This is the phase where the executable code usually gets generated.

Luo, Chen, and Yu[877] found that an equation of the form L^x, where L is the number of bytes in the source file (i.e., header file contents are not included) and x some constant, provided a good estimate for the elapsed time needed to translate a source file (an x value of approximately 0.66 was found for GCC 3.4.2) and to link it (an x value of approximately 0.1 was found for GCC). 108 source files

Coding Guidelines

Coding guidelines are not just about how the semantics phase of translation processes its input. Previous phases of translation are also important, particularly preprocessing. The visible source, the input to translation phase 1, is probably the most important topic for coding guidelines.

---

139 8. All external object and function references are resolved. translation phase 8

Commentary

This resolution is normally carried out by a program commonly known as a linker. Although the standard says nothing about what such resolution means its common usage (in linker terminology) is that references to declarations are made to refer to their corresponding definitions.

C++

The C translation phase 8 is numbered as translation phase 9 in C++ (in C++, translation phase 8 specifies the instantiation of templates).

Common Implementations

The code generated for a single translation unit invariably contains unresolved references to external objects and functions. The tool used to resolve these references, a linker, may be provided by the implementation vendor or it may have been supplied as part of the host environment.

Resolving references that involve addresses larger than the length of a machine code instruction can lead to inefficiencies and wasted space. For instance, generating a 32-bit address using instructions that have a maximum length of 16 bits requires at least three instructions (some bits are needed to specify what the instruction does; for instance, load constant). In practice most addresses do not require a full 32-bit value, but this information is not available until link-time, while translators have been forced to make worst-case assumptions. Many processors solve this problem by having variable-length instructions.

The simplifications derived from the principles behind RISC mean that their instructions have a fixed length. It is possible to handle 32 bit addresses using a 32-bit instruction width by appropriate design conventions (e.g., the call instruction encoded in 2 bits, leaving 30 bits for addresses and requiring that functions start on a 4-byte address boundary). The move to a 64-bit address space reintroduces problems seen in the 16/32-bit era two decades earlier. However, processor performance and storage capabilities have moved on and link-time optimizations are now practical. In particular the linker knows the values of addresses and can generate the minimum number of instructions needed.[1276]

The quest for higher-quality machine code has led research groups to look at link-time optimizations.[1437] Having all of the components of a program available opens up opportunities for optimizations that are not available when translating a single translation unit. A study by Muth, Debray, Watterson, and De Bosschere[985] found that on average 18% of a programs instructions could have their operands and result determined at link time. This does not imply that 18% of a program's instructions could be removed; knowing information provides opportunities for optimization, like replacing an indirect call with a direct one.

Levine[848] discusses the principles behind linking object files to create a program image and loading that program image, into storage, prior to executing it.

Coding Guidelines

The problem of ensuring that the same identifier, declared in different translation units, always resolves to a definition having the same type is discussed elsewhere.

identifier declared in one file 422.1

Library components are linked to satisfy external references to functions and objects not defined in the current translation. 140

Commentary

The term *library components* is a broad one and can include previously translated translation units. The implementation is responsible for linking in any of its provided C Standard library functions, if needed.

translation units preserved 111

The wording of this requirement can be read to imply that all external references must be satisfied. This would require definitions to exist for objects and functions, even if they were never referenced during program execution (but were referenced in the translated source code). This is the behavior enforced by most linkers.

Since there is no behavior defined for the case where a reference cannot be resolved, it is implicitly undefined behavior.

undefined behavior indicated by 85

Other Languages

This linking phase is common to many implementations of most programming languages that support some form of separate compilation. In a few cases the linking process can occur on an as-needed basis during program execution, as for instance in Java.

translation unit syntax 1810

Common Implementations

linkers

Most linkers assume that all of the definitions in the developer-supplied list of object files, given to the linker, are needed, but that definitions from the implementation system libraries only need be included if they are referenced from the developer-written code.

Optimizing linkers build a function call tree, starting from the function `main`. This enables them to exclude functions, supplied by the developer, from the program image that are never referenced during execution.

The two commonly used linking mechanisms are static and dynamic linking. Static linking creates a program image that contains all of the function and object definitions needed to execute the program. A statically linked program image has no need for any other library functions at execution time. This method of linking is suitable when distributing programs to host environments where very little can be assumed about the availability of support libraries. If many program images are stored on a host, this method has the disadvantage of keeping a copy of library functions that are common to a lot of programs. Also if any libraries are updated, all programs will need to be relinked.

Dynamic linking does not copy library functions into the program image. Instead a call to a dynamic linking system function is inserted. When a dynamically linked function is first called, the call is routed

via the dynamic link loader, which resolves the reference to the desired function and patches the executing program so that subsequent calls jump directly to that routine. Provided there is support from the host OS, all running programs can access a single copy of the library functions in memory. On hosts with many programs running concurrently, this can have a large impact on memory performance (reduced swapping). Any library updates will be picked up automatically. The program image lets the dynamic loader decide which version of a library to call.

An implementation developed by Neamtiu, Hicks, Stoyle and Oriol[999] supports what they call *dynamic software updating*, whereby an executing program can be patched at a fine level of granularity, e.g., a modified version of a function (the parameter and return types have to be compatible) can replace the one currently in the executing program image.

Coding Guidelines

The standard does not define the order in which separately translated translation units and implementation supplied libraries are scanned to resolve external references. Many implementations scan files in the order in which they are given to the linker.

Most implementations define additional library functions. The names of such functions rarely follow the conventions, defined in the C Standard, for implementation-defined names. There is the possibility that one of these names will match that of an externally visible, developer-written function definition. Placing system libraries last on the list to be processed helps to ensure that any developer-provided definitions, whose names match those in system libraries, are linked in preference to those in the system library. Of course there may then be the problem of the system library referencing the incorrect definition.

Linking is often an invisible part of building the program image (diagnostics are sometimes issued for multiply defined identifiers). Checking which references have been resolved to which definitions is often very difficult. In the case of an incorrect function definition being used, a set of tests that exercise all called functions is likely to highlight any incorrect usage. In the case of incorrect objects, things might appear to work as expected. A guideline recommendation dealing with the incorrect definition being used to build the program image sounds worthwhile. However, this usage is likely to be unintended (a fault) and these coding guidelines are not intended to recommend against the use of constructs that are obviously faults.

0 guidelines not faults

---

141 All such translator output is collected into a program image which contains information needed for execution in its execution environment.

program image

Commentary

This wording implies a single location, perhaps a file (containing all of the information needed) or a directory (potentially containing more than one file with all of the necessary information). Several requirements can influence how a program image is built, including the following:

- *Developer convenience.* Like all computer users, developers want things to be done as quickly as possible. During the coding and debugging of a program, its image is likely to be built many times per hour. Having a translator that builds this image quickly is usually seen as a high priority by developers.
- *Support for symbolic debugging.* Here information on the names of functions, source line number to machine code offset correspondence, the object identifier corresponding to storage locations, and other kinds of source-related mappings needs to be available in the program image. Requiring that it be possible to map machine code back to source code can have a significant impact on the optimizations that can be performed. Research on how to optimize and include symbolic debugging information has been going on for nearly 20 years. Modern approaches[1485] are starting to provide quality optimizations while still being able to map code and data locations.
- *Speed of program execution.* Users of applications want them to execute as quickly as possible. The organization of a program image can have a significant impact on execution performance.

- *Hiding information.* Information on the internal workings of a program may be of interest to several people. The owner of the program image may want to make it difficult to obtain this information from the program image.[1440]
- *Distrust of executable programs.* Executing an unknown program carries several risks: It may contain a virus, it may contain a trojan that attempts to obtain confidential information, it may consume large amounts of system resources or a variety of other undesirable actions. The author of a program may want to provide some guarantees about a program, or some mechanism for checking its integrity. There has been some recent research on translated programs including function specification and invariant information about themselves, so-called proof carrying programs.[1001] Necula's proposed method includes a safety policy and operating in the presence of untrusted agents. On the whole the commonly used approach is for the host environment to ring fence an executing program as best it can, although researchers have started to look at checking program images[1488] before loading them, particularly into a trusted environment.

Other Languages

Most language specifications are silent on the issue of building program images. The Java specification explicitly specifies a possible mechanism supporting a distributed, across separate files, program image.

Common Implementations

Some program images contain all of the necessary machine code and data; they don't reference other files containing additional definitions— static linking. While other program images copy the object code derived from developer-written code in a single file, which also contains references to system-supplied definitions that need to be supplied during execution (held in other files)— dynamic linking.

The file used to hold a program image usually has some property to indicate its status as an executable program. Under MS-DOS the name the file extension is used (`.exe` or `.com`). Under Unix the list of possible file attributes, held by the file system, includes a flag to indicate an executable program.

The information in a program image may be laid out so that it can be copied directly into memory, as is. For instance, a MS-DOS `.com` file is completely copied into memory, starting at address 0x100. A Unix ELF (Executable and Linking Format) file contains segments that are copied to memory, as is (additional housekeeping information is also held in the file). Arranging for a program image to contain an exact representation of what needs to be held in memory has the advantage of simplifying swapping (assuming that the host performs this relatively high-level memory-management function) of unused code. It can simply be read back in from the program image; it does not have to be copied from memory to a swap partition and read back in.

On some hosts the layout of the program image, on a storage device, is different from its execution-time layout in storage. In this case the information in the program image is used to construct the execution-time layout when the program is first invoked. Such image formats include COFF (Common Object File Format) under Unix, MS-DOS `.exe` files and the IBM 360 object format (based on fixed-length records of 80 characters).

The ANDF (Architecture Neutral Distribution Format) project, http://www.tendra.org, aimed to produce a program image that could be installed on a variety of different hosts. The image contained a processed form of the original source code. An installer, running on a particular host, took this intermediate program image and a platform-specific program image (containing the appropriate machine code) from it, thus installing the program on that host. Installers were produced for a number of different host processors. The technology has not thrived commercially and much of the source code has now been made publicly available.

The performance of an application during certain parts of its execution is sometimes more important than during other parts. Program startup is often one such instance. Users of applications often want them to start as quickly as possible. How the program image is organized can affect the time taken for a program to start executing. One study by Lee, Crowley, Baer, Anderson, and Bershad[819] found that program startup

only required a subset of the information held in the program image. They also found that in some cases applications had scattered this information over the entire program image, requiring significantly more information to be read than was required for startup. They showed that by reordering how the program image was structured it was possible to reduce application startup latency by more than 58% (see Table 141.1).

Table 141.1: *Total* is the number of code pages in the application; *Touched* the number of code pages touched during startup; *Utilization* the average fraction of functions used during startup in each code page. Adapted from Lee.[819]

Application	Total	Touched (%)	% Utilization
acrobat	404	246 (60)	28
netscape	388	388 (100)	26
photoshop	594	479 (80)	28
powerpoint	766	164 (21)	32
word	743	300 (40)	47

Program images contain sequences of machine code instructions that are executed by the host processor. In some application domains the instructions making up a program can account for a large percentage of memory usage. Several techniques are available to reduce this overhead: Compression techniques can be applied to the sequence of instructions, or function abstraction can be applied.

instruction compression

A variety of instruction compression schemes have been proposed. The optimal choice can depend on the processor instruction format (RISC processors with fixed-length instructions, or DSP processors using very wide instruction words) and whether decompression is supported in hardware or software.[828] Compression ratios in excess of 50% are commonly seen. Performance penalties on decompression range from a few percent to 1,000% (for software decompression). At the time of this writing IBM's PowerPC 405 is the only commercially available processor that makes use of hardware compression (the CodePack algorithm). A good discussion of the issues and experimental results can be found in[829]

On early Acorn RISC Unix machines, the bottleneck in loading a program image was the disk drive. Analysis showed that it was quicker to load a smaller image and decompress it, on the fly, than to fetch the extra disk blocks with no decompression (a simple compression program was included with each system). The encoding of the ARM machine code created opportunities for compression. For instance, the first 4 bits of each opcode are a conditional. Most instructions are always executed and these four bits contained the value 0xE; a value of 0xF meant *never* and rarely occurred in the image.

Another approach to reducing the memory footprint of a program is to use compression on a function-by-function basis. Kirovski[739] reported an average memory reduction of 40% with a runtime performance overhead of 10% using a scheme that held uncompressed functions in a cache; a call to a compressed function causes it to be uncompressed and placed in the cache, possibly removing the uncompressed code for a function already in the cache.

The ordering of functions within the program image can also affect performance by affecting what is loaded into any instruction cache. In one study[1198] it was found that in an Oracle database running an online transaction-processing application (with an instruction footprint of about 1 M byte) 25% to 30% of the execution time was caused by instruction stalls. By reordering functions in memory (dynamically, during program execution, based on runtime behavior), it was possible to improve performance by 6% to 10%[1198]. 1710 basic block

function abstraction

Function abstraction (sometimes called *procedure abstraction*) is the process of creating functions from sequences of machine instructions. A call to this translator-created function replaces the sequence of instructions that it duplicates. On its own this process would slow program execution and make the program image larger. However, if the same sequence of instructions occurs at other places in the program, they can also be replaced by a call. Provided the sequence being replaced is larger than the substituted call instruction, the program image will shrink in size. Zastre[1501] provides a discussion of the issues.

For a collection of embedded applications, Cooper and McIntosh[276] were able to reduce the number of instructions in the program image by 4.88%, with a corresponding increase of executed instructions of 6.47%.

Using profile information, they were able to reduce the dynamic overhead to 0.86%, with a corresponding decrease in the static instruction count of 3.89%.

Many optimization techniques will result in the same sequence of source statements being translated into different sequences of machine instructions. Context can be an important issue in optimization. Performing function abstraction prior to some optimizations can increase the number of duplicate sequences of instructions.[1189]

Coding Guidelines

Use of static linking may be thought to ensure that program images continue to produce the same behavior when a host's libraries are updated. Experience shows that changes to these libraries can cause changes of behavior, particularly when low-level device drivers are involved.

Use of dynamic linking ensures that programs can take advantage of any bug fixed or performance improvements associated with updated libraries. Use of dynamically linked libraries also helps to ensure that all programs use the same libraries (reducing the likelihood of different programs failing to cooperate because of execution-time incompatibilities, for instance through use of a shared memory interface). If a required library is not available in the host environment, either it will not be possible to execute the program image or it will fail during execution.

The issue of static versus dynamic linking is a configuration-management issue and is outside the scope of these coding guidelines.

Forward references: universal character names (6.4.3), lexical elements (6.4), preprocessing directives (6.10), trigraph sequences (5.2.1.1), external definitions (6.9). 142

---

footnote 6

6) As described in 6.4, the process of dividing a source file's characters into preprocessing tokens is context-dependent. 143

Commentary

In only a few cases does a lexer, for C language, need information on the context in which it is encountering characters. The issue of whether an identifier is defined as a typedef or not is not applicable during the creation of preprocessing tokens; both have the same lexical syntax. However, the syntax used by most translators makes a distinction between identifiers and typedef names, so a symbol table lookup is needed when the preprocessing token is converted to a token (or at some other time, prior to translation phase 7).

Other Languages

In most languages no knowledge of context is needed to create tokens from a character sequence. It has become accepted practice in language design that it be possible to implement a lexer using a finite state automata. There are several tools that automatically produce lexers from a specification; for example, `flex` from the Open Software Foundation.

In Fortran white space is not significant and in some cases it is necessary to scan ahead of the current input character to decide the lexical form of a given sequence of characters.

Fortran 777 spaces not significant

For example, see the handling of < within a **`#include`** preprocessing directive. 144

Commentary

This issue is discussed elsewhere.

header name 924 recognized within #include

---

footnote 7

7) An implementation need not convert all non-corresponding source characters to the same execution character. 145

Commentary

An implementation may choose to convert all source characters without a corresponding member in the execution character set to a single execution character whose interpretation implies, for instance, that there was no corresponding member. Your author knows of no implementation that takes this approach.

correspond-ing member 134 if no

C++

The C++ Standard specifies that the conversion is implementation-defined (2.1p1, 2.13.2p5) and does not explicitly specify this special case.

5.1.1.3 Diagnostics

146 A conforming implementation shall produce at least one diagnostic message (identified in an implementation-defined manner) if a preprocessing translation unit or translation unit contains a violation of any syntax rule or constraint, even if the behavior is also explicitly specified as undefined or implementation-defined.

diagnostic shall produce

Commentary

This is a requirement on the implementation. The first violation may put the translator into a state where there are further, cascading violations. The extent to which a translator can recover from a violation and continue to process the source in a meaningful way is a quality-of-implementation issue.

The standard says nothing about what constitutes a diagnostic message (usually simply called a *diagnostic*). Although each implementation is required to document how they identify such messages, playing a different tune to represent each constraint or syntax violation is one possibility. Such an implementation decision might be considered to have a low quality-of-implementation.

65 diagnostic message

The Rationale uses the term *erroneous program* in the context of a program containing a syntax error or constraint violation. Developers discussing C often use the term *error* and *erroneous*, but the standard does not define these terms.

C++

> *— If a program contains a violation of any diagnosable rule, a conforming implementation shall issue at least one diagnostic message, except that*
>
> *— If a program contains a violation of a rule for which no diagnostic is required, this International Standard places no requirement on implementations with respect to that program.*

1.4p2

A program that contains "a violation of a rule for which no diagnostic is required", for instance on line 1, followed by "a violation of any diagnosable rule", for instance on line 2; a C++ translator is not required to issue a diagnostic message.

Other Languages

Java contains no requirement that any violations of its compile-time requirements be diagnosed.

Common Implementations

Traditionally C compilers have operated in a single pass over the source (or at least one complete pass for preprocessing and another complete pass for syntax and semantics, combined), with fairly localized error recovery.

10 implementation single pass

Constraint violations during preprocessing can be difficult to localize because of the unstructured nature of what needs to be done. If there is a separate program for preprocessing, it will usually be necessary to remove all constraint violations detected during preprocessing. Once accepted by the preprocessor the resulting token stream can be syntactically and semantically analyzed. Constraint violations that occur because of semantic requirements tend not to result in further, cascading, violations.

Syntax violations usually causing a message of the form "Unexpected token", or "One of the following . . . was expected" to be output. Recovering from syntax violations without causing some additional, cascading violations can be difficult.

161 translated invalid program

147 Diagnostic messages need not be produced in other circumstances.[8)]

diagnostic message produced other circumstances

Commentary

The production of diagnostics in other circumstances is a quality-of-implementation issue. Implementations are free to produce any number of diagnostics for any reason, but they are not required to do so.

Common Implementations

Over time the number of diagnostics produced by implementations has tended to increase. Minimalist issuance of diagnostics is not considered good translator practice.

Coding Guidelines

Some translators contain options to generate diagnostics for constructs that are they consider suspicious, or a possible mistake on the developer's part. Making use of such options is to be recommended as a way of helping to find potential problems in source code.

A guideline recommendation of the form "The translator shall be run in a configuration that maximizes the likelihood of it generating useful diagnostic messages." is outside the scope of these coding guidelines. A guideline recommendation of the form "The source code shall not cause the translator to generate any diagnostics, or there shall be rationale (in a source code comment) for why the code has not been modified to stop them occurring." is also outside the scope of these coding guidelines.

EXAMPLE constraint violation and undefined behavior

EXAMPLE An implementation shall issue a diagnostic for the translation unit: 148

```
char i;
int i;
```

because in those cases where wording in this International Standard describes the behavior for a construct as being both a constraint error and resulting in undefined behavior, the constraint error shall be diagnosed.

Commentary

An implementation is not allowed to define undefined behavior to be: No diagnostic is issued.

5.1.2 Execution environments

Two execution environments are defined: *freestanding* and *hosted*. 149

Commentary

Freestanding is often referred as an *embedded system*, outside of the C Standard's world.

Other Languages

Most languages are defined (often implicitly) to operate in a hosted environment. The Java environment has a single, fully specified environment, which must always be provided.

Common Implementations

Vendors tend to sell their products into one of the two environments. The `gcc` implementation has been targeted to both environments.

program startup

In both cases, *program startup* occurs when a designated C function is called by the execution environment. 150

Commentary

Executing the developer-written functions is only part of the process of executing a program. There are also various initialization and termination activities (discussed later).

The C Standard does not deal with situations where there may be more than one program executing at the same time. Its model is that of a single program executing a single thread of execution.

Common Implementations

Implementations use one of two techniques to call the designated function (called `main` here):

```
1   result_code=main(argc, argv);
```

or,

```
1   exit(main(argc, argv));
```

The method used to make the call does not affect startup, but it can affect what happens when control is handed back to the startup function by the program.

---

151 All objects with static storage duration shall be *initialized* (set to their initial values) before program startup.

static storage duration initialized before startup

Commentary

This is a requirement on the implementation.

This initialization applies to all objects having file scope and objects in block scope that have internal linkage. The initial values may have been provided explicitly by the developer or implicitly by the implementation. Once set, these objects are never reinitialized again during the current program invocation, even if `main` is called recursively (permitted in C90, but not in C99 or C++).

455 static storage duration
1677 object initialized but not explicitly

C++

In C++ the storage occupied by any object of static storage duration is first zero-initialized at program startup (3.6.2p1, 8.5), before any other initialization takes place. The storage is then initialized by any nonzero values. C++ permits static storage duration objects to be initialized using nonconstant values (not supported in C). The order of initialization is the textual order of the definitions in the source code, within a single translation unit. However, there is no defined order across translation units. Because C requires the values used to initialize objects of static storage duration to be constant, there are no initializer ordering dependencies.

Other Languages

Some languages (e.g., the original Pascal Standard) do not support any mechanism for providing initial values to objects having static storage duration. Java allows initialization to be delayed until the first active use of the class or interface type. The order of initialization is the textual order of the definitions in the source code.

Common Implementations

Using the as-if rule to delay initialization until the point of first reference often incurs a high execution-time performance penalty. So most implementations perform the initialization, as specified, prior to startup.

In freestanding environments where there are warm resets, realtime constraints on startup and other constraints sometimes mean that this initialization is omitted on startup. A program can rely on objects being explicitly assigned values through executed statements (appearing in the source code).

The IAR PICmicro compiler[612] supports the `__no_init` specifier which causes the translator to not generate machine code to initialize the so-designated objects on program startup.

Coding Guidelines

It is guaranteed that all objects having file scope will have been initialized to some value prior to program startup. Some coding guideline documents require that all initializations be explicit in the source code and implicit initialization not be relied on. However, it is unclear what the proposers of such a guideline recommendation are trying to achieve. Experience suggests that these authors are applying rationales whose cost/benefit is only worthwhile for objects defined in block scope.

use initializers discussion
1641 initialization syntax

---

152 The manner and timing of such initialization are otherwise unspecified.

initialization timing

Commentary

For objects defined at file scope the standard only supports initialization expressions whose value is known at translation-time. This means that there are no dependencies on the order of these initializations. It is not possible to write a conforming C program that can deduce the manner and timing of initialization.

1644 initializer static storage duration object

Floating-point constants, the representation of which can vary between hosts, may be stored in a canonical form in the program image, and be converted by startup code to the representation used by the host.

Common Implementations

The manner in which initialization occurs can take several forms. The program image may simply contain a list of values that need to be copied into memory; many linkers merge the initializations of sequences of contiguous memory locations into a single block, this exact memory image being copied on startup. For large blocks of memory being initialized to a single value, translators may generate code that loops over those locations, explicitly setting them. Some host environments set the memory they allocate to programs to zero, removing the need for much initialization on behalf of the developer, which for large numbers of locations is zero.

linkers 140

Addresses of objects that have been assigned to pointers may have to be fixed up during this initialization (information will have been stored in the program image by the linker).

In a freestanding environment values may be held in ROM, ready for use on program startup.

Coding Guidelines

Use of the C++ functionality of having nonconstant expressions for the initializers of static storage duration objects may be intended or accidental. Using this construct intentionally is making use of an extension. It may also be necessary to be concerned with order of initialization issues (the order is defined by the C++ Standard).

The use may be accidental because some C++ compilers do not diagnose such usage when running in their C mode. Checking the behavior of the translator using a test case is straight-forward. The action taken, if any, in those cases where the use is not diagnosed will depend on the cost of independent checking of the source (via some other tool, even a C translator) and the benefit obtained. This is a management, not a coding guidelines, issue.

Example

```
1  extern int glob_1;
2
3  static int sglob = glob_1; /* not conforming */
4                             // conforming
```

Program termination returns control to the execution environment. 153

Commentary

freestanding 157
environment
program termination

There are many implications hidden beneath this simple statement. Just because control has been returned to the execution environment does not mean that all visible side effects of executing that program are complete. For instance, it may take some time for the output written to files to appear in those files.

Program termination also causes all open files to be closed.

C++

3.6.1p1 *[Note: in a freestanding environment, start-up and termination is implementation defined;*

3.6.1p5 *A* **`return`** *statement in* `main` *has the effect of leaving the main function (destroying . . . duration) and calling* `exit` *with the return value as the argument.*

18.3p8

The function `exit()` *has additional behavior in this International Standard:*

. . . Finally, control is returned to the host environment.

Common Implementations

In a hosted environment program, termination may, or may not, have a large effect on the execution environment. If the host does not support concurrent execution of programs, termination of one program allows another to be executed.

In a hosted environment the call to the designated function, when startup occurs, usually makes use of a stack that has already been created by the host environment as part of its process of getting a program image ready to execute. Program termination is the point at which this designated function returns (or a call to one of the library functions `exit`, `abort`, or `_Exit` causes the implementation to unwind this stack internally). Control then returns to the code that performed the original invocation.

---

154 **Forward references:** storage durations of objects (6.2.4), initialization (6.7.8).

5.1.2.1 Freestanding environment

Commentary

As little as possible is said about freestanding environments, since little is served by constraining them. Rationale

---

155 In a freestanding environment (in which C program execution may take place without any benefit of an operating system), the name and type of the function called at program startup are implementation-defined. freestanding environment startup

Commentary

The function called at program startup need not be spelled `main`.

The parameters to the called function are defined by the implementation and can be very different from those defined here for `main` (in a hosted environment). If there is no operating system, there are not likely to be any command line parameters, but information may be passed into the function called.

Without the benefit of an operating system, the issue of how to provide the ability to startup different programs becomes important. Having available a set of functions, which can be selected amongst just prior to program startup, provides one solution.

Common Implementations

In many cases there is no named program at all. Switching on, or resetting, the freestanding host causes the processor instruction pointer to be set to some predefined location in storage, whichever instructions are located at that and subsequent locations being executed. Traditionally there is a small bootstrap loader at this location, which copies a larger program from a storage device into memory and jumps to the start of that program (it might be a simple operating system). In other cases that storage device is ROM and the program will already be in memory at the predefined location. Translated program instructions are executed directly from the storage device. Once switched on, the host may have buttons that cause the processor to be reset to a different location, causing different functions to be invoked on startup.

---

156 Any library facilities available to a freestanding program, other than the minimal set required by clause 4, are implementation-defined. environment freestanding implementation

Commentary

conforming 94 freestanding implementation

The Committee wanted it to be practical to create a conforming implementation for a freestanding environment. In such an environment the basic facilities needed to provide all of the functionality required by the full library are often not available. The requirement to supply a full library needed to be relaxed. The full language can always be supported, although this may mean supplying a set of internal functions for handling arithmetic operations on **long long** and floating-point types. If a particular program does not make use of **long long** or floating-point types, a linker will usually take the opportunity to reduce the size of the final executable by not linking in these internal library functions.

Common Implementations

Freestanding environments vary enormously between those that offer a few hundred bytes of storage and no library, to those having megabytes of memory and an operating system offering full POSIX realtime functionality.

Coding Guidelines

Care needs to be taken, in a freestanding environment, when using library facilities beyond the minimal set required by Clause 4. There is no requirement for an implementation that supplies additional functions to completely follow the specification given in the standard. It is not uncommon to see only partial functionality implemented.

---

freestanding environment program termination

The effect of program termination in a freestanding environment is implementation-defined. 157

Commentary

It may not even be possible to terminate a program in a freestanding environment. The program may be the only execution environment there is. Switching the power off may be the only way of terminating a program.

Common Implementations

A **return** statement executed from the function called on program startup, or a call to `exit` (if the freestanding implementation supports such a call) may return control to a host operating system or return to the random address held on the top of the stack.

Coding Guidelines

Specifying how program termination, in a freestanding environment, should be handled is outside the scope of these coding guidelines.

5.1.2.2 Hosted environment

---

hosted environment

A hosted environment need not be provided, but shall conform to the following specifications if present. 158

Commentary

This is a requirement on the implementation. The standard defines a specification, not an implementation. Issues such as typing the name of the program on a command line or clicking on an icon are possible implementations, which the standard says nothing about.

C++

1.4p7 *For a hosted implementation, this International Standard defines the set of available libraries.*

17.4.1.3p1 *For a hosted implementation, this International Standard describes the set of available headers.*

Common Implementations

Most hosted environments provide the full set of functionality specified here. The POSIX (ISO/IEC 9945) standard defines some of the functions in the C library. On the whole the specification of this functionality is a pure extension of the C specification.

Coding Guidelines

This specification is the minimal set of requirements that a program can assume will be provided by a conforming hosted implementation. The application domain may influence developer expectations about the minimal functionality available. This issue is discussed elsewhere.

0 coding guidelines applications

---

159 8) The intent is that an implementation should identify the nature of, and where possible localize, each violation.

footnote 8

Commentary

The Committee is indicating their intent here; it is not a requirement of the standard that this localization be implemented.

The US government has also had something to say on this issue: FIPS PUB 160 (Federal Information Processing Standards PUBlication), issued March 13, 1991, said:

> *The message provided will identify:*
>
> *— The statement or declaration that directly contains the nonconforming or obsolete syntax.*

FIPS PUB 160, 10pc

Paragraph c also included a fuller definition and requirements. A change notice, issued on August 24 1992, changed these requirements to:

> *Page 3, paragraph 10.c, Specifications: remove paragraph 10.c.*

FIPS PUB 160 no longer contains any requirements on the localization of violations in C source by implementations.

Common Implementations

Violations detected during the expansion of a macro invocation can be difficult to localize beyond the original name of the macro being expanded and perhaps the line causing the original invocations.

macro replacement

Many implementations handle C syntax by using a LALR(1) grammar to control an associated parser. Grammars having this property are guaranteed to be able to localize a syntax violation on the first unexpected token[9] (i.e., no possible sequence of tokens following it could produce a valid parse).

Violations arising out of semantic constraints are usually localized within a few tokens.

Translators tend to generate a diagnostic based on a localized cause for the constraint violations. Experience has shown that assuming a localized cause for a violation is a good strategy (it is often also the simplest to implement). For instance, in:

```
1  static char g;
2
3  void f(void)
4  {
5  char *v;
6
7  if (g)
8     {
9     int v;
10      /*
11       * Other code.
12       */
13    v = &g;
14    }
15 }
```

the assignment to v is likely to be diagnosed as an incompatible assignment, rather than a misplaced **}** token. Many violations do have a localized cause. Looking for a nonlocalized cause requires a lot more effort on the part of vendors' implementations and is only likely to improve the relevance of diagnostics in a few cases. Most implementations generate diagnostic messages that specify what the violation is, not what needs to be done to correct it. In:

```
1  struct {
2          int mem;
3         } s;
4  int glob;
5
6  void f(void)
7  {
8  int loc;
9
10 loc = s + mem;
11 }
```

the implementation diagnostic is likely to point out that the binary plus operator cannot be applied to an operand having a structure type. One of the skills learned by developers is interpreting what different translators' diagnostic messages mean.

Example

```
1  #define COMPARE(x, y) ((y) < (x))
2
3  struct {
4          int mem;
5         } s;
6  int glob;
7
8  void f(void)
9  {
10 int loc;
11
12 /*
13  * Where should an implementation point, on the following line,
14  * as an indication of where the violations occurred?
15  */
16 loc = COMPARE(glob, s);
17 }
```

Of course, an implementation is free to produce any number of diagnostics as long as a valid program is still correctly translated. 160

Commentary

A valid program, as in a strictly conforming program.

C++

The C++ Standard does not explicitly give this permission. However, producing diagnostic messages that the C++ Standard does not require to be generated might be regarded as an extension, and these are explicitly permitted (1.4p8).

Other Languages

Most languages are silent on the topic of extensions. Languages that claim to have Java as a subset have been designed and compilers written for them.

Common Implementations

One syntax, or constraint violation, may result in diagnostic messages being generated for tokens close to the original violation. These may be caused by a translators' incorrect attempts to recover from the first violation, or they may have the same underlying cause as the first violation. In many cases these are localized and translation usually continues (on the basis that there may be other violations and developers would like to have a complete list of them).

Some translators support options whose purpose is to increase the number of messages generated. It is intended that these messages be of use to developers. For instance, the `gcc` option *-Wall* issues diagnostics for constructs which it considers to be potential faults. Some translators support an option that causes any usage of an extension, provided by the implementation, to be diagnosed.

100 implementation document

There is a market for tools that act like translators but do not produce a program image. Rather, they analyze the source code looking for likely coding and portability problems— so-called *static analysis tools*. The term *lint-like tools* is often heard, after the first such tool of their ilk, called `lint` (lint being the fluff-like material that clings to clothes and finds its way into cracks and crevices).

Implementation vendors receive a lot of customer requests for improvements in the performance of generated code and support for additional library functionality. The quality of diagnostic messages produced by translators is rarely given a high priority by purchasers. Experience shows that developers can adapt themselves to the kinds of diagnostics produced by a translator.

Example

Many translators now attempt to diagnose likely programmer errors. The classic example is:

```
1   if (x = y)
```

where:

```
1   if (x == y)
```

had been intended.

Experience suggests that developers will ignore such diagnostics, or disable them, if they are incorrect more than 40% of the time.

---

161 It may also successfully translate an invalid program.

translated invalid program

Commentary

The term *invalid program* is not defined by the C Standard. Common usage suggests that a program containing violations of syntax or constraints was intended.

Before the spread of desktop computers, it was common for programs to be translated via a batch process on a central computer. The edit/compile/run cycle could take an hour or more. Having the translator fail to translate a program, even if it contained errors, was often considered unacceptable. Useful work could often be done with an invalid (only a part of it was likely to be invalid) but executable program while waiting for the next cycle to complete. Within multiperson projects a change made by one person can have widespread consequences. Having a translator continue to operate, while a particular issue is resolved, often increases its perceived quality.

Common Implementations

There have been several parsers that perform very sophisticated error recovery.[337] In the case of the C language, inserting a semicolon token is a remarkably effective, and simple, recovery strategy from a syntax violation (another is deleting tokens up to and including the next semicolon).

Prior to the invention of desktop computers and even before the spread of minicomputers, when translation requests had to be submitted as a batch job, vendors found it worthwhile investing effort in sophisticated syntax error recovery.[282, 337] The turnaround of a batch-processing system being sufficiently long (in the

past, several hours was not considered unusual) that anything a translator could do to repair simple developer typing mistakes, in order to obtain a successful program build, was very welcome. Once the turnaround time on submitting source for translation became almost instantaneous, by providing developers with direct access to a computer, customer demand for sophisticated syntax error recovery disappeared.

Commonly recovered semantic errors include the use of undeclared objects (many implementations recover by declaring them with type **int**) or missing structure members (adding them to the structure type is a common recovery strategy).

Coding Guidelines

A guideline recommendation of the form "The translated output from an invalid program shall never be executed in a production environment." is outside the scope of the guidelines.

5.1.2.2.1 Program startup

hosted environment startup

The function called at program startup is named **main**. 162

Commentary

That is, the user-defined function called at program startup. This function must have external linkage (it is possible for a translation unit to declare a function or object, called `main`, with internal linkage). There is no requirement that the function appear in a source file having a specific name.

Other Languages

A Java Machine starts execution by invoking the method main of some specified class, . . .

In Fortran and Pascal the function called on startup is defined using the keyword **PROGRAM**.

Common Implementations

Implementations use a variety of techniques to start executing a program image. These usually involve executing some internal, implementation-specific, function before `main` is called. The association between this internal function and `main` is usually made at link-time by having the internal function make a call to `main`, which is resolved by the linker in the same way as other function calls.

Coding Guidelines

Having the function `main` defined in a source file whose name is the same as the name of the executable program is a commonly seen convention.

The implementation declares no prototype for this function. 163

Commentary

There is no declaration of `main` in any system header, or internally within the translator. For this reason translators rarely check that the definition of `main` follows one of the two specifications given for it.

Common Implementations

A function named `main` is usually treated like any other developer-defined function.

Coding Guidelines

Because the implementation is not required to define a prototype for `main` no consistency checks need be performed against the definition of `main` written by the developer.

It shall be defined with a return type of **int** and with no parameters: 164

```
int main(void) { /* ... */ }
```

Commentary

Many lazy developers use the form:

```
1  main() { /* ...  */ }
```

C99 does not allow declaration specifiers to be omitted; a return type must now be specified. 1379 declaration at least one type specifier

Usage

There was not a sufficiently large number of instances of `main` in the `.c` files to provide a reliable measure of the different ways this function is declared.

---

165 or with two parameters (referred to here as **argc** and **argv**, though any names may be used, as they are local to the function in which they are declared): main prototype

```
int main(int argc, char *argv[]) { /* ... */ }
```

Commentary

The parameters of `main` are treated just like the parameters in any other developer-defined function.

Other Languages

. . . , passing it a single argument, which is an array of strings. Java

```
class Test {
   public static void main(String[] args) {
      /* ... */
      }
   }
```

Coding Guidelines

The identifiers `argc` and `argv` are commonly used by developers as the names of the parameters to `main` (the standard does not require this usage).

---

166 or equivalent;[9)]

Commentary

Many developers use the form:

```
1  int main(int argc, char **argv)
```

on the basis that arrays are converted to pointers to their element type.

C++

The C++ Standard gives no such explicit permission.

---

167 or in some other implementation-defined manner.

Commentary

The Committee recognized that there is additional information that a host might need to pass to `main` on startup, but they did not want to mandate anything specific. The following invocations are often seen in source code:

```
1  void main()
```

and

```
1  int main(argc, argv, envp)
```

C90

Support for this latitude is new in C99.

C++

The C++ Standard explicitly gives permission for an implementation to define this function using different parameter types, but it specifies that the return type is **int**.

3.6.1p2 *It shall have a return type of* ***int****, but otherwise its type is implementation-defined.*

. . .

[Note: it is recommended that any further (optional) parameters be added after `argv`*.]*

Common Implementations

In a wide character hosted environment, `main` may be defined as:

```
int main (int argc, wchar_t *argv[])
```

Some implementations[600] support a definition of the form:

```
int main (int argc, char *argv[], char *env[])
```

where the third parameter is an array environment strings such as `"PATH=/home/derek"`.

The POSIX `execv` series of functions pass this kind of additional information to the invoked program. However, `main` is still defined to take two parameters for these functions; the environment information is assigned to an external object `extern char **environ`.

Coding Guidelines

Programs that need to make use of the implementation-defined functionality will obviously define `main` appropriately. If it is necessary to access environmental information, it is best done through use of implementation-supported functionality.

If they are declared, the parameters to the **main** function shall obey the following constraints: 168

Commentary

This is a list of requirements on implementations. It lists the properties that the values of `argc` and `argv` can be relied on, by a program, to possess. The standard does not define any constraints on the values of any, implementation-defined, additional parameters to `main`.

Common Implementations

The constraints have proved to be sufficiently broad to be implementable on a wide range of hosts.

Coding Guidelines

These constraints are the minimum specification that can be relied on to be supported by an implementation.

— The value of **argc** shall be nonnegative. 169

Commentary

The value of `argc`, as set by the implementation on startup is nonnegative. The parameter has type **int** and could be set to a negative value within the program.

Common Implementations

Most hosts have a limit on the maximum number of characters that may be passed to a program on startup (via, for instance, the command line). This limit is also likely to be a maximum upper limit on the value of `argc`.

Coding Guidelines

Knowing that `argc` is always set to a nonnegative value, a developer reading the code might expect it to always have a nonnegative value. Assigning a negative value to `argc` as a flag to indicate a special condition is sometimes seen. The extent to which this might be considered poor practice because of violated developer expectations is discussed elsewhere.

1352 object role

---

170 — **`argv[argc]`** shall be a null pointer.

Commentary

Some algorithmic styles prefer to decrement a count of the remaining elements. Some prefer to walk a data structure until a null pointer is encountered. The standard supports both styles.

---

171 — If the value of **`argc`** is greater than zero, the array members **`argv[0]`** through **`argv[argc-1]`** inclusive shall contain pointers to strings, which are given implementation-defined values by the host environment prior to program startup.

argv values

Commentary

The storage occupied by the strings has static storage-duration. This wording could be interpreted to imply an ordering between the contents of the host environment and the contents of `argv`. What the user typed on a command line may not be what gets passed to the program. The host environment is likely to process the arguments first, possibly performing such operations as expanding wildcards and environment variables.

455 static storage duration

Common Implementations

A white-space character is usually used to delimit program parameters. Many hosts offer some form of quoting mechanism to allow any representable character, in the host environment, to be passed as a value to `argv` (including character sequences that contain white space). The behavior most often encountered is that the elements of `argv`, in increasing subscript order, correspond to the white-space delimited character sequences appearing on the command line in left-to-right order.

POSIX defines `_POSIX_ARG_MAX`, in **`<limits.h>`**, as "The length of the arguments for one of the exec functions, in bytes, including environment data." and requires that it have a value of at least 4,096. Under MS-DOS the command processor, `command.com`, reads a value on startup that specifies the maximum amount of the space to use for its environment (where command line information is held).

Coding Guidelines

Most implementations have a limit on the total number of characters, over all the strings, that can be passed via `argv`. There is a possibility that one of the character sequences in one of the strings pointed to by `argv` will be truncated.

For GUI-based applications the values passed to `argv` may be hidden from the user of the application.

Many hosts offer some form of quoting mechanism to allow any typeable character, in that environment, to be passed to a program. If `argv` is used, a program may need to handle strings containing characters that are not contained in the basic execution character set.

---

172 The intent is to supply to the program information determined prior to program startup from elsewhere in the hosted environment.

main parameters intent

Commentary

The `argc`/`argv` mechanism provides a simple-to-use, from both the applications' users' point of view and the developer's, method of passing information (usually frequently changing) to a program. The alternative being to use a file, read by the application, which would need to be created or edited every time options changed. This is not to say that an implementation might not choose to obtain the information by reading from a file (e.g., in a GUI environment where there is no command line).

C++

The C++ Standard does not specify any intent behind its support for this functionality.

Common Implementations

If the program was invoked from the command line, the arguments are usually the sequence of characters appearing after the name of the program on the line containing the program image name. The order of the strings appearing in successive elements of the `argv` array is the same order as they appeared on the command line and the space character is treated as the delimiter.

In GUI environments more information is likely to be contained in configuration files associated with the program to be executed. Many GUIs implement click, or drag-and-drop, by invoking a program with `argv[1]` denoting the name of the clicked, or dropped-on, file and `argv[2]` denoting the name of the dropped file, or some similar convention.

Coding Guidelines

Making use of `argv` necessarily relies on implementation-defined behavior. Where the information is obtained, and the ordering of strings in `argv`, are just some of the issues that need to be considered.

---

argv lowercase

If the host environment is not capable of supplying strings with letters in both uppercase and lowercase, the implementation shall ensure that the strings are received in lowercase. 173

Commentary

This choice reflects C's origins in Unix environments. Some older host environments convert, by default, all command line character input into a single case. A commonly occurring program argument is the name of a file. Unix filenames tend to be in lowercase and the file system is case-sensitive. Having an application accept non-filename arguments in lowercase has a lower cost than insisting that filenames be in uppercase.

C++

The C++ Standard is silent on this issue.

Common Implementations

In some mainframe environments, the convention is often to use uppercase letters. Although entering lowercase letters is difficult, it has usually proven possible to implement.

Coding Guidelines

Most modern hosts support the use of both upper- and lowercase characters. The extent to which a program needs to take account of those cases where they might not both be available will depend on the information passed via `argv` and the likelihood that the program will need to be ported to such a host.

---

argv program name

— If the value of **`argc`** is greater than zero, the string pointed to by **`argv[0]`** represents the *program name*; 174

Commentary

What is the program name? It is usually thought of as the sequence of characters used to invoke the program, which in turn relates in some way to the program image (perhaps the name of a file).

Common Implementations

Under MS-DOS typing, *abc* on the command line causes the program `abc.exe` to be executed. In most implementations, the value of `argv[0]` in this case is *abc.exe* even though the extension `.exe` may not have appeared on the command line.

Unix based environments use the character sequence typed on the command line as the name of the program. This does not usually include the search path along which the program was found. For symbolic links the name of the symbolic link is usually used, not the name of the file linked to.

Coding Guidelines

Some programs use the name under which they were invoked to modify their behavior, for instance, the GNU file compression program is called `gzip`. Running the same program, having renamed it to `gunzip`, causes it

to uncompress files. Running the same program, renamed to `gzcat`, causes it to read its input from `stdin` and send its output to `stdout`. The standard distribution of this software has a single program image and various symbolic links to it, each with different names.

The extent to which the behavior of a program depends on the value of `argv[0]` is outside the scope of these coding guidelines.

175 **`argv[0][0]`** shall be the null character if the program name is not available from the host environment.

Commentary

Not all host environments can provide information on the name of the currently executing program.

Common Implementations

Most hosts can provide the name of the program via `argv[0]`.

176 If the value of **`argc`** is greater than one, the strings pointed to by **`argv[1]`** through **`argv[argc-1]`** represent the *program parameters*.

program parameters

Commentary

This defines the term *program parameters*. It does not require that the value of the parameters come from the command line, although this is the background to the terminology.

Example

```
1  #include <stdio.h>
2
3  int main(int argc, char *argv[])
4  {
5  printf("The program parameters were:\n");
6
7  for (int a_index = 0; a_index < argc; a_index++)
8     printf("%s\n", argv[a_index]);
9  }
```

177— The parameters **`argc`** and **`argv`** and the strings pointed to by the **`argv`** array shall be modifiable by the program, and retain their last-stored values between program startup and program termination.

Commentary

Although the strings pointed to by the `argv` array are required to be modifiable, the array itself is not required to be modifiable. Calling `main` recursively (permitted in C90, but not in C99) does not cause the original values to be assigned to those parameters.

C++

The C++ Standard is silent on this issue.

Common Implementations

The addresses of the storage used to hold the `argv` strings may be disjoint from the stack and heap storage areas assigned to a program on startup. Some implementations choose to place the program parameter strings in an area of storage specifically reserved, by the host environment, for programs' parameters.

5.1.2.2.2 Program execution

178 In a hosted environment, a program may use all the functions, macros, type definitions, and objects described in the library clause (clause 7).

Commentary

There are no library subsets; C is a single implementation conformance level standard. However, although functions of the specified name may be present to link against, in translation phase 8, the functionality provided by an implementation's library may vary (including doing nothing and effectively being optional).

Some library functionality was known to be difficult, if not impossible, to implement on certain host environments. In these cases the library functions have minimal required functionality; for instance, signal handling.

implementation extensions 95

The C Standard, unlike POSIX, does not prohibit the use of functions, macros, type definitions, and objects from other standards, but such libraries must not change the behavior of any of the C-defined library functionality.

Other Languages

Cobol, SQL, and Pascal are multi-conformance level standards. They contain additional language constructs at each level. A program is defined to be at the level of the highest level construct it uses.

---

footnote 9

9) Thus, **int** can be replaced by a typedef name defined as **int**, or the type of **argv** can be written as **char** ** **argv**, and so on. 179

Commentary

typedef is synonym 1633

The return type might also be specified as **signed int**. A typedef name in C is a synonym.

Some implementations choose to process a function called `main` differently from other function definitions (because of its special status as the function called on program startup). This wording makes it clear that the recognition of `main`, its return type, and arguments cannot be based on a textual match. Semantic analysis is required.

C++

The C++ Standard does not make this observation.

Coding Guidelines

Replacing one or more of these types by a typedef name suggests that the underlying type may change at some point. Gratuitous use of a typedef name is not worth a guideline recommending against it. Other uses are for a purpose and there is no reason for them to be the subject of a guideline.

5.1.2.2.3 Program termination

---

main return equivalent to

If the return type of the **main** function is a type compatible with **int**, a return from the initial call to the **main** function is equivalent to calling the **exit** function with the value returned by the **main** function as its argument;[10)] 180

Commentary

The call to `exit` will invoke any functions that have been registered with the `atexit` function. This behavior is not the same as a return from `main` simply returning control to whatever startup function called it, which in turn calls `exit`. After `main` returns, any objects defined in it with automatic storage will no longer have storage reserved for them, rendering any access (i.e., in the functions registered with `atexit`) to them as undefined behavior.

C90

Support for a return type of `main` other than **int** is new in C99.

C++

The C++ wording is essentially the same as C90.

Common Implementations

The value returned is often used as the termination status of the executed program in the host environment. Many host environments provide a mechanism for testing this status immediately after program termination.

Example

```
1  #include <stdio.h>
2  #include <stdlib.h>
3
4  signed char *gp;
5
6  void clean_up(void)
7  {
8  /*
9   * The lifetime of the object pointed to by gp
10  * has terminated by the time we get here.
11  */
12 printf("Value=%c\n", *gp);
13 }
14
15 int main(void)
16 {
17 signed char lc;
18
19 if (atexit(clean_up) != 0)
20    printf("Ho hum\n");
21
22 gp=&lc;
23
24 return 0;
25 }
```

181 reaching the **}** that terminates the **main** function returns a value of 0.

Commentary

The standard finally having to bow to sloppy existing practices.

C90

This requirement is new in C99.

If the main function executes a return that specifies no value, the termination status returned to the host environment is undefined.

Common Implementations

Many implementations followed this C99 specification in C90, prior to it being explicitly specified in C99.

A translator can choose to special case functions defined with the name `main` or simply provide, where necessary, an implicit return of 0 for all functions returning type **int**.

182 If the return type is not compatible with **int**, the termination status returned to the host environment is unspecified.

main termination status unspecified

Commentary

The return type can only be incompatible with **int** if `main` has been defined to return a different, incompatible, type. If `main` has a return type of **void**, an implementation may choose not to return any value. In this case, the standard does not guarantee that a call to the `exit` library function will return the requested status to the host environment.

C90

Support `main` returning a type that is not compatible with **int** is new in C99.

C++

3.6.1p2 *It shall have a return type of* ***int****, . . .*

Like C90, C++ does not support `main` having any return type other than **`int`**.

Forward references: definition of terms (7.1.1), the **`exit`** function (7.20.4.3). 183

5.1.2.3 Program execution

program execution
abstract machine
C

The semantic descriptions in this International Standard describe the behavior of an abstract machine in which issues of optimization are irrelevant. 184

Commentary

The properties of this abstract machine are never fully defined in the standard. The term can be thought of as a conceptual model used to discuss C, not as a formal definition for a full-blown specification. Several research projects have produced formal specifications of substantial parts of Standard C (using operational semantics based on evolving algebras,[528] structural operational semantics,[1016] and denotational semantics[1052]). These have investigated the language only (no preprocessor and a subset of the library).

The semantic descriptions also ignore other possible ways of modifying values in storage; for instance, by irradiating the processor or storage chips, forming the computing platform, with nuclear or electromagnetic radiation.[509]

Other Languages

The definition of most computer languages is written in a form of stylized English. The Modula-2 Standard[646] was defined using a formal definition language[647] (which in turn is defined in terms of Zermelo-Fraenkel set theory; which in turn is based on nine axioms, {although only four of these have been proved to be consistent and independent}) and English. Neither language was given priority over the other. Any difference in meaning between the two formalisms has to be decided by a discussing the intended behavior, not by giving one set of wording preference over the other. The original definition of Lisp was written in terms of a subset of itself and the Prolog Standard[644] provides (in an informative annex) a formal semantics written in a subset of Prolog. A Model Implementation (an implementation that exactly implements all of the requirements of a language standard, irrespective of performance issues) was created for Pascal.[1453]

Common Implementations

Most vendors regard optimizations as being very important and sometimes invest more effort on performing them than doing anything else.

A Model Implementation was produced for C.[681] This implementation aimed to mimic the behavior of the abstract machine and diagnose all implementation-defined, unspecified and undefined behaviors (as well as the usual constraint and syntax violations). It generated code for an abstract machine whose instruction set had a one-to-one mapping to C operations, the idea being that such a one-to-one mapping helped simplify code generation and reduce possible bugs. The interpreter for this abstract machine did all the pointer checks and uninitialized object checks that caused undefined behavior.

At the time of this writing there is one formally verified compiler[127] for a substantial subset of C.

Coding Guidelines

Many developers spend a relatively large amount of time trying to optimize their code. The extent to which their efforts have any effect is often marginal. There are a lot of misconceptions about how to write efficient C. By far the biggest improvements in performance come from design and algorithmic optimization. Trying to second guess what machine code a translator will generate requires a great deal of knowledge on the target architecture and the code-generation techniques used by an implementation, skills that very few developers

have. The only effective way to tune at the statement level is by looking at the generated machine code. Changes based on ideas about what the translator *should do* are often wrong.

While the benefits of using formal methods when writing software are often promoted by their followers, the associated costs[424] and lack of any evidence that the benefits can be realized in practice[529] are rarely mentioned.

---

185 Accessing a volatile object, modifying an object, modifying a file, or calling a function that does any of those operations are all *side effects*,[11] which are changes in the state of the execution environment.

side effect

Commentary

An operation, in a C program, that does not generate a side effect is, at the very least, considered to be of no practical interest.

190 redundant code

The state of the execution environment includes information on the current flow of control (nested function calls and the current statement being executed). This means that the control expression in, for instance, an `if` statement has the side effect of selecting the flow of control. Accessing a volatile object is not guaranteed to change the state of the execution environment, but a translator must act as-if it does. The C library treats all I/O operations as occurring on files, and therefore generating a side effect. The C++ Standard is more explicit in stating, 1.9, " . . . calling a library I/O function, . . . ".

Other Languages

Some languages, usually functional, have been specifically designed to be side effect free. The advantage of being side effect free is that it significantly simplifies the task of mathematically proving various properties about programs.

Common Implementations

Calling a function, or one of the memory allocation functions, also changes the state of the execution environment. This state is part of the housekeeping performed by an implementation and does not normally cause an external effect. Such operations only become noticeable if there are insufficient resources to satisfy them.

Coding Guidelines

C is what is known as an imperative language. The design of C programs (and nearly every commercially written program, irrespective of language used) is generally based on using side effects to implement the desired functionality. Coding guideline documents that recommend against the use of side effects (which they do with surprising regularity) are rather missing the point. Developers need to ensure that side effects occur in a predictable order. The relevant issues are discussed elsewhere.

944 expression order of evaluation

Comprehending source code requires readers to deduce the changes it makes to the state of the abstract machine. This process requires that readers remember, and later recall, a sequence of abstract machine states. Some of the issues involved in organizing changes of machine state into a meaningful pattern are discussed elsewhere, as are issues of locally minimizing the number of changes of state that need to be remembered.

1707 statement syntax
1046 postfix operator constraint

---

186 Evaluation of an expression may produce side effects.

Commentary

An expression may also be evaluated for its result value. This value is used to decide the flow of control, or returned as the value of a function call.

940 expressions

Operations on objects having floating-point type may also set status flags, which is a change of state of the execution environment.

196 footnote 11

Common Implementations

Some optimizers invoke the as-if rule to delay the updating of storage after the evaluation of an expression. The storage may not be necessary if the value can be kept in a register and accessed their for all subsequent accesses (or at least until it is modified again).

Coding Guidelines

One of the most common reader activities when performing source code comprehension is the analysis of the consequences of side effects in the evaluation of expressions. An expression that does not produce side effects, when evaluated, is redundant. The issue of redundant code is discussed elsewhere.

redundant code 190

Example

```
1  extern int glob;
2
3  void f(void)
4  {
5  glob+4;          /* No side effect. */
6
7  if (glob+4 == 0) /* Evaluation selects the flow of control. */
8     glob--;       /* A side effect. */
9  }
```

---

sequence points

At certain specified points in the execution sequence called *sequence points*, all side effects of previous evaluations shall be complete and no side effects of subsequent evaluations shall have taken place. 187

Commentary

This defines the term *sequence points*. Sequence points are points of stability. At these points there are no outstanding modifications to objects waiting to be completed. The ordering of sequence points during program execution is not always guaranteed. The freedom given to translators in evaluating binary operands leaves open the possibility of there being more than one possible ordering of sequence points. The following are some of the more important orderings implied by sequence points:

sequence points 187

object initializer evaluated when 1711
statement executed in sequence 1709
comma operator syntax 1313

- Declaration evaluation order.
- Statement execution order.
- A left then right evaluation ordering of operands of some binary operators.

In some situations the specification given in the standard has been found to be open to more than one interpretation. Various C Committee members are working on a more formal specification of the semantics of expressions. Several notations have been proposed (e.g., using sets or trees); the intent is to select the one that developers will find the simplest to use. Whether the final document will be published as a TR or in some other form has not yet been decided. The working papers are available via the WG14 Web site.

WG14/N899 *To define a formalism for the semantics of expressions in the C language (as defined in ISO/IEC 9899:1999) to enable users of the Standard to determine unambiguously what expressions do or do not conform to the language and their level of conformance.*

An example of the nontrivial issues that surround the analysis of expressions that contain more than one sequence point is provided by DR #087. In the following code, is the behavior for the expressions in lines A, B, and C defined?

```
1  static int glob;
2
3  int f(int p)
4  {
5  glob = p;
6  return 0;
7  }
```

```
8
9   void DR_087(void)
10  {
11  int loc;
12
13  loc = (glob = 1) + (glob = 2);                 /* Line C */
14  loc = (10, glob = 1, 20) + (30, glob = 2, 40); /* Line A */
15  loc = (10, f (1), 20) + (30, f (2), 40);       /* Line B */
16  }
```

In *Line C* there are two assignments to `glob` between two sequence points. The behavior is undefined. In *Line A* the assignments to `glob` are bracketed by sequence points. It might be thought that there is no possibility that the two assignments could both occur between the same pair of sequence points. However, there is no requirement that an operator be performed immediately after one or more of its operands is evaluated. One of the evaluation orders an implementation could choose is:

```
evaluate 10
sequence point
evaluate 30
sequence point
evaluate glob=1
evaluate glob=2
sequence point
evaluate 20
sequence point
evaluate 40
perform addition
perform assignment
sequence point
```

Just like the case in *Line C* there are two assignments to `glob` between two sequence points. The behavior is undefined.

function call interleave

In *Line B* there are two calls to the function `f`; however, calls to functions cannot be interleaved (although this requirement appears in a number of committee papers dealing with sequence point and is part of the question in DR #087, it has never been stated in any normative document). This means that the two assignments to `glob`, which occur in the two calls to `f`, can never occur between the same pair of sequence points.

Other Languages

Most languages do not provide the operators, available in C, for modifying objects within an expression. However, most languages do allow function calls within an expression and these can modify objects with file scope or indirectly through parameters. Some language definitions specify that changing the value of a variable in an expression, while it is being evaluated (i.e., via function call), always results in undefined behavior (or some such term). Very few languages discuss the interaction of side effects and sequence points (if any such concept is defined).

Common Implementations

The as-if rule can be invoked to allow code motion across sequence points. However, implementations have to ensure that the behavior remains unchanged (in terms of external output or behavior, if not execution-time performance). The only way for a developer to find out if an implementation is using the as-if rule to reorder side effects around sequence points is to examine the generated code. Many implementations do provide an option to list the machine code generated.

Most C expressions are very simple, offering little opportunity for clever optimization in themselves. Obtaining high-quality code requires finding similarities within expressions occurring in sequences of statements, that is across sequence points. Value numbering is a commonly used technique.[160]

Coding Guidelines

The sequence point definition suggests, on first glance, a well-defined ordering of events. In most cases the ordering is predictable, but in a few cases the ordering of sequence points is not unique. Some of the constructs that are sequence points can themselves be evaluated in different orders. The two sequence points that cannot have multiple orderings are the `;` punctuator at the end of a statement and initialization of block scope definitions, and the evaluation of a full expression that is also a controlling expression. The possible orderings of these sequence points is fully specified by the standard and cannot vary between implementations.

All other sequence points can occur within a subexpression that is the operand of a larger expression. A sequence point may guarantee an evaluation order within a subexpression. However, there might not be any guarantee that the subexpression is always evaluated at the same point in the evaluation of its containing full expression. For instance in:

```
1  f(c++) + g(c -= 3);
```

the sequence point before a `( )` operator is invoked guarantees that either `c` will be incremented before `f` is called, or that `c` will be incremented before `g` is called. The standard does not specify which function should be called first, so there are two possible orderings of sequence points. In:

```
1  (x--, p = x+y) + (y++, q = x+y)
```

the sequence point on the comma operator guarantees that its left operand will be evaluated and all side effects will take place before the right operand is evaluated. But nothing is said about which operand of the plus operator is evaluated first.

Cg 187.1 The value of a full expression shall not depend on the order of evaluation of any sequence points it contains.

Cg 187.2 Any types declared in a declaration shall not depend on the order of evaluation of any expressions it contains.

object 1711 initializer evaluated when

The corresponding coding guideline issues for initializers are discussed elsewhere.

Example

```
1  extern int glob;
2  extern int g(int);
3
4  void f(void)
5  {
6  int loc = g(glob = 3) + g(glob = 4);
7  }
```

(A summary of the sequence points is given in annex C.) 188

---

expression evaluation abstract machine

In the abstract machine, all expressions are evaluated as specified by the semantics. 189

Commentary

The abstract machine has no concern for the size of the program being executed, or its execution-time performance.

C++

The C++ Standard specifies no such requirement.

Common Implementations

When translating programs for use with a symbolic debugger, most implementations tend to closely follow the requirements of the abstract machine. This ensures that the values of objects, in memory, closely follow their evaluations in the source code. This simplifies things considerably for developers, who might be having enough trouble following the behavior of a program, and don't need the additional confusion of objects receiving values at different times to those specified in the source.

This seemingly innocuous requirement prohibits implementations from performing expression rewriting. 943 expression grouping

Coding Guidelines

Trying to second-guess how an implementation might process a given construct is generally a fruitless exercise. Assuming that an implementation behaves like the abstract machine is a useful starting point that does not often need to be improved on.

Example

In the following an implementation may spot that the subexpression `x*y` occurs in two places and the values of `x` and `y` are not modified between these two points. The extent to which this information can be used will depend on the number of registers available for holding temporary values, the relative cost of evaluating `x*y`, and the priority given to this optimization opportunity relative to other opportunities within the function `f`.

```
1  extern int x, y;
2
3  void f(void)
4  {
5  int a,
6      b;
7
8  a = x * y;
9  /*
10  * Code that does not change the values of x and y.
11  */
12 b = x * y;
13 }
```

---

190 An actual implementation need not evaluate part of an expression if it can deduce that its value is not used and that no needed side effects are produced (including any caused by calling a function or accessing a volatile object).

expression need not evaluate part of

Commentary

This statement forms part of the as-if rule. 122 as-if rule

In the following the value is used, but it is also known at translation time. To answer the question of whether there are any needed side effects requires varying degrees of source analysis sophistication:

```
1  extern int g(void);
2  extern int glob;
3
4  void f(void)
5  {
6  int loc;
7
8  loc = 0 * g();        /* Result always zero, but could have needed side effect. */
9  loc = 0 * (glob + 4); /* Result always zero, no side effects. */
10 }
```

The value assigned to `loc` is known in both cases. In the first case the call to the function `g` must occur if it causes needed (the program output depends on them) side effects. In the second case `(glob + 4)` only need be evaluated if the object `glob` is declared with the volatile storage qualifier. The cases differ only in the easy with which a translator can deduce that a needed side effect occurs.

Those cases where there may be no needed side effect apply to binary operators. Operator/operand pairs where evaluations need not occur and consequently there may be no needed side effects include:

```
0 * (expr)
0 & (expr) always 0
0xffff | (expr) always 0xffff (or appropriate sized constant)
(expr) - (expr) always 0
(expr) / (expr) always 1
```

The expression `expr / expr` might cause a side effect because of the undefined behavior that occurs when `expr` is 0. An implementation is at liberty to deliver the result `1` (if the original code is simplified), raise an exception (if that is what the host processor does for this case), or carry out some other action.

There are also cases where a constant operand does not affect the result of an expression, but the other operand still needs to be evaluated. For instance: adding zero, shifting by zero bits positions, the **%** operator with a right-hand side of one, or multiplying by one. In some cases the cast operator can have no effect. In the function:

```
1  static long glob;
2
3  int f(void)
4  {
5  return (int)glob;
6  }
```

the cast to **int** would be redundant if **int** and **long** had the same representation.

Common Implementations

The extent to which implementations perform the analysis necessary to deduce that an expression, or part of it, is not used varies enormously. The simpler optimizing translators tend to spend their time producing the best code from the source code on a statement-by-statement basis. These tend to treat all parts of an expression as being needed. More sophisticated optimizers analyze blocks of statements, trying locate common subexpressions, CSEs, and performing some level of flow analysis. This level of optimization is willing to believe that certain kinds of subexpressions may be redundant.

A translator that generates very high performance code is of no use if the final behavior is incorrect. The savings to be made from removing some redundant subexpressions are sometimes not worth the risk of getting it wrong. The translator that optimizes:

```
1  #define A_OFFSET(x) (1+(x))
2
3  extern int p, q;
4  static volatile int r;
5
6  void f(void)
7  {
8  p=A_OFFSET(q) - r / r;
9  }
```

into `p=q` would either be foolhardy or perform a great deal of analysis of the program and its environment.

A translator can optimize those cases where the operands always have known values. However, studies have shown[1164] that a significant number of these redundant operations still occur during program execution (because the calculated values of operands happen to be zero or one).

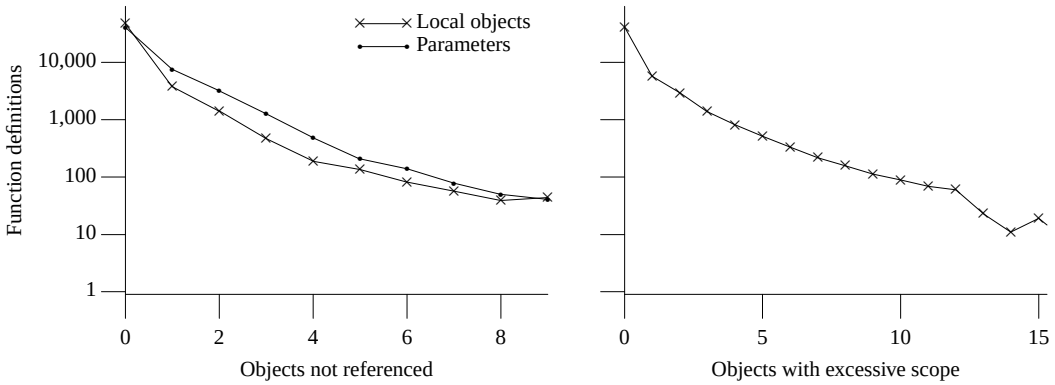

Figure 190.1: Number of parameters or locally defined objects that are not referenced within a function definition (left graph); number of objects declared in a scope that is wider than that needed for any of the references to them within a function definition (right graph). Based on the translated form of this book's benchmark programs.

In some cases code is only redundant under certain conditions. For instance, its evaluation may only be necessary along a subset of the control flow paths that pass through it. So called *partial redundancy elimination* algorithms involve code restructuring to remove this redundancy. Ensuring that this code motion and duplication does not result in excessive code bloat requires information on the execution-time characteristics of the program.[131] partial redundancy elimination

There have been proposals[954] for detecting, in hardware, common subexpression evaluations during program execution and reusing previously computed (and stored in a special table) results.

Coding Guidelines

There are cases where, technically, part of an expression has no effect on the final result but where from the human point of view the operation needs to exist in the source code— including the following:

- Source code that is translated and forms part of the program image, but is never executed, is known as *dead code*. There is no commonly used equivalent term denoting objects that are defined but never referenced (see Figure 190.1). dead code
- Source code that is translated and forms part of the program image, whose execution does not affect the external appearance or output of a program, is known as *redundant code*. Declaring objects to have a scope wider than is necessary (e.g., an object declared in the outermost block that is only referenced within one nested block— Figure 190.1) is not generally considered to be giving them a redundant scope. redundant code
- Source code that appears within conditional inclusion directives (e.g., **`#if`**/**`#endif`**) is not classified as dead code. It may not be translated to form part of a program image in some cases, but in other cases it may be.

The issue of duplicate code is discussed elsewhere. Dead, or redundant, code can increase costs in a number of ways, including the following: 1821 duplicate code

- *Additional maintenance effort.* It is source code that developers do not need to read. They may even make changes to it in the mistaken belief that it affects program output.
- *Consume host processor resources.* For instance, in the case of unused storage, execution performance can be affected through its effect on cache behavior. 0 cache

This kind of code can exist for a number of reasons, including:

- Defensive programming:
  - providing a default label even when it can be shown that all possible switch values are covered by labels
  - guideline recommendations that require a return at the end of a function, even though flow analysis shows it is never reached
- Conditional compilation based on translation-time constants in the conditional expressions of **`if`** statements, instead of using **`#if`**/**`#endif`**.
- Coding error.
- Using symbolic representations. For instance, a symbolic name, representing a numeric value, appearing as an operand, or the typedef name used in a cast operation that happens to denote the same C type as operand.

symbolic 822 name cast-1133 expression syntax

- Design oversight:
  - an **`if`** statement that can never be true, or is always false, based on characteristics of the application
- Cut-and-paste of existing code rather than creating a new function.
- Specification changes:
  - conditions that could previously have been true become impossible to satisfy
- At the highest level, code may only be executed when certain hardware is available (e.g., joystick).
- A developer is aware of the situation but does not consider it worth investing effort to remove the code.

Locating all dead code within a program is technically a very difficult problem. The most commonly seen levels of analysis operate at the function and statement level. Automatic tools provide a partial solution to dealing with the complexities of detecting dead code. Such tools can operate at differing levels of sophistication:

- analyze each expression in isolation:
  - detects expressions that do not contain any side effects
- simple flow analysis within a function:
  - detects redundant statements
- symbolic flow analysis within a function, called intraprocedural analysis:
  - detects **`if`**/**`while`**/**`for`** never/always executed
- flow analysis, including information across function calls, called interprocedural analysis:
  - the additional information allows a more thorough job to be done
- complete program analysis:
  - Many linkers do not include function definitions that are never referenced in the program image. The extent to which objects that are not references are included in a program image varies.

linkers 140 program 141 image

In practice, given current tool limitations, and theoretical problems associated with incomplete information (i.e., the set of values input to a program), it is unlikely that all dead code be detected.

Locating redundant code requires additional effort since it is necessary to show that particular side effects, which are performed, have no effect on the external behavior. An example of a case that is often flagged in an object defined and assigned a value within a function, but which is never referenced.

A study by Xie and Engler[1486] attempted to find a correlation between redundant code and faults that existed in that code.

The extent to which the cost of including dead and redundant code in a program outweighs the cost of removing it is a management decision. It is not unusual to find that 30%, or more, of the functions in an application, which has evolved over many years, to be uncalled (i.e., they are dead code)[1355] (see Table 1821.3). It is also common to find objects that are defined and never referenced, and **#include**s that are unnecessary (see Figure 1896.2). Dead code within functions that are called does occur, but not in significant quantities. In the case of duplicate code 5.9% of the lines of `gcc` have been found to be duplicate,[370] a study[102] of a 400 K C source line commercial application found an average duplication rate of 12.7%.

1740 controlling expression if statement

Example

```
#include <stdio.h>

extern int get_status(void);
static unsigned int glob_2;

void f(void)  /* Never called. */
{
glob_1++;
}

int main(void)
{
int local_1 = 11;

glob_1 = get_status();

if (0)
   local_1--; /* Never executed. */
if (local_1 == 12)
   glob_1--;  /* Never executed. */

if (glob_1 == 0)
   glob_1 = 1;
if (glob_1 > 0) /* Always true, but needs logical deduction. */
   printf("Hello world\n");
else
   printf("Illogical world\n"); /* Never executed. */
}
```

191 When the processing of the abstract machine is interrupted by receipt of a signal, only the values of objects as of the previous sequence point may be relied on.

signal interrupt abstract machine processing

Commentary

C has no restrictions on when a signal can be raised. If it occurs via a call to the `raise` function there will have been a sequence point before the call. If the signal is raised as a result of some external mechanism, for instance a timer interrupt or the instruction being executed raising some signal, then the developer has no control over when it occurs.

Assuming an average of 3 machine code instructions for every source code statement gives a 66% chance (ignoring the issue of sequence points within the statement) of a C statement being partially executed when a signal occurs.

C++

1.9p9 *When the processing of the abstract machine is interrupted by receipt of a signal, the value of any objects with type other than* `volatile sig_atomic_t` *are unspecified, and the value of any object not of* `volatile sig_atomic_t` *that is modified by the handler becomes undefined.*

This additional wording closely follows that given in the description of the `signal` function in the library clause of the C Standard.

Common Implementations

processor 0 pipeline

To improve performance modern processors hold a pipeline of instructions at various stages of completion. On some such processors, a signal is not processed until the pipeline has completed executing all of the instructions it contained when the signal was first received. For such processors it might not even be possible to associate a signal with a given, previous sequence point. Roberts[1172] and Gehani[477] describe various implementation and application issues associated with signal handling.

Coding Guidelines

Because a signal handler does not have any knowledge of where a signal is likely to be raised, it cannot assume anything about the values of objects it references. Through knowledge of the source code and the host environment, a developer may be able to narrow down the locations where certain signals might be expected to be raised. Because it is not possible to say anything with certainty and the difficultly of performing automatic checking a guideline review recommendation is made.

Rev 191.1

When designing and implementing programs that operate in the presence of signals no assumptions shall be made about the values of objects modified by statements in the vicinity of the flow of control where a caught signal could be raised.

Example

In the following:

```
1  #include <signal.h>
2  #include <stdio.h>
3
4  extern volatile sig_atomic_t flag;
5  extern double value,
6                A, B;
7
8  void sig_handler(int sig_number)
9  {
10 if (flag == 1)
11    printf("Need not be after A / B\n");
12 }
13
14 void f(void)
15 {
16 signal(SIGFPE, sig_handler);
17
18 flag = 0;
19 value = A / B;
20 flag = 1;
21 }
```

The instructions to assign 1 to f might already be in the processor pipeline when the floating-point divide raises a signal. The function sig_handler cannot assume anything about the value of flag even though it has sig_atomic_t type.

The only solution to the pipeline problem is to insert sufficient statements between the floating-point operation and the assignment to flag to ensure that the assignment instructions are not in the pipeline when the signal is raised. Even this is not a guaranteed solution because the translator might deduce (incorrectly in this case) that the machine code for these intervening statements could be moved to some other point in the flow of execution.

---

192 Objects that may be modified between the previous sequence point and the next sequence point need not have received their correct values yet.

modified objects received correct value

Commentary

It is not even possible to assume that objects will have one of two possible values (their previous or new value). In the two assignment:

```
A = 0x00ff;
/* Some code. */
A = 0xff00;
```

if a signal occurs during the evaluation of the second expression statement, the possible values the object A can take include 0x0000, 0x00ff, 0xffff, or 0xff00. These alternatives can occur if the underlying processor transfers multibyte values to storage one byte at a time.

The requirements on the Library typedef sig_atomic_t ensure that objects defined with this type will be accessed as an atomic operation. In the preceding example, for a processor with the byte at a time characteristics, the implementation would probably choose to use a character type in the definition of sig_atomic_t.

C++

The C++ Standard does not make this observation.

Common Implementations

It is rare for processors to support the handling of an interrupt after the partial execution of an instruction. This behavior is sometimes seen for instructions that move large amounts of data; for instance, string-handling instructions, where the processor may loop until some condition is met, can potentially take a very (relatively) long time to execute. Processors generally want to respond to an interrupt within a specified time limit.

Coding Guidelines

The myriad of possible problems that can occur as a result of an object not receiving its correct value, because of a signal being raised, are to0 diverse (and specialized) to be covered in a few guidelines.

---

193 The least requirements on a conforming implementation are:

implementation least requirements

Commentary

The *least requirements* listed provide the basis for ensuring that the output appears in the order required by the author of the code. However, the standard says nothing about how quickly it will appear after the statement performing the operation has finished executing. The only way of telling whether an implementation has ordered the operations that occurred during the execution of a program according to these requirements is to examine the output produced.

The workings of the abstract machine between the user issuing the command to execute a program image and the termination of that program is unknown to the outside world. For instance, a translator may recognize that a particular sequence of source code will output a given number of digits of the value of π. It may then translate the source into a program that prints Ascii characters from an internal table, to the desired precision, instead of executing the algorithm to calculate the digits contained in the program's source.

184 abstract machine C
205 semantics stringent correspondence

Some naive benchmark programs contain loops that have no effect on the output of the program (usually for some timing purpose). Users of such benchmarks continue to be confused by the timing results obtained from using an optimizing translator that deduces that it does not need to generate any executable code for these loops.

Other Languages

Most programming languages define the order in which statements are executed (in some languages that support a model of parallel execution, the order of some statement executions is indeterminate). Many of them have a more abstract view of program execution than C (which in many ways is more closely tied to host processor execution) and say little more than assignments update the value of a variable.

Coding Guidelines

Most order of execution coding problems occur because developers assumed an ordering that is not guaranteed by the standard; for instance, expressions containing multiple sequence points. The details of when this occurs is a developer education issue, not a coding guidelines issue (other coding guideline documents sometimes simply recommend against writing such expressions).

— At sequence points, volatile objects are stable in the sense that previous accesses are complete and subsequent accesses have not yet occurred. 194

Commentary

This requirement ensures that if there is no more than one volatile access between consecutive sequence points, the order in which the accesses occur is the same as the order in which the sequence points are reached. Also this requirement deals with accesses, not values. Almost nothing can be said about the values of volatile objects.

Except for the sequence point that occurs at the semicolon punctuator, usually little can be said about the order in which sequence points occur.

sequence points 187

Common Implementations

Implementations usually treat expressions containing volatile objects with great caution. In some cases many optimizations are not performed for the full expression referencing such objects.

Coding Guidelines

Experience suggests that developers sometimes have their own beliefs on access ordering relationships that goes beyond the minimum requirements of the C Standard. These beliefs only become a potential problem when the same object is modified more than once between two sequence points.

sequence points 187

Example

In the following there is no guaranteed order of object access to `b` or `c` in the first statement. A comma operator provides the necessary sequence point in the second expression.

```
1  int a;
2  volatile int b, c;
3
4  void f(void)
5  {
6  int t;
7
8  a = b + c;
9  a = ((t = b), t + c);
10 }
```

while in:

```
1  int x,
2      y;
```

```
3   volatile int b, c;
4
5   void f(void)
6   {
7   x = b + c;
8   y = b + c;
9   }
```

the common subexpression b+c cannot be optimized in the assignment to y. Normally a translator would have the option of keeping the value of this calculation in a register, or loading it from x. However, because the operands have the volatile storage class, they must be accessed to obtain their values.

---

195 10) In accordance with 6.2.4, the lifetimes of objects with automatic storage duration declared in **main** will have ended in the former case, even where they would not have in the latter. footnote 10

C90

This footnote did not appear in the C90 Standard and was added by the response to DR #085.

Example

```
1   #include <stdio.h>
2   #include <stdlib.h>
3
4   int *pi;
5
6   void DR_085(void)
7   {
8   /*
9    * The lifetime of the object accessed by *pi
10   * has terminated.  Undefined behavior.
11   */
12  printf("Value is %d\n", *pi);
13  }
14
15  int main(void)
16  {
17  int i;
18
19  atexit(DR_085);
20  i = 42;
21  pi = &i;
22  return 0; /* Causes wording in DR #85 apply. */
23  }
```

---

196 11) The IEC 60559 standard for binary floating-point arithmetic requires certain user-accessible status flags and control modes. footnote 11

Commentary

The footnote is making the observation that modifying the values of these user-accessible status flags and control modes is to be considered a change of state of the execution environment. However, the response to DR #287 states that status flags are not objects (and modifying them between sequence points does not generate undefined behavior).

200 status flag floating-point
200 control mode floating-point
957 footnote DR287
941 object modified once between sequence points

> *When set, a status flag may contain additional system-dependent information, possibly inaccessible to some users. The operations of this standard may, as a side-effect, set some of the following flags: inexact result, underflow, overflow, divide by zero and invalid operation.*

IEC 60559

Inexact occurs if the rounded result of an operation is not identical to the exact (infinitely precise) result. This happens when the result of an operation overflows, or underflows, or is not exactly representable in the precision used. For instance, when `FLT_RADIX == 2`, the value of `1.0/10.0` is inexact, but is exact when `FLT_RADIX == 10` (in the past, computers sold into the business market, where division by powers of 10 is common, were often designed to use a base 10-radix for this reason). One use for this flag is to support integer arithmetic in a floating-point unit.

subnormal numbers 338

Underflow: the result of an arithmetic operation, needs to be represented as a subnormal number or between zero and the smallest subnormal number. Underflow can also cause an exception to be raised.[305]

Overflow: the result of an arithmetic operation, is greater than the largest finite floating-point number. For, divide-by-zero, as the name suggests, an attempt has been made to divide by zero (except for the special case where the numerator is also zero). It also occurs if an operation on a finite value yields an exact infinite result. Invalid operation— this might include subtracting infinity from infinity, or dividing infinity by infinity, or zero by zero.

IEC 60559 *The following modes shall be implemented:*

1. *rounding, to control the direction of rounding errors,*
2. *and in certain implementations, rounding precision, to shorten the precision of the result. [This is not required for chips that do: single = single OP single. It is required for chips that do everything in more precision than single, such as Intel x87].*
3. *The implementation may, at his option, implement the following modes: traps disabled/enabled, to handle exceptions.*

Warning: The IEC 559 Standard copied the preceding words from the IEEE-754 and IEEE-854 standards incorrectly, changing the meaning. Make sure you have a copy of the IEC 60559 document, not IEC 559.

C90

The dependence on this floating-point format is new in C99. But, it is still not required.

C++

The C++ Standard does not make these observations about IEC 60559.

Common Implementations

Most processors implement the status flags listed here. The function `_control87` was supported by many MS-DOS based (with continuing compatibility support under Windows) implementations hosted on Intel x86 processors. This function enabled various Intel x87 maths coprocessor (now integrated with the CPU) control flags to be read and set.

Most implementations assume that the developer will not change the control modes (such usage is rare and handling it can introduce a large performance penalty) and that the processor will be running in round-to-nearest and default precision. If the user changes either mode and then calls a library function, defined in the headers **`<math.h>`** or **`<stdio.h>`**, incorrect results could be returned. The better vendors may supply two versions of the library: one that assumes the floating-point environment is the default one, and a slower one that allows for the developer altering the environment.

Coding Guidelines

The setting of the status flags and control modes defined in IEC 60559 represents information about the past and future execution of a program. Floating-point operations are a technically complex subject and the extent to which developers or source code alter or test this information will depend on many factors. Apart from the general exhortation to developers to be careful and to make sure they know what they are doing, there is little of practical use that can be recommended.

Commentary

In a sense floating-point operations may have semantic similarities with accesses to objects declared with a **volatile** qualified type. 1476 type qualifier syntax

Integer operations may also set status flags. The difference between the two sets of flags is that the floating-point flags are sticky (i.e., once set, they stay set until they are explicitly reset). This property of IEC 60559 status flags is now a recognized state of the C abstract machine. 200 status flag floating-point

C++

The C++ Standard does not say anything about status flags in the context of side effects. However, if a C++ implementation supports IEC 60559 (i.e., `is_iec559` is true, 18.2.1.2p52) then floating-point operations will implicitly set the status flags (as required by that standard).

Coding Guidelines

Checking status flags after every floating-point operation usually incurs a significant performance penalty. The status flags were designed to be sticky to enable checks to be made after a series of floating-point operations. However, the more operations performed before a check is made, the less detailed information is available about where the potential problem occurred. The extent to which it is cost effective to use the information provided by the status flags is outside the scope of these coding guidelines.

Example

```
#include <fenv.h>

extern float f_glob;

void f(void)
{
fexcept_t status_info;
float f_loc = f_glob * f_glob;

fegetexceptflag(&status_info, FE_ALL_EXCEPT);
/*
 * Now check the information returned in status_info.
 */
}
```

---

198 modes affect result values of floating-point operations.

Commentary

The modes affect such things as the rounding of arithmetic operations. To some extent developers have some control over them through the use of the FENV_ACCESS pragma. 352 FLT_ROUNDS

C++

The C++ Standard does not say anything about floating-point modes in the context of side effects.

---

199 Implementations that support such floating-point state are required to regard changes to it as side effects—see annex F for details. side effect floating-point state

Commentary

In practice the status flags associated with floating-point state differ from those associated with other operations (e.g., the flags set as the result of integer operations, such as result is zero) in that they can affect the results of floating-point operations. A processor's ability to select how integer overflow is handled might, in theory, be considered a mode. However, in practice few processors provide such functionality.[284]

The FENV_ACCESS pragma provides a mechanism for developers to inform implementations that they are accessing the floating-point environment.

C++

The C++ Standard does not specify any such requirement.

Common Implementations

In a multiprocess environment any floating-point state flags have to be saved and restored on each context switch. This saving and restoring is usually handled by the operating system.

Processors rarely have any status flags that affect operations on integer types (although some processors have the ability to dynamically change their endianness, which is usually only done at boot time). For this reason, the C Standard limits its discussion to floating-point state.

endian 570

Coding Guidelines

An algorithm may depend on a particular floating-point state for its correct operation. Programs using such algorithms need to ensure that this state is set up as part of the initialization done prior to using the algorithm. They may also need to restore any previous state, if it was different from the one used for the algorithm.

The floating-point environment library **<fenv.h>** provides a programming facility for indicating when these side effects matter, freeing the implementations in other cases. 200

Commentary

status flag
floating-point exception
floating-point control mode
floating-point

The following except from "7.6 Floating-point environment <fenv.h>" of the library section defines the terms *floating-point environment*, *floating-point status flag*, *floating-point exception*, and *floating-point control mode*.

7.6 Floating-point environment **<fenv.h>**

> *A floating-point status flag is a system variable whose value is set (but never cleared) when a floating-point exception is raised, which occurs as a side effect of exceptional floating-point arithmetic to provide auxiliary information. A floating-point control mode is a system variable whose value may be set by the user to affect the subsequent behavior of floating-point arithmetic.*[DR287a)]

The WG14 document N753 says:

WG14/N753

> *It is assumed that the integer and floating-point environments each consist of a control word and a status word. The status word contains bits (sticky flags) to indicate the state of past operations. The status word need not be a hardware register, it may be in memory and maintained by system software.*
>
> *The floating-point environment consists of:*

```
status
   sticky flags
      invalid
      div-by-zero
      overflow
      underflow
      inexact
   optional
      current operation being performed
      exception(s) of current operation
      exception(s) still pending
      operand values
      destination's precision
      rounded result
control
   rounding
   precision (optional)
   trap enable/disable (optional)
```

```
            invalid
            div-by-zero
            overflow
            underflow
            inexact
```

While the Rationale says:

Rationale

The floating-point environment as defined here includes only execution-time modes, not the myriad of possible translation-time options that can affect a program's results. Each such option's deviation from this specification should be well documented.

Dynamic vs. static modes

Dynamic modes are potentially problematic because

1. the programmer may have to defend against undesirable mode settings, which imposes intellectual as well as time and space overhead.

2. the translator may not know which mode settings will be in effect or which functions change them at execution time, which inhibits optimization.

C99 addresses these problems without changing the dynamic nature of the modes.

An alternate approach would have been to present a model of static modes with explicit utterances to the translator about what mode settings would be in effect. This would have avoided any uncertainty due to the global nature of dynamic modes or the dependency on unenforced conventions. However, some essentially dynamic mechanism still would have been needed in order to allow functions to inherit (honor) their caller's modes. The IEC 60559 standard requires dynamic rounding direction modes. For the many architectures that maintain these modes in control registers, implementation of the static model would be more costly. Also, standard C has no facility, other than pragmas, for supporting static modes.

An implementation on an architecture that provides only static control of modes, for example through opword encodings, still could support the dynamic model, by generating multiple code streams with tests of a private global variable containing the mode setting. Only modules under an enabling `FENV_ACCESS` pragma would need such special treatment.

Translation

An implementation is not required to provide a facility for altering the modes for translation-time arithmetic, or for making exception flags from the translation available to the executing program.

The language and library provide facilities to cause floating-point operations to be done at execution time when they can be subjected to varying dynamic modes and their exceptions detected. The need does not seem sufficient to require similar facilities for translation.

C90

Support for the header **<fenv.h>** is new in C99.

C++

Support for the header **<fenv.h>** is new in C99, and there is no equivalent library header specified in the C++ Standard.

Other Languages

There is an ISO Technical Report[651] that deals with floating-point exception handling in Fortran.

— At program termination, all data written into files shall be identical to the result that execution of the program according to the abstract semantics would have produced. 201

Commentary

A strictly conforming program has a unique sequence of output data for a given sequence of input data. The output from a conforming program is not guaranteed to be unique (an unspecified behavior may cause different implementations to generate different).

interactive device intent 203

The standard says very little about when output appears. Program termination causes all open files to be closed. Although closing a file causes any buffered data to be written to it, nothing is said about when this flushing needs to be completed. The only thing that can be said about program termination is that there will be no more output from that program (during that execution).

The library file-handling functions deal with the issue from a single executing program's perspective. How another program, running on a host capable of supporting more than one program executing at the same time, might view the contents of a file being written to by more than one conforming C program at the same time is not dealt with by the C Standard.

C++

1.9p11 — *At program termination, all data written into files shall be identical to one of the possible results that execution of the program according to the abstract semantics would have produced.*

The C++ Standard is technically more accurate in recognizing that the output of a conforming program may vary, if it contains unspecified behavior.

Common Implementations

Many file systems' cache writes, to a file, into blocks. Once a block is full the data it contains is written to the file. Any cached data is also written to a file when it is closed. Many modern environments have multiple caches. Whether a buffer flushed from an individual program's I/O cache ever gets physically written, as a pattern of bits, on to an actual storage device might never be known. A temporary file may be opened, written to, closed and then removed; all associated data being held in one or more caches.

— The input and output dynamics of interactive devices shall take place as specified in 7.19.3. 202

Commentary

Clause 7.19.3 does not say what shall happen, only what is intended to happen.

Rationale The class of interactive devices is intended to include at least asynchronous terminals, or paired display screens and keyboards. An implementation may extend the definition to include other input and output devices, or even network inter-program connections, provided they obey the Standard's characterization of interactivity.

Common Implementations

Having the host processor, in a multiuser environment, deal with every key press from all users can consume a large amount of resources. Some mainframe environments require an escape key to be pressed to indicate to the host that input is being sent. It can be more efficient to have the local input device store the characters until a response is required from the host (e.g., at the end of a newly typed line of characters).

Most, nonmainframe, implementations can support a line-oriented conversation.

---

interactive device intent

The intent of these requirements is that unbuffered or line-buffered output appear as soon as possible, to ensure that prompting messages actually appear prior to a program waiting for input. 203

Commentary

Such buffering is very desirable when attempting to have a realtime conversation with a person or computer at the sending/receiving end of the input/output. Not all hosts provide the ability to perform anything other than buffered I/O, hence this specification is an intent rather than a requirement.

Line-buffered output is intended to appear every time a new-line character is written to a stream. The individual characters need not appear as they are written by the program, for instance if a string is output, followed several source statements later by the output of a number. The output might appear a line at a time.

The closing of a stream is another event that is likely to cause output to appear fairly promptly.

Common Implementations

Having the host dispatch output characters one at a time for writing to a file is very inefficient. In a multiuser environment there are performance gains to be had in passing complete lines to the output device.

There can be a significant performance penalty associated with continually opening and closing streams.

Coding Guidelines

I/O handling is an important issue for applications and vendors often put a lot of effort into this functionality. It is one area where extensions are often used and where following guidelines can help minimize dependencies on a particular implementation. The extent to which an application depends on output appearing in a timely manner is a design issue that is outside the scope of these coding guidelines.

95.1 extensions cost/benefit

Example

Once consequence of buffered output handling is that the same program may behave differently depending on how it is executed:

```
1  #include <stdio.h>
2  #include <sys/types.h>
3
4  int main(void)
5  {
6  printf("Started\n");
7  if (fork() == 0)
8     printf("Child\n");
9  }
```

If, when executed, `stdout` is an interactive device, the preceding program will produce:

```
Started
Child
```

If, when executed, `stdout` is not an interactive device, there is a high probability that the program will produce:

```
Started
Started
Child
```

The reason is that the `fork` system call (it's in POSIX, but not C) duplicates all of the parents' data structures, including its internal I/O buffers (defined by the C header **<stdio.h>**) for the child process. If buffered I/O is taking place (likely when writing to a noninteractive device), the string generated by the first `printf` will be held in one of these buffers before being copied to the O/S output buffers. When the **<stdio.h>** buffers are copied, their contents, including any pending output, is also copied. When these buffers are finally flushed, two copies of the string **Started** appear on the output stream (see section 8.2 of Zlotnick[1515] for a detailed discussion and possible solutions).

---

204 What constitutes an interactive device is implementation-defined.

interactive device what constitutes

Commentary

Not only the type of device, but how it is used may affect whether it is treated as an interactive device. Serial devices (i.e., those that send and receive data as a stream of bytes) are often implemented as interactive devices. However, if access to a device is occurring as some background task because the program is executing in batch mode, the host may decide not to treat it as an interactive device.

Block devices (i.e., those that handle data in blocks, usually of 512 bytes or more) are not usually interactive devices. If more than one program is accessing data written to a block device, it may be necessary to ensure that all writes to that device occur when they are executed. But, support for such multiprogram behavior is outside the scope of the C Standard. One block device that is sometimes treated as an interactive device is a tape. Here the output is assembled into blocks for efficient writing and storage, but is written serially.

Other Languages

Most languages do not specify anything about low-level device details.

Common Implementations

The devices connected to `stdin`, `stdout`, and `stderr` on program startup are often interactive devices, if such are available.

Hard disks are block devices and are rarely interactive devices.

Coding Guidelines

Programs that require their output to appear in a timely fashion need to ensure that the devices they are using support such behavior. The C Standard provides intent to implementors, not guarantees to developers. Coding guidelines can say nothing, other than reminding developers that the intended behavior may vary between implementations.

---

semantics stringent correspondence

More stringent correspondences between abstract and actual semantics may be defined by each implementation. 205

Commentary

This is really a warning that implementations may have a low quality of implementation in this area. They might not perform any code optimizations, updating all objects at the point their values are modified; I/O could be performed on a character-by-character basis (input and output is defined in terms of `fgetc` and `fputc`).

Common Implementations

The commercial pressures on vendors is rarely to conform more strictly to standards (although a strong interest in conformance to standards is invariably claimed). Rather, it is to provide features that improve a program's ability to interact with the host environment. Many implementations provide several additional functions to ensure that characters are written to a device in a timely manner.

Coding Guidelines

More stringent correspondences would not change the behavior of a strictly conforming program. It may change the behavior of a conforming program to one of the set of possible behaviors that any implementation could produce.

A general principle of coding guidelines is to recommend usage that minimizes a program's exposure to the latitude available to an implementation in executing it. More stringent correspondences might be viewed as enabling programs to produce more reliable results. However, using a more stringent implementation only saves costs if the program has been written to that specification. Porting existing code to such an environment is simply that, another port.

---

abstract machine example

EXAMPLE 1 An implementation might define a one-to-one correspondence between abstract and actual 206

semantics: at every sequence point, the values of the actual objects would agree with those specified by the abstract semantics. The keyword **volatile** would then be redundant.
Alternatively, an implementation might perform various optimizations within each translation unit, such that the actual semantics would agree with the abstract semantics only when making function calls across translation unit boundaries. In such an implementation, at the time of each function entry and function return where the calling function and the called function are in different translation units, the values of all externally linked objects and of all objects accessible via pointers therein would agree with the abstract semantics. Furthermore, at the time of each such function entry the values of the parameters of the called function and of all objects accessible via pointers therein would agree with the abstract semantics. In this type of implementation, objects referred to by interrupt service routines activated by the **signal** function would require explicit specification of **volatile** storage, as well as other implementation-defined restrictions.

Commentary

Use of **volatile** is usually treated as a very strong indicator that the designated object may change in unexpected ways. For it to be redundant the implementation would also have to specify the order of evaluations of an expression containing objects defined using this qualifier. If an optimizer were clever enough, it could even ignore these sequence points (which is leading edge optimizer technology). Commercially available optimizers tend to limit themselves to what they can analyze in a single translation unit.

Requiring that the program declare all objects accessed by an interrupt service routine with the **volatile** storage-class specifier is overly restrictive. Such routines can be invoked other than via a call to the `abort` or `raise` functions. The values of objects, as of the previous sequence point, can be relied on.

191 signal interrupt
abstract machine processing

Common Implementations

On average every fifth statement is a function call. This is very frustrating for writers of optimizers (long sequences of C code without any function calls provide more opportunities to generate high-quality machine code). The introduction of support for the **inline** function specifier, in C99, offers one way around this problem for time-critical code.

1522 function specifier
syntax

Cross function call optimization is made easier if all of the source of the called function is available (i.e., it is in the same translation unit as the caller), something that does not often occur in practice. Generation of the highest quality code requires that code generation be delayed until link-time, when all of the information about a program is available.[985, 1437]

The ability of an expression to raise a signal ruins the potential for optimization. For instance, in:

```
glob_flag = 1;

x=expr1_could_raise_signal;

glob_flag = 2;

x=expr2_could_raise_signal;

glob_flag = 3;
```

a function registered to handle the signal that may be raised in either expression might want to examine `glob_flag` to get some idea of which expression raised the signal.

Calls to the `raise` function can be detected and code generated to ensure that objects have the values required by the abstract machine.

---

207 EXAMPLE 2 In executing the fragment

```
char c1, c2;
/* ... */
c1 = c1 + c2;
```

the "integer promotions" require that the abstract machine promote the value of each variable to **int** size and then add the two **int**s and truncate the sum. Provided the addition of two **char**s can be done without overflow,

or with overflow wrapping silently to produce the correct result, the actual execution need only produce the same result, possibly omitting the promotions.

Commentary

Silently wrapping to produce the correct result is the most commonly seen processor behavior. Because `c1` and `c2` have the same types in this example, there are no potential complications introduced by them having different signed types.

Common Implementations

Modern processor instructions invariably operate on the contents of registers. These having been zero filled or sign extended, if necessary, when the value was loaded from storage, irrespective of the size of the value loaded. The cast, for promoted values, is thus implicit in the load instruction.

Older processors (including the Intel x86 processor family) have the ability to load values into particular bytes of a register. It is possible for some instructions to operate on these subparts of a register. The original rationale of such a design is that instructions operating on smaller ranges of values could be made to execute faster than those operating on larger ranges. Technology has now advanced (the Intel x86 in particular) to the stage where there are no longer any performance advantages to such a design. The issue is now one of economics— wider processor buses incur higher costs.

Some implementations (e.g., Tasking[20]) support an option that causes operations on operands having character type to be performed using processor instructions that manipulate 8-bit values (i.e., the integer promotions are not performed).

Coding Guidelines

In expressions such as:

```
1  unsigned char c1, c2, c3;
2
3  void f(void)
4  {
5  if (c1 == c2 + c3)
6     c1=3;
7  }
```

there is a commonly encountered incorrect assumption made by developers that in this case the equality and arithmetic operations are all performed at character type, the result of the addition always being kept within range of the type **`unsigned char`**. Recommending that all developers' be trained on the default integer promotions and the usual arithmetic conversions is outside the scope of these coding guidelines. These coding guidelines are not intended to recommend against the use of constructs that are obviously faults (perhaps resulting from poor training).

guidelines 0
not faults

EXAMPLE 3 Similarly, in the fragment 208

```
float f1, f2;
double d;
/* ... */
f1 = f2 * d;
```

the multiplication may be executed using single-precision arithmetic if the implementation can ascertain that the result would be the same as if it were executed using double-precision arithmetic (for example, if **`d`** were replaced by the constant **`2.0`**, which has type **`double`**).

Commentary

Such ascertaining is very hard, in practice, to do for floating-point arithmetic. It is also very tempting (instructions that operate on single-precision values are sometimes much faster than those that operate on double-precision values; not on Intel x87 where operations on objects having type **`long double`** are fastest).

FLT_EVAL_METHOD 354

The precision in which floating-point operations take place is not just a matter of performance. A numerical

algorithm may depend on a particular level of accuracy. More-than-expected accuracy can sometimes be just as damaging to the final result as less-than-expected accuracy.

---

209 EXAMPLE 4 Implementations employing wide registers have to take care to honor appropriate semantics. Values are independent of whether they are represented in a register or in memory. For example, an implicit *spilling* of a register is not permitted to alter the value. Also, an explicit *store and load* is required to round to the precision of the storage type. In particular, casts and assignments are required to perform their specified conversion. For the fragment

```
double d1, d2;
float f;
d1 = f = expression;
d2 = (float) expression;
```

the values assigned to **d1** and **d2** are required to have been converted to **float**.

Commentary

register spilling

Spilling is a technical code-generation term for what happens when the generator runs out of free working registers. It has to temporarily copy the contents of a register to a holding area in storage, freeing that register to be used to hold another value. Compiler writers hate register spills (not being able to generate code that only requires the available registers is seen as a weakness in the quality of their product).

There may not need to be an explicit store-and-load operation to round a value to the precision of the storage type. A processor instruction may be available to perform such as a conversion, which has the same effect. Even if they are converted back to the type **double** prior to the assignment, the sequence of cast operations `(double)(float)` is not a no-operation. The conversion to type **float** may result in a loss of precision in the value converted.

C90

This example is new in C99.

Common Implementations

The floating-point unit for the Intel x86 processor family[627] uses 80 bits internally to represent floating-point values. All floating-point operations are usually performed using this representation. A precision-control word allows this behavior to be changed during program execution for the floating add, subtract, multiple, divide, and square root instructions. However, this control word only affects the precision of the significand; the range of possible exponent values is not reduced (15 bits are always used). Because the range of exponent values is not reduced, it is possible to represent smaller values than would be possible in the single- or double-precision type. The only way to ensure that all additional bits used in the 80-bit representation are removed is to store the value, to storage, and reload it. The specification of the Java virtual machine requires that floating-point operations be carried out to the accuracy of the type, only. Performing the store/load operations needed to meet this requirement causes a factor of 10 performance penalty, although techniques to reduce this to a factor of 2 to 4 have been proposed.[665]

Some implementations (e.g., Microsoft Visual C++, `gcc`) provide an option that results in all reads of objects (having a real type) to be loaded from the object (all assignments also cause the object value to be updated). By not optimizing the generated machine code to reuse any value that happens to be in one of the floating-point registers, the consistency of expression evaluations is improved. If this option is not enabled, there is the possibility that a reference to an object will have greater precision in some cases because the value used was one already present in an 80-bit register, with potentially greater accuracy because it had been returned as the result of an arithmetic operation, and not loaded from storage.

A register spill has the potential for altering the value of a floating-point number. For instance, if registers hold values to greater precision than the representation of a subexpression's C type, the instructions used to perform the spill may chose to save the exact register contents to temporary storage or may round the result to the C type. On some processors the overhead of storing the exact register contents is much higher than using

the ordinary floating store instructions; some implementations have been known to chose to use the faster instructions, effectively rounding an intermediate result in those cases where a register spill had to be made.

Example

In the following:

```
#include <stdio.h>

double f3, f1, f2;

void f(void)
{
f3=f1+f2; /* The assignment. */

if (f3 == (f1+f2)) /* A simple comparison. */
   printf("As expected\n");
else
   printf("Did not expect to get here (but it can happen)\n");

if (f3 == (double)(f1+f2)) /* Another comparison. */
   printf("As expected\n");
else
   printf("This never appears\n");
}
```

the assignment will scrape off any extra bits that may be held by the processor performing the addition. In the simple comparison it would be tempting (and permitted by the standard) for an implementation, in terms of quality of generated machine code, to perform the addition of `f1` and `f2`, hold the result in a register, and then compare against `f3`. However, if the result of the addition is not adjusted to contain the same number of representation bits as were stored into `f3`, there is the possibility that any extra bits returned by the addition operation will cause the *another comparison* to fail.

EXAMPLE 5 Rearrangement for floating-point expressions is often restricted because of limitations in precision as well as range. The implementation cannot generally apply the mathematical associative rules for addition or multiplication, nor the distributive rule, because of roundoff error, even in the absence of overflow and underflow. Likewise, implementations cannot generally replace decimal constants in order to rearrange expressions. In the following fragment, rearrangements suggested by mathematical rules for real numbers are often not valid (see F.8). 210

```
double x, y, z;
/* ... */
x = (x * y) * z;  // not equivalent to x *= y * z;
z = (x - y) + y ; // not equivalent to z = x;
z = x + x * y;    // not equivalent to z = x * (1.0 + y);
y = x / 5.0;      // not equivalent to y = x * 0.2;
```

Commentary

The normal arithmetic identities that hold for unsigned integer types (and sometimes for signed integer types) rarely hold for floating-point types.

C90

This example is new in C99.

Other Languages

Fortran is known for its sophistication in handling floating-point calculations.

Common Implementations

The average application does not use floating-point types. Applications involving intensive floating-point calculations tend to be niche markets, and there are niche vendors who specialize in translating programs that perform lots of floating-point operations.

Coding Guidelines

The average translator is not very sophisticated with respect to optimizing expressions containing floating-point values. If possible, such optimizations need to be disabled unless purchasing a product from a vendor known to specialize in numerical computation.

---

211 EXAMPLE 6 To illustrate the grouping behavior of expressions, in the following fragment

EXAMPLE expression grouping

```
int a, b;
/* ... */
a = a + 32760 + b + 5;
```

the expression statement behaves exactly the same as

```
a = (((a + 32760) + b) + 5);
```

due to the associativity and precedence of these operators. Thus, the result of the sum **(a + 32760)** is next added to **b**, and that result is then added to **5** which results in the value assigned to **a**. On a machine in which overflows produce an explicit trap and in which the range of values representable by an **int** is [-32768, +32767], the implementation cannot rewrite this expression as

```
a = ((a + b) + 32765);
```

since if the values for **a** and **b** were, respectively, -32754 and -15, the sum **a + b** would produce a trap while the original expression would not; nor can the expression be rewritten either as

```
a = ((a + 32765) + b);
```

or

```
a = (a + (b + 32765));
```

since the values for **a** and **b** might have been, respectively, 4 and -8 or -17 and 12. However, on a machine in which overflow silently generates some value and where positive and negative overflows cancel, the above expression statement can be rewritten by the implementation in any of the above ways because the same result will occur.

Commentary

This example illustrates how a left-to-right parse of the input token stream associates the operands. The binding of operands to operators having the same precedence is specified by the language syntax. The brackets do not imply any ordering on the accessing of the objects a and b. An implementation may choose to load b into a register before evaluating (a+32760). Such behavior will not be noticeable unless both operands have a volatile-qualified type and their values change during execution.

943 expression grouping
943 operator precedence
1481 volatile qualified attempt modify

C90

The C90 Standard used the term *exception* rather than *trap*.

Common Implementations

Host processors that trap on overflow of signed integer operations are rare and many translators would freely rewrite the expression. Issues of instruction performance and implementation simplicity have won the day, in most cases.

---

212 EXAMPLE 7 The grouping of an expression does not completely determine its evaluation. In the following fragment

```
#include <stdio.h>
int sum;
char *p;
/* ... */
sum = sum * 10 - '0' + (*p++ = getchar());
```

the expression statement is grouped as if it were written as

```
sum = (((sum * 10) - '0') + ((*(p++)) = (getchar())));
```

but the actual increment of **p** can occur at any time between the previous sequence point and the next sequence point (the **;**), and the call to **getchar** can occur at any point prior to the need of its returned value.

Commentary

A C translator also has complete freedom, subject to sequence point requirements, to select the order in which the various parts of an expression are evaluated. Perhaps even reusing a result from a previously calculated subexpression.

Common Implementations

With optimizations switched off, many translators will generate code to evaluate the expression in either left-to-right, or right-to-left order.

Forward references: expressions (6.5), type qualifiers (6.7.3), statements (6.8), the **signal** function (7.14), files (7.19.3). 213

5.2 Environmental considerations

Commentary

Rationale

The C89 Committee ultimately came to remarkable unanimity on the subject of character set requirements. There was strong sentiment that C should not be tied to Ascii, despite its heritage and despite the precedent of Ada being defined in terms of Ascii. Rather, an implementation is required to provide a unique character code for each of the printable graphics used by C, and for each of the control codes representable by an escape sequence. (No particular graphic representation for any character is prescribed; thus the common Japanese practice of using the glyph "¥" for the C character "\" is perfectly legitimate.) Translation and execution environments may have different character sets, but each must meet this requirement in its own way. The goal is to ensure that a conforming implementation can translate a C translator written in C.

For this reason, and for economy of description, source code is described as if it undergoes the same translation as text that is input by the standard library I/O routines: each line is terminated by some newline character regardless of its external representation.

5.2.1 Character sets

---

source character set
execution character set

Two sets of characters and their associated collating sequences shall be defined: the set in which source files are written (the *source character set*), and the set interpreted in the execution environment (the *execution character set*). 214

Commentary

This is a requirement on the implementation. This defines the terms *source character set* and *execution character set*.

A collating sequence is defined, but the particular values for the characters are not specified. These, and only these, characters are guaranteed to be supported by a conforming implementation.

The purpose for defining these two character sets is to separate out the environment in which the source is translated from the environment in which the translated output is executed. When these two environments are different, the translation process is commonly known as *cross compiling*. An implementation may add additional characters to either the source or execution character set. There is no requirement that any additional characters exist in either environment.

The characters used in the definition of the C language exist within both the source and execution character sets. It is intended that a C translator be able to successfully translate a C translator written in C.

Rationale

ISO (the International Organization for Standardization) uses three technical terms to describe character sets: repertoire, collating sequence, and codeset. The repertoire is the set of distinct printable characters. The term abstracts the notion of printable character from any particular representation; the glyphs R, R, R, *R*, **R**, R, and **R**, all represent the same element of the repertoire, "upper-case-R", which is distinct from "lower-case-r". Having decided on the repertoire to be used (C needs a repertoire of 91 characters plus whitespace), one can then pick a collating sequence which corresponds to the internal representation in a computer. The repertoire and collating sequence together form the codeset.

What is needed for C is to determine the necessary repertoire, ignore the collating sequence altogether (it is of no importance to the language), and then find ways of expressing the repertoire in a way that should give no problems with currently popular codesets.

C90

The C90 Standard did not explicitly define the terms *source character set* and *execution character set*.

C++

The C++ Standard does not contain a requirement to define a collating sequence on the character sets it specifies.

Other Languages

Many languages are designed for a hosted environment and do not need to make the distinction between source and execution character sets. Ada is explicitly defined in terms of the Ascii character set. After all, it was designed as a language for use by the US Department of Defense.

Common Implementations

On most implementations the two characters sets have the same representations.

Coding Guidelines

Developers whose native tongue is English tend to be unaware of the distinction between source and execution character sets. Most of these developers do most of their development in environments where they are identical.

---

215 Each set is further divided into a *basic character set*, whose contents are given by this subclause, and a set of zero or more locale-specific members (which are not members of the basic character set) called *extended characters*.

basic character set
extended characters

Commentary

This defines the terms *basic character set* and *extended characters*. It separates out the two components of the character set used by an implementation; the one which is always required to be provided and the extended set which is optional.

C90

This explicit subdivision of characters into sets is new in C99. The wording in the C90 Standard specified the minimum contents of the basic source and basic execution character sets. These terms are now defined exactly, with all other characters being called extended characters.

214 source character set

. . . ; any additional members beyond those required by this subclause are locale-specific.

C++

2.2p3 *The values of the members of the execution character sets are implementation-defined, and any additional members are locale-specific.*

The C++ Standard more closely follows the C90 wording.

Other Languages

In the past most programming languages tended not say anything about supporting other character set members, although most implementations usually supported some additional characters. This situation is starting to change as the predominantly English-speaking standards world starts to recognize the importance of supporting programs written in the developer's native character set (the introduction of ISO 10646 also helped).

ISO 10646 28

Common Implementations

A large number of C translators originate in the USA, or target this market. This locale usually requires support for extended characters in the form of those members in the Ascii character set that are not in the basic source character set (the *$* and @ characters being the most obvious).

Vendors selling into non-English-speaking markets commonly add support for extended characters in the execution character set to support a native language. These implementations usually also support the occurrence of extended characters in comments. Support for extended characters outside of character constants, string literals, and comments has been much less common.

Coding Guidelines

Using extended characters to make applications comprehensible to their users is obviously essential. However, the handling of such characters is part of the application domain and outside the scope of these coding guidelines. The issues involved in programs written in one locale targeted at another locale is also largely outside the scope of these coding guidelines.

Using characters from the developer's native language can make an important contribution to program readability for those developers who share that native language. Some applications are now developed using people whose native languages differ from each other. The issue of using extended characters to improve source code readability is not always clear-cut. What is the best way to handle programs made up of translation units developed by developers from different locales; should all developers working on the same application use the same locale? To a large extent these questions involve predicting the future. Who will be doing the future development and maintenance of the software? It may not be possible to provide a reliable answer to this question. The issue of what characters to use in identifier names is discussed elsewhere.

identifier 792 syntax

Example

```
1  char dollar = '$';
```

---

extended character set

The combined set is also called the *extended character set*.

216

Commentary

A somewhat confusing use of terminology. A developer might be forgiven for thinking that this term applied to the set of extended characters only. For both the source character set and the execution character set, the following statement is true:

```
1  extended_character_set = basic_character_set + extended_characters;
```

Coding Guidelines

A coding guideline document needs to be very careful in its use of terminology when dealing with character set issues.

---

217 The values of the members of the execution character set are implementation-defined.

Commentary

This has already been stated for the members of the source character set. Although it might not specify their values, the standard does specify some of the properties of objects that hold them.

116 translation phase 1
222 basic character set fit in a byte

Common Implementations

Many implementations use the Ascii character set, with the EBCDIC character set appearing to be restricted to use on IBM mainframes and their derivatives. Most implementations use the same values for the corresponding members of both the source and execution character set.

Coding Guidelines

Developers tend to make several assumptions about the values of the execution character set:

- They are the same as the source character set.
- All the uppercase letters, all the lowercase letters, and all the digits are contiguous.
- They are less than 128.
- The actual values used by a translator (e.g., space being 32).

Only the assumption about the digits being contiguous is guaranteed to be true.

223 digit characters contiguous

A program may contain implicit dependencies on the representation of members of the execution character set because developers are not aware they are making assumptions about something that is not fixed. Designing programs to accommodate the properties of different character sets is not a trivial matter that can be covered in a few guideline recommendations.

Example

```
#if 'a' == 99 /* Not the execution character set. */
#endif

int f(void)
{
return 'b' == 88;
}
```

---

218 In a character constant or string literal, members of the execution character set shall be represented by corresponding members of the source character set or by *escape sequences* consisting of the backslash \ followed by one or more characters.

execution character set represented by

Commentary

This describes the two methods specified by the standard for representing members of the execution character set in character constants and string literals. They are one route through which characters appearing in the source code can appear in the output produced by a program. Comments are removed in translation phase 3. Identifier spellings are represented by objects in the program image, and are not directly involved in execution-time behavior.

126 comment replaced by space

Escape sequences are a method of representing execution characters in the source, which may not be representable in the source character set. They make it possible to explicitly specify a particular numeric value, which is known to represent a given character in the execution character set (as defined by the implementation).

Other Languages

The convention of mapping source characters to their corresponding execution characters is common to the majority of programming languages. Some of the more recently designed, or updated, programming languages also support some form of escape sequence mechanism.

Common Implementations

The POSIX locale mechanism defines a representation for characters based on their names. For instance, *LETTER-A* is used to denote the character *A*. This approach removes the need for representing characters on keyboards and displays. The main use, to date, for this character specification methodology has been within POSIX locale specifications, where the meaning of a sequence of one or more characters might otherwise be uncertain.

Coding Guidelines

String literals are not always used to simply represent character sequences. A developer may choose to embed other, numeric, information within a string literal. Relying on characters to have the desired value would create a dependence on a particular character set being used and create literals that were harder to interpret (use of escape sequences makes it explicit that a numeric value is required). The contents of string literals therefore need to be interpreted in the context in which they are used.

The value of an escape sequence may, or may not, be the same as that of a member of the basic character set. The extent to which the value of an escape sequence does, or does not, represent a member of the basic character set is one of intent on the part of the developer. This issue is discussed elsewhere.

escape sequence 866 syntax

Example

```
1  #include <stdio.h>
2
3  void f(void)
4  {
5  printf("\110ello World\n"); /* ASCII \110 == H */
6  printf("Be \100 one\n");    /* @ symbol not on an ASCII keyboard. */
7  }
```

---

null character

A byte with all bits set to 0, called the *null character*, shall exist in the basic execution character set; 219

Commentary

This defines the term *null character* (an equivalent one for a null wide character is given in the library section). The null character is used to terminate string literals.

string literal 902 zero appended

The C committee once received a request from a communications-related standards committee asking that this requirement be removed from the C Standard. The sending of null bytes was causing problems on some communications links. The C committee pointed out that C's usage was a long-established practice and that they had no plans to change it.

Other Languages

Some form of null character occurs in any language that uses a terminating character (rather than a length count) to represent strings. SQL has a null value. It is used to indicate *value unknown*, or *value not present* (no two NULL values can ever compare equal).

Coding Guidelines

There is a common beginner's mistake that is sometimes not diagnosed because an implementation has defined the `NULL` macro to be `0`, rather than `(void *)0`. If C++ compatible headers are being used, the problem is not helped by that language's explicit requirement that the null pointer be represented by `0`.

220 it is used to terminate a character string.

character string terminate

Commentary

A string literal may contain more than one null character, or none at all. In the former case the literal will contain more than one string (according to the definition of that term given in the library section) — for instance, `"abc\000xyz"` and `char s[3] = "abc"`. Each null character terminates a string even though more than one of them may appear in a string literal.

C++

After any necessary concatenation, in translation phase 7 (2.1), '\0' is appended to every string literal so that programs that scan a string can find its end. 2.13.4p4

In practice the C usage is the same as that specified by C++.

Other Languages

Not all languages specify a particular representation for strings. Some implementations of these languages use a numeric count, usually stored before the first character of the string, representation to specify the length of the string. Many Pascal implementations use this approach.

In some languages the representation of strings is completely hidden from the developer. Perl and Snobol have sophisticated built-in support for string creation and manipulation. Their implementations can use whatever representation techniques they choose. Programs attempting to access the representation, for this kind of language, are failing to operate in the algorithmic domain that the language designers intended.

Common Implementations

The MrC[263] compiler from Apple Computer provides the escape sequence \p so that developers can specify that a string literal is a *Pascal string*. It has to occur as the first character and causes the implementation to maintain a byte count, rather than a null terminator.

Coding Guidelines

Null characters are different from other escape sequences in a string literal in that they have the special status of acting as a terminator (e.g., the library string searching routines terminate when a null character is encountered, leaving any subsequent characters in the literal unchecked). Any surprising behavior occurring because of this usage is a fault and these coding guidelines are not intended to recommend against the use of constructs that are obviously faults.

0 guidelines not faults

221 Both the basic source and basic execution character sets shall have the following members: the 26 *uppercase letters* of the Latin alphabet

basic source character set
basic execution character set

```
A  B  C  D  E  F  G  H  I  J  K  L  M
N  O  P  Q  R  S  T  U  V  W  X  Y  Z
```

the 26 *lowercase letters* of the Latin alphabet

```
a  b  c  d  e  f  g  h  i  j  k  l  m
n  o  p  q  r  s  t  u  v  w  x  y  z
```

the 10 decimal *digits*

```
0  1  2  3  4  5  6  7  8  9
```

the following 29 graphic characters

```
!  "  #  %  &  '  (  )  *  +  ,  -  .  /  :
;  <  =  >  ?  [  \  ]  ^  _  {  |  }  ~
```

the space character, and control characters representing horizontal tab, vertical tab, and form feed.

Commentary

The original C Standard's work aimed to codify existing practice, and the K&R definition used the preceding collection of characters. The character values occupied by the #, [,], {, }, & and | characters in the Ascii character set are sometimes used to represent different characters in some Scandinavian character sets. Whether an awareness of this issue would have made any difference to the characters chosen can be debated (as could the extent to which a problem experienced by a minority of developers should have any noticeable impact on the majority of developers). It certainly made no difference to the design of Java, which occurred well after this issue had become well-known.

The characters vertical tab, form feed, carriage return, and new-line are sometimes referred to as line break characters. This term describes the most commonly seen visual effect of their appearance in a text file, not how a translator is required to interpret them.

C90

The C90 Standard referred to these characters as the *English alphabet*.

C++

2.2p1 *The basic source character set consists of 96 characters: the space character, the control characters representing horizontal tab, vertical tab, form feed, and new-line, plus the following 91 graphics characters:*

```
A B C D E F G H I J K L M N O P Q R S T U V W X Y Z
a b c d e f g h i j k l m n o p q r s t u v w x y z
0 1 2 3 4 5 6 7 8 9
_ { } [ ] # ( ) < > % : ; . ? * + - / ^ & | ~ ! = , \ " '
```

basic execution character set 226
control characters

The C++ Standard includes new-line in the basic source character set (C only includes it in the basic execution character set).

The C++ Standard does not separate out the uppercase, lowercase, and decimal digits from the graphical characters, so technically they are not defined for the basic source character set (the library functions such as `toupper` effectively define these terms for the execution character set).

Other Languages

Not all languages require as many characters to be supported as C does. The APL language contains so many characters especially designed for the language that they have their own standard – ISO 2575 *Registered Character Set 68— APL* – to describe them.

Common Implementations

The basic execution character set does not include three printable characters that appear in the first 127 positions of the ISO 10646 standard (and also in Ascii)— *$* (dollar), @ (commercial at), and ‘ (grave accent)

Coding Guidelines

A high priority might be given to supporting the *$* and @ characters in a money-oriented, wired world. But what about other characters that are not in the basic character set? When these characters are intended to appear in the source character set, the issue is one of displaying and potentially inputting them to a source file. Experience shows that developers usually have access to computers capable of displaying and inputting characters from the Ascii character set. This is an issue that is considered to be outside the scope of these coding guidelines. When these characters are intended to appear in the execution character set, it becomes an applications issue that is outside the scope of these coding guidelines.

Horizontal tab is a single white-space character. However, when viewing source code containing such a character, many display devices appear to replace it with more than one white-space character. There is no agreed-on spacing for the horizontal tab character and its use can cause the appearance of the source code to vary between display devices. The standard contains an alternative method of representing horizontal tab in string literals and character constants.

horizontal tab escape sequence 263

Most source code is displayed using a fixed-width font. Research[108] has shown that people read text faster (a 6% time difference, most of which can be attributed to the greater amount of information that a variable-width font allows to appear within the readers visual field) when it is displayed in a variable-width font than a fixed-width font. Comparing text has also been found to be quicker, but not searching for specific words. Use of a variable width font would also enable more characters to be displayed on a line, reducing the need to split statements across more than one line.

770 visual field

Support for use of variable-width fonts is not always available to developers. The issue of source, written using a variable-width font, having to be read in an environment where only a fixed-width font is available also needs to be considered (long lines may not be displayed as intended).[221.1]

Table 221.1: Occurrence of characters as a percentage of all characters and as a percentage of all noncomment characters (i.e., outside of comments). Based on the visible form of the `.c` files. For a comparison of letter usage in English language and identifiers see Figure 792.16.

Letter or ASCII Value	All	Non-comment	Letter or ASCII Value	All	Non-comment	Letter or ASCII Value	All	Non-comment	Letter or ASCII Value	All	Non-comment

basic character set fit in a byte

The representation of each member of the source and execution basic character sets shall fit in a byte. 222

Commentary

character 59 single-byte character constant 883 type basic character set 478 positive if stored in char object

This is a requirement on the implementation. The definition of character already specifies that it fits in a byte. However, a character constant has type **int**; which could be thought to imply that the value representation of characters need not fit in a byte. This wording clarifies the situation. The representation of members of the basic execution character set is also required to be a nonnegative value.

C++

1.7p1 *A byte is at least large enough to contain any member of the basic execution character set and . . .*

This requirement reverses the dependency given in the C Standard, but the effect is the same.

Common Implementations

On hosts where characters have a width 16 or 32 bits, that choice has usually been made because of addressability issues (pointers only being able to point at storage on 16- or 32-bit address boundaries). It is not usually necessary to increase the size of a byte because of representational issues to do with the character set.

CHAR_BIT 307 macro

In the EBCDIC character set, the value of `'a'` is 129 (in Ascii it is 97). If the implementation-defined value of `CHAR_BIT` is 8, then this character, and some others, will not be representable in the type **signed char** (in most implementations the representation actually used is the negative value whose least significant eight bits are the same as those of the corresponding bits in the positive value, in the character set). In such implementations the type **char** will need to have the same representation as the type **unsigned char**.

The ICL 1900 series used a 6-bit byte. Implementing this requirement on such a host would not have been possible.

representation information using 569.1

Coding Guidelines

A general principle of coding guidelines is to recommend against the use of representation information. In this case the standard is guaranteeing that a character will fit within a given amount of storage. Relying on this requirement might almost be regarded as essential in some cases.

Example

```
1  void f(void)
2  {
3  char C_1 = 'W';        /* Guaranteed to fit in a char. */
4  char C_2 = '$';        /* Not guaranteed to fit in a char. */
5  signed char C_3 = 'W'; /* Not guaranteed to fit in a signed char. */
6  }
```

223 In both the source and execution basic character sets, the value of each character after **0** in the above list of decimal digits shall be one greater than the value of the previous.

digit characters contiguous

Commentary

This is a requirement on the implementation. The Committee realized that a large number of existing programs depended on this statement being true. It is certainly true for the two major character sets used in the English-speaking world, Ascii, EBCDIC, and all of the human language digit encodings specified in Unicode, see Table 797.1. The Committee thus saw fit to bless this usage.

Not only is it possible to perform relational comparisons on the digit characters (e.g, `'0'<'1'` is always true) but arithmetic operations can also be performed (e.g., `'0'+1 == '1'`). A similar statement for the alphabetic characters cannot be made because it would not be true for at least one character set in common use (e.g., EBCDIC).

C++

The above wording has been proposed as the response to C++ DR #173.

Other Languages

Most languages that have not recently had their specifications updated do not specify any representational properties for the values of their execution character sets. Java specifies the use of the Unicode character set (newer versions of the language specify newer versions of the Unicode Standard; all of which are the same as Ascii for their first 128 values), so this statement also holds true. Ada specifies the subset of ISO 10646 known as the Basic Multilingual Plane (the original language standard specified ISO 646).

28 ISO 10646

Coding Guidelines

This requirement on an implementation provides a guarantee of representation information that developers can make use of (e.g., in relational comparisons, see Table 866.3). The following are suggested wordings for deviations from the guideline recommendation dealing with making use of representation information.

569.1 representation information using

Dev 569.1 An integer character constant denoting a digit character may appear in the visible source as the operand of an *additive-operator*.

Example

```
1  #include <stdio.h>
2
3  extern char c_glob = '4';
4
5  int main(void)
6  {
7  if ('0' + 3 == '3')
8     printf("Sentence 221 is TRUE\n");
9
10 if (c_glob < '5')
11    printf("Sentence 221 may be TRUE\n");
12 if (c_glob < 53) /* '5' == 53 in ASCII */
13    printf("Sentence 221 does not apply\n");
14 }
```

224 In source files, there shall be some way of indicating the end of each line of text;

end-of-line representation

Commentary

This is a requirement on the implementation.

The C library makes a distinction between text and binary files. However, there is no requirement that source files exist in either of these forms. The worst-case scenario: In a host environment that did not have a native method of delimiting lines, an implementation would have to provide/define its own convention and supply tools for editing such files. Some integrated development environments do define their own conventions for storing source files and other associated information.

C++

The C++ Standard does not specify this level of detail (although it does refer to end-of-line indicators, 2.1p1n1).

Common Implementations

Unicode Technical Report #13: "Unicode newline guidelines" discusses the issues associated with representing new-lines in files. The ISO 6429 standard also defines NEL (NExt Line, hexadecimal 0x85) as an end-of-line indicator. The Microsoft Windows convention is to indicate this end-of-line with a carriage return/line feed pair, \r\n (a convention that goes back through CP/M to DEC RT-11); the Unix convention is to use a single line feed character \n; the MacIntosh convention is to use the carriage return character, \r.

Some mainframes implement a form of text files that mimic punched cards by having fixed-length lines. Each line contains the same number of characters, often 80. The space after the last user-written character is sometimes padded with spaces, other times it is padded with null characters.

---

this International Standard treats such an end-of-line indicator as if it were a single new-line character. 225

Commentary

translation phase 1 (116)

The standard is not interested in the details of the byte representation of end-of-line on storage media. It makes use of the concept of end-of-line and uses the conceptual simplification of treating it as if it were a single character.

C++

2.1p1n1 . . . *(introducing new-line characters for end-of-line indicators)* . . .

---

basic execution character set control characters

In the basic execution character set, there shall be control characters representing alert, backspace, carriage return, and new line. 226

Commentary

This is a requirement on the implementation.

basic execution character set (221), translation phase 1 (116), escape sequence syntax (866)

These characters form part of the set of 96 execution character set members (counting the null character) defined by the standard, plus new line which is introduced in translation phase 1. However, these characters are not in the basic source character set, and are represented in it using escape sequences.

Other Languages

Few other languages include the concept of control characters, although many implementations provide semantics for them in source code (they are usually mapped exactly from the source to the execution character set). Java defines the same control characters as C and gives them their equivalent Ascii values. However, it does not define any semantics for these characters.

Common Implementations

ECMA-48 Control Functions for Coded Character Sets, Fifth Edition (available free from their Web site, http://www.ecma-international.ch) was fast-tracked as the third edition of ISO/IEC 6429. This standard defines significantly more control functions than those specified in the C Standard.

227 If any other characters are encountered in a source file (except in an identifier, a character constant, a string literal, a header name, a comment, or a preprocessing token that is never converted to a token), the behavior is undefined.

Commentary

The standard does not prohibit such characters from occurring in a source file outright. The Committee was aware of implementations that used such characters to extend the language. For instance, the use of the @ character in an object definition to specify its address in storage.

The list of exceptions is extensive. The only usage remaining, for such characters, is as a punctuator. *Any other character* has to be accepted as a preprocessing token. It may subsequently, for instance, be stringized. It is the attempt to convert this preprocessing token into a token where the undefined behavior occurs.

1950 # operator
137 preprocessing token converted to token

C90

Support for additional characters in identifiers is new in C99.

C++

Any source file character not in the basic source character set (2.2) is replaced by the universal-character-name that designates that character. 2.1p1

The C++ Standard specifies the behavior and a translator is required to handle source code containing such a character. A C translator is permitted to issue a diagnostic and fail to translate the source code.

Other Languages

Most languages regard the appearance of an unknown character in the source as some form of error. Like C, most language implementations support additional characters in string literals and comments.

Common Implementations

Most implementations generate a diagnostic, either when the preprocessing token containing one of these characters is converted to a token, or as a result of the very likely subsequent syntax violation. Some implementations[717] define the @ character to be a token, its usual use being to provide the syntax for specifying the address at which an object is to be placed in storage. It is generally followed by an integer constant expression.

Coding Guidelines

An occurrence of a character outside of the basic source character set, in one of these contexts, is most likely to be a typing mistake and is very likely to be diagnosed by the translator. The other possibility is that such characters were intended to be used because use is being made of an extension. This issue is discussed elsewhere.

95.1 extensions cost/benefit

Example

```
1  static int glob @ 0x100; /* Put glob at location 0x100. */
```

228 A *letter* is an uppercase letter or a lowercase letter as defined above; letter

Commentary

This defines the term *letter*.

There is a third kind of case that characters can have, *titlecase* (a term sometimes applied to words where the first letter is in uppercase, or titlecase, and the other letters are in lowercase). In most instances titlecase is the same as uppercase, but there are a few characters where this is not true; for instance, the titlecase of the Unicode character U01C9, *lj*, is U01C8, *Lj*, and its uppercase is U01C7, *LJ*.

C90

This definition is new in C99.

---

in this International Standard the term does not include other characters that are letters in other alphabets. 229

Commentary

All implementations are required to support the basic source character set to which this terminology applies. Annex D lists those universal character names that can appear in identifiers. However, they are not referred to as letters (although they may well be regarded as such in their native language).

orthography 792

The term *letter* assumes that the orthography (writing system) of a language has an alphabet. Some orthographies, for instance Japanese, don't have an alphabet as such (let alone the concept of upper- and lowercase letters). Even when the orthography of a language does include characters that are considered to be matching upper and lowercase letters by speakers of that language (e.g., æ and Æ, å and Å), the C Standard does not define these characters to be *letter*s.

C++

The definition used in the C++ Standard, 17.3.2.1.3 (the footnote applies to C90 only), implies this is also true in C++.

Coding Guidelines

The term *letter* has a common usage meaning in a number of different languages. Developers do not often use this term in its C Standard sense. Perhaps the safest approach for coding guideline documents to take is to avoid use of this term completely.

The universal character name construct provides a way to name other characters. 230

Commentary

ISO 10646 28

In theory all characters on planet Earth and beyond. In practice, those defined in ISO 10646.

C90

Support for universal character names is new in C99.

Other Languages

Other language standards are slowly moving to support ISO 10646. Java supports a similar concept.

Common Implementations

Support for these characters is relatively new. It will take time before similarities between implementations become apparent.

Forward references: universal character names (6.4.3), character constants (6.4.4.4), preprocessing directives (6.10), string literals (6.4.5), comments (6.4.9), string (7.1.1). 231

5.2.1.1 Trigraph sequences

trigraph sequences replaced by

~~All occurrences in a source file~~ Before any other processing takes place, each occurrence of one of the following sequences of three characters (called *trigraph sequences*[12)]) are replaced with the corresponding single character. 232

Commentary

Trigraphs were an invention of the C committee. They are a method of supporting the input (into source files, not executing programs) and the printing of some C source characters in countries whose alphabets, and keyboards, do not include them in their national character set. Digraphs, discussed elsewhere, are another sequence of characters that are replaced by a corresponding single character.

digraphs 916

string literal 895 syntax

The \? escape sequence was introduced to allow sequences of ?s to occur within string literals.

The wording was changed by the response to DR #309.

Other Languages

Until recently many computer languages did not attempt to be as worldly as C, requiring what might be called an *Ascii keyboard*. Pascal specifies what it calls lexical alternatives for some lexical tokens. The character sequences making up these lexical alternatives are only recognized in a context where they can form a single, complete token.

Common Implementations

On the Apple MacIntosh host, the notation `'????'` is used to denote the unknown file type. Translators in this environment often disable trigraphs by default to prevent unintended replacements from occurring.

---

trigraph sequences mappings

233

```
??= #   ??) ]   ??! |
??( [   ??' ^   ??< }
??/ \   ??< {   ??- ~
```

Commentary

The above sequences were chosen to minimize the likelihood of breaking any existing, conforming, C source code.

Other Languages

Many languages use a small subset, or none, of these problematic source characters, reducing the potential severity of the problem. The Pascal standard specifies `(.` and `.)` as alternative lexical representations of `[` and `]` respectively.

Common Implementations

Recognizing trigraph sequences entails a check against every character read in by the translator. Performance profiling of translators has shown that a large percentage of time is spent in the lexer. A study by Waite[1436] found 41% of total translation time was spent in a handcrafted lexer (with little code optimization performed by the translator). An automatically produced lexer, the `lex` tool was used, consumed 3 to 5 as much time.

One vendor, Borland, who used to take pride, and was known, for the speed at which their translators operated, did not include trigraph processing in the main translator program. A standalone utility was provided to perform trigraph processing. Those few programs that used trigraphs needed to be processed by this utility, generating a temporary file that was processed by the main translator program. While using this pre-preprocessor was a large overhead for programs that used trigraphs, performance was not degraded for source code that did not contain them.

Usage

There are insufficient trigraphs in the visible form of the `.c` files to enable any meaningful analysis of the usage of different trigraphs to be made.

---

234 No other trigraph sequences exist.

trigraph sequences no other

Commentary

The set of characters for which trigraphs were created to provide an alternative spelling are known, and unlikely to be extended.

Coding Guidelines

Although no other trigraph sequences exist, sequences of two adjacent questions marks in string literals may lead to confusion. Developers may be unsure about whether they represent a trigraph or not. Using the escape sequence `\?` on at least one of these questions marks can help clarify the intent.

Example

```
1  char *unknown_trigraph = "??++";
2  char *cannot_be_trigraph = "?\?--";
```

Usage

The visible form of the `.c` files contained 593 (`.h` 10) instances of two question marks (i.e., ??) in string literals that were not followed by a character that would have created a trigraph sequence.

Each `?` that does not begin one of the trigraphs listed above is not changed. 235

Commentary

Two ?s followed by any other character than those listed above is not a trigraph.

Common Implementations

No implementation is known to define any other sequence of ?s to be replaced by other characters.

Coding Guidelines

No other trigraph sequences are defined by the standard, have been notified for future addition to the standard, or used in known implementations. Placing restrictions on other uses of other sequences of ?s provides no benefit.

EXAMPLE 1 236

```
??=define arraycheck(a,b) a??(b??) ??!??! b??(a??)
```

becomes

```
#define arraycheck(a,b) a[b] || b[a]
```

Commentary

This example was added by the response to DR #310 and is intended to show a common trigraph usage.

EXAMPLE 2 The following source line 237

```
printf("Eh???/n");
```

becomes (after replacement of the trigraph sequence `??/`)

```
printf("Eh?\n");
```

Commentary

This illustrates the sometimes surprising consequences of trigraph processing.

5.2.1.2 Multibyte characters

---

multibyte character source contain

The source character set may contain multibyte characters, used to represent members of the extended character set. 238

Commentary

multibyte 60 character transla- 116 tion phase 1 UCN 115 models of

The mapping from physical source file multibyte characters to the source character set occurs in translation phase 1. Whether multibyte characters are mapped to UCNs, single characters (if possible), or remain as multibyte characters depends on the model used by the implementation.

C++

The representations used for multibyte characters, in source code, invariably involve at least one character that is not in the basic source character set:

2.1p1 *Any source file character not in the basic source character set (2.2) is replaced by the universal-character-name that designates that character.*

The C++ Standard does not discuss the issue of a translator having to process multibyte characters during translation. However, implementations may choose to replace such characters with a corresponding universal-character-name.

Other Languages

Most programming languages do not contain the concept of multibyte characters.

Common Implementations

Support for multibyte characters in identifiers, using a shift state encoding, is sometimes seen as an extension. Support for multibyte characters in this context using UCNs is new in C99. The most common implementations have been created to support the various Japanese character sets.

815 universal character name syntax

Coding Guidelines

The standard does not define how multibyte characters are to be represented. Any program that contains them is dependent on a particular implementation to do the right thing. Converting programs that existed before support for universal character names became available may not be economically viable.

Some coding guideline documents recommend against the use of characters that are not specified in the C Standard. Simply prohibiting multibyte characters because they rely on implementation-defined behavior ignores the cost/benefit issues applicable to the developers who need to read the source. These are complex issues for which your author has insufficient experience with which to frame any applicable guideline recommendations.

---

239 The execution character set may also contain multibyte characters, which need not have the same encoding as for the source character set.

Commentary

Multibyte characters could be read from a file during program execution, or even created by assigning byte values to contiguous array elements. These multibyte sequences could then be interpreted by various library functions as representing certain (wide) characters.

The execution character set need not be fixed at translation time. A program's locale can be changed at execution time (by a call to the `setlocale` function). Such a change of locale can alter how multibyte characters are interpreted by a library function.

C++

There is no explicit statement about such behavior being permitted in the C++ Standard. The C header **<wchar.h>** (specified in Amendment 1 to C90) is included by reference and so the support it defines for multibyte characters needs to be provided by C++ implementations.

Other Languages

Most languages do not include library functions for handling multibyte characters.

Coding Guidelines

Use of multibyte characters during program execution is an applications issue that is outside the scope of these coding guidelines.

---

240 For both character sets, the following shall hold:

Commentary

This is a set of requirements that applies to an implementation. It is the minimum set of guaranteed requirements that a program can rely on.

Coding Guidelines

The set of requirements listed in the following C-sentences is fairly general. Dealing with implementations that do not meet the requirements listed in these sentences is outside the scope of these coding guidelines.

---

241 — The basic character set shall be present and each character shall be encoded as a single byte.

Commentary

This is a requirement on the implementation. It prevents an implementation from being purely multibyte-based. The members of the basic character set are guaranteed to always be available and fit in a byte.

basic character set 222
fit in a byte

Common Implementations

An implementation that includes support for an extended character set might choose to define CHAR_BIT to be 16 (most of the commonly used characters in ISO 10646 are representable in 16 bits, each in UTF-16; at least those likely to be encountered outside of academic research and the traditional Chinese written on Hong Kong). Alternatively, an implementation may use an encoding where the members of the basic character set are representable in a byte, but some members of the extended character set require more than one byte for their encoding. One such representation is UTF-8.

extended character set 216
CHAR_BIT 307
macro
ISO 10646 28
UTF-16 28
UTF-8 28

— The presence, meaning, and representation of any additional members is locale-specific. 242

Commentary

On program startup the execution locale is the "C" locale. During execution it can be set under program control. The standard is silent on what the translation time locale might be.

Common Implementations

The full Ascii character set is used by a large number of implementations.

Coding Guidelines

It often comes as a surprise to developers to learn what characters the C Standard does not require to be provided by an implementation. Source code readability could be affected if any of these additional members appear within comments and cannot be meaningfully displayed. Balancing the benefits of using additional members against the likelihood of not being able to display them is a management issue.

The use of any additional members during the execution of a program will be driven by the user requirements of the application. This issue is outside the scope of these coding guidelines.

---

multibyte character
state-dependent encoding
shift state

— A multibyte character set may have a *state-dependent encoding*, wherein each sequence of multibyte characters begins in an *initial shift state* and enters other locale-specific *shift states* when specific multibyte characters are encountered in the sequence. 243

Commentary

State-dependent encodings are essentially finite state machines. When a state encoding, or any multibyte encoding, is being used the number of characters in a string literal is not the same as the number of bytes encountered before the null character. There is no requirement that the sequence of shift states and characters representing an extended character be unique.

extended characters 215

combining characters

There are situations where the visual appearance of two or more characters is considered to be a single character. For instance, (using ISO 10646 as the example encoding), the two characters *LATIN SMALL LETTER O* (U+006F) followed by *COMBINING CIRCUMFLEX ACCENT* (U+0302) represent the grapheme cluster (the ISO 10646 term[329] for what might be considered a *user character*) **ô** not the two characters **o ^**. Some languages use grapheme clusters that require more than one combining character, for instance ô̲. Unicode (not ISO 10646) defines a canonical accent ordering to handle sequences of these combining characters. The so-called *combining characters* are defined to combine with the character that comes immediately before them in the character stream. For backwards compatibility with other character encodings, and ease of conversion, the ISO 10646 Standard provides explicit codes for some accent characters; for instance, *LATIN SMALL LETTER O WITH CIRCUMFLEX* (U+00F4) also denotes **ô**.

A character that is capable of standing alone, the **o** above, is known as a *base* character. A character that modifies a base character, the **ô** above, is known as a *combining* character (the visible form of some combining characters are called *diacritic* characters). Most character encodings do not contain any combining characters, and those that do contain them rarely specify whether they should occur before or after the modified base

character. Claims that a particular standard require the combining character to occur before the base character it modifies may be based on a misunderstanding. For instance, ISO/IEC 6937 specifies a single-byte encoding for base characters and a double-byte encoding for some visual combinations of (diacritic + base) Latin letter. These double-byte encodings are precomposed in the sense that they represent a single character; there is no single-byte encoding for the diacritic character, and the representation of the second byte happens to be the same as that of the single-byte representation of the corresponding base character (e.g., 0xC14F represents *LATIN CAPITAL LETTER O WITH GRAVE* and 0xC16F represents *LATIN SMALL LETTER O WITH GRAVE*).

C90

The C90 Standard specified implementation-defined shift states rather than locale-specific shift states.

C++

The definition of multibyte character, 1.3.8, says nothing about encoding issues (other than that more than one byte may be used). The definition of multibyte strings, 17.3.2.1.3.2, requires the multibyte characters to begin and end in the initial shift state.

Common Implementations

Most methods for state-dependent encoding are based on ISO/IEC 2022:1994 (identical to the standard ECMA-35 "Character Code Structure and Extension Techniques", freely available from their Web site, http://www.ecma.ch). This uses a different structure than that specified in ISO/IEC 10646–1. The encoding method defined by ISO 2022 supports both 7-bit and 8-bit codes. It divides these codes up into control characters (known as *C0* and *C1*) and graphics characters (known as *G0*, *G1*, *G2*, and *G3*). In the initial shift state the *C0* and *G0* characters are in effect. ISO 2022

Table 243.1: Commonly seen ISO 2022 Control Characters. The alternative values for SS2 and SS3 are only available for 8-bit codes.

Name	Acronym	Code Value	Meaning
Escape	ESC	0x1b	Escape
Shift-In	SI	0x0f	Shift to the G0 set
Shift-Out	SO	0x0e	Shift to the G1 set
Locking-Shift 2	LS2	ESC 0x6e	Shift to the G2 set
Locking-Shift 3	LS3	ESC 0x6f	Shift to the G3 set
Single-Shift 2	SS2	ESC 0x4e, or 0x8e	Next character only is in G2
Single-Shift 3	SS3	ESC 0x4f, or 0x8f	Next character only is in G3

Some of the control codes and their values are listed in Table 243.1. The codes SI, SO, LS2, and LS3 are known as *locking shifts*. They cause a change of state that lasts until the next control code is encountered. A stream that uses locking shifts is said to use *stateful encoding*.

ISO 2022 specifies an encoding method: it does not specify what the values within the range used for graphic characters represent. This role is filled by other standards, such as ISO 8859. A C implementation that supports a state-dependent encoding chooses which character sets are available in each state that it supports (the C Standard only defines the character set for the initial shift state). 24 ISO 8859

Table 243.2: An implementation where G1 is ISO 8859–1, and G2 is ISO 8891–7 (Greek).

Encoded values	0x62	0x63	0x64	0x0e	0xe6	0x1b	0x6e	0xe1	0xe2	0xe3	0x0f
Control character				SO		LS2					SI
Graphic character	a	b	c		æ			α	β	γ	

Having to rely on implicit knowledge of what character set is intended to be used for G1, G2, and so on, is not always satisfactory. A method of specifying the character sets in the sequence of bytes is needed. The

ESC control code provides this functionality by using two or more following bytes to specify the character set (ISO maintains a *registry of coded character sets*). It is possible to change between character sets without any intervening characters. Table 243.3 lists some of the commonly used Japanese character sets.

C source code written by Japanese developers probably has the highest usage of shift sequences. There are several JIS (Japanese Industrial Standard) documents specifying representations for such sequences. Shift JIS (developed by Microsoft) belies its name and does not involve shift sequences that use a state-dependent encoding.

Table 243.3: ESC codes for some of the character sets used in Japanese.

Character Set	Byte Encoding	Visible Ascii Representation
JIS C 6226–1978	1B 24 40	<ESC> $ @
JIS X 0208–1983	1B 24 42	<ESC> $ B
JIS X 0208–1990	1B 26 40 1B 24 42	<ESC> & @ <ESC> $ B
JIS X 0212–1990	1B 24 28 44	<ESC> $ (D
JIS-Roman	1B 28 4A	<ESC> (J
Ascii	1B 28 42	<ESC> (B
Half width Katakana	1B 28 49	<ESC> (I

Table 243.4: A JIS encoding of the character sequence かな漢字(“kana and kanji”).

Encoded values	0x1b	0x24	0x42	0x242b	0x244a	0x3441	0x3b7a	0x1b	0x28	0x4a
Control character	<ESC>	$	B					<ESC>	(	J
Graphic character				か	な	漢	字			
Ascii characters				$+	$J	4A	;z			

Coding Guidelines

Developers do not need to remember the numerical values for extended characters. The editor, or program development environment, used to create the source code invariably looks after the details (generating any escape sequences and the appropriate byte values for the extended character selected by the developer). How these tools decide to encode multibyte character sequences is outside the scope of these coding guidelines.

It is usually possible to express an extended character in a minimal number of bytes using a particular state-dependent encoding. The extent to which developers might create fixed-length data structures on the assumption that multibyte characters will not contain any redundant shift sequences is outside the scope of this book. The value of the MB_LEN_MAX macro places an upper limit on the number of possible redundant shift sequences.

footnote 152 2017
MB_LEN_MAX 313

Example

```
1  #include <stdio.h>
2
3  char *p1 = "^[$B$3$l$OF|K\8lI=8=^[(J";  /* ^[$BF|K\8lJ8;zNs^[(J */
4  char *p2 = "^[$B$3$l$OF|1Q^[(Jmixed^[$BJ8;zNs^[(J";     /* Ascii + ^[$BF|K\8l^[(J */
5  char *p3 = "^[$B$3$l$OH>3Q^[(J^N6@6E^O^[$B$H^[(JASCII^[$B:.9g^[(J";
6
7  int main(void)
8  {
9  printf("%s^[$B$H^[(J%s^[$B$H^[(J%s\n", p1, p2, p3);
10 }
```

While in the initial shift state, all single-byte characters retain their usual interpretation and do not alter the shift state.

Commentary

The implementation of a stateful encoding has to pick a special character, which is not in the basic character set, to indicate the start of a shift sequence. When not in the initial shift state, it is very unlikely that single bytes will be interpreted the same way as when in the initial shift state.

C++

The C++ Standard does not explicitly specify this requirement.

Common Implementations

The ESC character, 0x1b, is commonly used to indicate the start of a shift sequence.

---

245 12) The trigraph sequences enable the input of characters that are not defined in the Invariant Code Set as described in ISO/IEC 646, which is a subset of the seven-bit US ASCII code set. footnote 12

Commentary

When trigraphs are used, it is possible to write C source code that contains only those characters that are in the Invariant Code Set of ISO/IEC 646.

C90

The C90 Standard explicitly referred to the 1983 version of ISO/IEC 646 standard.

---

246 The interpretation for subsequent bytes in the sequence is a function of the current shift state.

Commentary

This wording is really a suggestion for the design of multibyte shift states (it is effectively describing the processing performed by finite state machines, which is what a shift state encoding is). Being able to interpret a byte independent of the current shift state would indicate that the sequence of bytes that resulted in the current state were redundant.

The specification of the macro `MB_LEN_MAX` requires that the maximum number of bytes needed to handle a supported multibyte character be provided. It may, or may not, be possible to represent some redundant shift sequence within the available bytes. The standard does not explicitly require or prohibit support for redundant shift sequences. [313] MB_LEN_MAX

C++

A set of virtual functions for handling state-dependent encodings, during program execution, is discussed in Clause 22, Localization library. But, this requirement is not specified.

Common Implementations

Implementations usually use a simple finite state machine, often automatically generated, to handle the mapping of shift states into their execution character value. The extent to which sequences of redundant shift sequences is supported will depend on the implementation.

Coding Guidelines

The sequence of bytes in a shift sequence are usually generated via some automated process. For this reason a guideline recommending against the use of redundant shift sequences is unlikely to be enforceable, and none is given.

---

247 — A byte with all bits zero shall be interpreted as a null character independent of shift state. byte all bits zero

Commentary

This is a requirement on the implementation. This requirement makes it possible to search for the end of a string without needing any knowledge of the encoding that has been used. For instance, string-handling functions can copy multibyte characters without interpreting their contents.

C++

2.2p3 *. . . , plus a null character (respectively, null wide character), whose representation has all zero bits.*

While the C++ Standard does not rule out the possibility of all bits zero having another interpretation in other contexts, other requirements (17.3.2.1.3.1p1 and 17.3.2.1.3.2p1) restrict these other contexts, as do existing character set encodings.

---

multibyte character end in initial shift state

— ~~A byte with all bits zero shall not occur in the second or subsequent bytes of a~~ Such a byte shall not occur as part of any other multibyte character. 248

Commentary

This is a requirement on the implementation. The effect of this requirement is that partial multibyte characters cannot be created (otherwise the behavior is undefined). A null character can only exist outside of the sequence of bytes making up a multibyte character. For source files this requirement follows from the requirement to end in the initial shift state. During program execution this requirement means that library functions processing multibyte characters do not need to concern themselves with handling partial multibyte characters at the end of a string.

token 250 shift state

The wording was changed by the response to DR #278 (it is a requirement on the implementation that forbids a two-byte character from having a first, or any, byte that is zero).

C++

This requirement can be deduced from the definition of null terminated byte strings, 17.3.2.1.3.1p1, and null terminated multibyte strings, 17.3.2.1.3.2p1.

For source files, the following shall hold: 249

Commentary

These C-sentences specify requirements on a program. A program that violates them exhibits undefined behavior.

locale-specific behavior 44

implementation-defined behavior 42

Use of multibyte characters can involve locale-specific and implementation-defined behaviors. A source file does not affect the conformance status of any program built using it, provided its use of multibyte characters either involves locale-specific behavior or the implementation-defined behavior does not affect program output (e.g., they appear in comments).

Coding Guidelines

The creation of multibyte characters within source files is usually handled by an editor. The developer involvement in the process being the selection of the appropriate character. In such an environment the developer has no control over the byte sequences used. A guideline recommending against such usage is likely to be impractical to implement and none is given.

---

token shift state

— An identifier, comment, string literal, character constant, or header name shall begin and end in the initial shift state. 250

Commentary

These are the only tokens that can meaningfully contain a multibyte character. A token containing a multibyte character should not affect the processing of subsequent tokens. Without this requirement a token that did not end in the initial shift state would be likely to affect the processing of subsequent tokens.

C90

Support for multibyte characters in identifiers is new in C99.

C++

In C++ all characters are mapped to the source character set in translation phase 1. Any shift state encoding will not exist after translation phase 1, so the C requirement is not applicable to C++ source files. 116 translation phase 1

Coding Guidelines

The fact that many multibyte sequences are created automatically, by an editor, can make it very difficult for a developer to meet this requirement. A developer is unlikely to intentionally end a preprocessing token, created using a multibyte sequence, in other than the initial state. A coding guideline is unlikely to be of benefit.

---

251 — An identifier, comment, string literal, character constant, or header name shall consist of a sequence of valid multibyte characters.

Commentary

What is a valid multibyte character? This decision can only be made by a translator, should it chose to accept multibyte characters.

In C90 it was relatively easy to lexically process a source file containing multibyte characters. The context in which these characters occurred often meant that a lexer simply had to look for the character that terminated the kind of token being processed (unless that character occurred as part of a multibyte character).

Identifier tokens do not have a single termination character. This means that it is not possible to generalise support for multibyte characters in identifiers across all translators. It is possible that source containing a multibyte character identifier supported by one translator will cause another translator to issue a diagnostic.

C90

Support for multibyte characters in identifiers is new in C99.

C++

In C++ all characters are mapped to the source character set in translation phase 1. Any shift state encoding will not exist after translation phase 1, so the C requirement is not applicable to C++ source files. 116 translation phase 1

Coding Guidelines

In some cases source files can contain multibyte characters and be translated by translators that have no knowledge of the structure of these multibyte characters. The developer is relying on the translator ignoring them in comments containing their native language, or simply copying the character sequence in a string literal into the program image. In other cases, for instance identifiers, knowledge of the encoding used for the multibyte character set is likely to be needed by a translator.

Ensuring that a translator capable of handling any multibyte characters occurring in the source is used, is a configuration-management issue that is outside the scope of these coding guidelines.

5.2.2 Character display semantics

Commentary

There is no guarantee that a character display will exist on any hosted implementation. If such a device is supported by an implementation, this clause specifies its attributes. character display semantics

C++

Clause 18 mentions "display as a wstring" in *Notes:*. But, there is no other mention of display semantics anywhere in the standard.

Common Implementations

Most Unix-based environments contain a database of terminal capabilities, the so-called *termcap* database.[1306] This database provides information to the host on a large number of terminal capabilities and characteristics. Knowing the display device currently being used (this usually relies on the user setting an environment variable) enables the database to be queried for device attribute information. This information can then be used by an application to handle its output to display devices. There is a similar database of information on printer characteristics. termcap database

The *active position* is that location on a display device where the next character output by the **fputc** function would appear. 252

Commentary

This defines the term *active position*; however, the term *current cursor position* is more commonly used by developers.

The wide character output functions act as if `fputc` is called.

C++

C++ has no concept of active position. The `fputc` function appears in "Table 94" as one of the functions supported by C++.

Other Languages

Most languages don't get involved in such low-level I/O details.

The intent of writing a printing character (as defined by the **isprint** function) to a display device is to display a graphic representation of that character at the active position and then advance the active position to the next position on the current line. 253

Commentary

The standard specifies an intent, not a requirement. Some devices produce output that cannot be erased later (e.g., printing to paper) while other devices always display the last character output at a given position (e.g., VDUs). The ability of printers to display two or more characters at the same position is sometimes required. For instance, programs wanting to display the **ô** character on a wide variety of printers might generate the sequence **o**, backspace, **^** (all of these characters are contained in the invariant subset of ISO 646).

The intended behavior describes the movement of the active position, not the width of the character displayed. There is nothing in this definition to prevent the writing of one character affecting previously written characters (which can occur in Arabic). This specification implies that the positions are a fixed width apart.

glyph 58

The graphic representation of a character is known as a *glyph*.

C++

The C++ Standard does not discuss character display semantics.

Common Implementations

In some oriental languages, character glyphs can usually be organized into two groups, one being twice the width as the other. Implementations in these environments often use a fixed width for each glyph, creating empty spaces between some glyph pairs.

Some orthographies, which use an alphabetic representation, contain single characters that use what appears to be two characters in their visual representation. For instance, the character denoted by the Unicode value U00C6 is *Æ*, and the character denoted by the Unicode value U01C9 is *lj*. Both representations are considered to be a single character (the former is also a single letter, while the latter is two letters).

Coding Guidelines

The concept of active position is useful for describing the basic set of operations supported by the C Standard. The applications' requirements for displaying characters may, or may not, be feasible within the functionality provided by the standard; this is a top-level application design issue. How characters appear on a display device is an application user interface issue that is outside the scope of this book.

writing direction
locale-specific

The direction of writing is locale-specific. 254

Commentary

Although left-to-right is used by many languages, this direction is not the only one used. Arabic uses right-to-left (also Hebrew, Urdu, and Berber). In Japanese it is possible for the direction to be from top to bottom with the lines going right-to-left (mainland Chinese has the columns going from left-to-right, in Taiwan it goes right-to-left), or left-to-right with the lines going top to bottom (the same directional conventions as English)

There is no requirement that the direction of writing always be the same direction, for instance, braille alternates in direction between adjacent lines (known as *boustrophedron*), as do Egyptian hieroglyphs, Mayan, and Hittite. Some Egyptian hieroglyphic characters can face either to the left or right (e.g.,  or ), information that readers can use to deduce the direction in which a line should be read.

Some applications need to simultaneously handle locales where the direction of writing is different, for instance, a word processor that supports the use of Hebrew and English in the same document. This level of support is outside the scope of the C Standard.

C++

The C++ Standard does not discuss character display semantics.

Coding Guidelines

The direction of writing is an application issue. Any developer who is concerned with the direction of writing will, of necessity, require a deeper involvement with this topic than the material covered by the C Standard or these coding guidelines.

Example

The direction of writing can change during program execution. For instance, in a word processor that handles both English and Arabic or Hebrew, the character sequence *ABCdefGHJ* (using lowercase to represent English and uppercase to represent Arabic/Hebrew) might appear on the display as **JHGdefCBA**.

---

255 If the active position is at the final position of a line (if there is one), the behavior of the display device is unspecified.

Commentary

The Committee recognized that there is no commonality of behavior exhibited by existing display devices when the final position on a line is reached.

C++

The C++ Standard does not discuss character display semantics.

Common Implementations

Some display devices wrap onto the next line, effectively generating an extra new-line character. Other devices write all subsequent characters, up to the next new-line character, at the final position. On some displays, writing to the bottom right corner of a display has an effect other than displaying the character output, for instance, clearing the screen or causing it to scroll. The `termcap` and `ncurses` both provide configuration options that specify whether writing to this display location has the desired effect.

Coding Guidelines

Organizing the characters on a display device is an application domain issue. The fact that the C Standard does not provide a defined method of handling the situation described here needs to be dealt with, if applicable, during the design process. This is outside the scope of these coding guidelines.

---

256 Alphabetic escape sequences representing nongraphic characters in the execution character set are intended to produce actions on display devices as follows:

Commentary

This is the behavior of Ascii terminals enshrined in the C Standard.

Rationale To avoid the issue of whether an implementation conforms if it cannot properly effect vertical tabs (for instance), the Standard emphasizes that the semantics merely describe *intent*.

These escape sequences can also be output to files. The data values written to a file may depend on whether the stream was opened in text or binary mode.

C++

The C++ Standard does not discuss character display semantics.

Other Languages

Java provides a similar set of functionality to that described here.

Common Implementations

Most display devices are capable of handling most of the functions described here.

Coding Guidelines

A program cannot assume that any of the functionality described will occur when the escape sequence is sent to a display device. The root cause for the variability in support for the intended behaviors is the variability of the display devices. In most cases an implementation's action is to send the binary representation of the escape sequence to the device. The manufacturers of display devices are aware of their customers expectations of behavior when these kinds of values are received.

There is little that coding guidelines can recommend to help reduce the dependency on display devices. The design guidelines of creating individual functions to perform specific operations on display devices and isolating variable implementation behaviors in one place are outside the scope of these coding guidelines.

\a (*alert*) Produces an audible or visible alert without changing the active position. 257

Commentary

The intent of an alert is to draw attention to some important event, such as a warning message that the host is to be shut down, or that some unexpected situation has occurred. A program running as a background process (a concept that is not defined by the C Standard) may not have a display device attached (does a tree falling in a forest with nobody to hear it make a noise?).

C++

Alert appears in Table 5, 2.13.2p3. There is no other description of this escape sequence, although the C behavior might be implied from the following wording:

17.4.1.2p3 *The facilities of the Standard C Library are provided in 18 additional headers, as shown in Table 12:*

Common Implementations

Most implementations provide an audible alert. On display devices that don't have a mechanism for producing a sound, a visible alert might be to temporarily blank the screen or to temporarily increase the brightness of the screen.

Coding Guidelines

Programs that produce too many alerts run the risk of having them ignored. The human factor involved in producing alerts are outside of the scope of these coding guidelines. Issues such as a display device not being able to produce an audible alert because its speaker is broken, is also outside the scope of these coding guidelines.

---

backspace escape sequence

\b (*backspace*) Moves the active position to the previous position on the current line. 258

Commentary

The standard specifies that the active position is moved. It says nothing about what might happen to any character displayed prior to the backspace at the new current active position.

Common Implementations

Some devices erase any character displayed at the previous position.

C++

Backspace appears in Table 5, 2.13.2p3. There is no other description of this escape sequence, although the C behavior might be implied from the following wording:

The facilities of the Standard C Library are provided in 18 additional headers, as shown in Table 12: 17.4.1.2p3

Example

```
1  #include <stdio.h>
2
3  int main(void)
4  {
5  printf("h\bHello \b World\n");
6  }
```

---

259 If the active position is at the initial position of a line, the behavior of the display device is unspecified.

Commentary

Some terminals have input locking states. In such cases an unspecified behavior put the display device into a state where it no longer displays characters written to it.

C90

If the active position is at the initial position of a line, the behavior is unspecified.

This wording differs from C99 in that it renders the behavior of the program as unspecified. The program simply writes the character; how the device handles the character is beyond its control.

C++

The C++ Standard does not discuss character display semantics.

Common Implementations

The most common implementation behavior is to ignore the request leaving the active position unchanged. Some VDUs have the ability to wrap back to the final position on the preceding line.

Coding Guidelines

While it may be technically correct to specify that the behavior of the display device as unspecified, it does indirectly affect the output behavior of a program in that subsequent output may not appear on that display device.

---

260 `\f` (*form feed*) Moves the active position to the initial position at the start of the next logical page.

Commentary

Whatever a page, logical or otherwise, is. This concept is primarily applied to printers. The functionality to move to the start of the next page, from anywhere on the current page, is generally provided by printer vendors. Programs might use this functionality since it frees them from needing to know the number of lines on a page (provided the minimum needed to support the generated output is available).

page
logical

C++

Form feed appears in Table 5, 2.13.2p3. There is no other description of this escape sequence, although the C behavior might be implied from the following wording:

17.4.1.2p3 *The facilities of the Standard C Library are provided in 18 additional headers, as shown in Table 12:*

Coding Guidelines

Use of this escape sequence could remove the need for a program to be aware of the number of lines on the page of the display device being written. However, it does place a dependency on the characteristics of the display device being known to the host executing the program, or on the device itself, to respond to the data sent to it.

termcap database

---

new-line escape sequence

\n (*new line*) Moves the active position to the initial position of the next line. 261

Commentary

What happens to the preceding lines is not specified. For instance, whether the display device scrolls lines or wraps back to the top of any screen. The standard is silent on the issue of display devices that only support one line. For instance, do the contents of the previous line disappear?

C++

New line appears in Table 5, 2.13.2p3. There is no other description of this escape sequence, although the C behavior might be implied from the following wording:

17.4.1.2p3 *The facilities of the Standard C Library are provided in 18 additional headers, as shown in Table 12:*

Other Languages

Some languages provide a library function that produces the same effect.

Common Implementations

On some hosts the new-line character causes more than one character to be sent to the display device (e.g., carriage return, line feed).

A printing device may simply move the media being printed on. A VDU may display characters on some previous line (wrapping to the start of the screen). On some display devices (usually memory-mapped ones), the start of a new line is usually indicated by an end-of-line character appearing at the end of the previous line. On other display devices, a fixed amount of storage is allocated for the characters that may occur on each line. In this case the end of line is not stored as a character in the display device.

end-of-line representation 224

Coding Guidelines

Issues, such as handling lines that are lost when a new line is written or display devices that contain a single line, are outside the scope of these coding guidelines.

---

carriage return escape sequence

\r (*carriage return*) Moves the active position to the initial position of the current line. 262

Commentary

The behavior might be viewed as having the same effect as writing the appropriate number of backspace characters. However, the effect of writing a backspace character might be to erase the previous character, while a carriage return does not cause the contents of a line to be erased. Like backspace, the standard says nothing about the effect of writing characters at the position on a line that has previously been written to.

backspace escape sequence 258

C++

Carriage return appears in Table 5, 2.13.2p3. There is no other description of this escape sequence, although the C behavior might be implied from the following wording:

The facilities of the Standard C Library are provided in 18 additional headers, as shown in Table 12: 17.4.1.2p3

---

263 `\t` (*horizontal tab*) Moves the active position to the next horizontal tabulation position on the current line. horizontal tab escape sequence

Commentary

Horizontal tabulation positions are provided by vendors of display devices as a convenient method of aligning data, on different lines, into columns. In some cases they can remove the need for a program to count the number of characters that have been written. The C Standard does not provide a method for controlling the location of horizontal tabulation positions. Neither does a program have any method of finding out which positions they occupy.

C++

Horizontal tab appears in Table 5, 2.13.2p3. There is no other description of this escape sequence, although the C behavior might be implied from the following wording:

The facilities of the Standard C Library are provided in 18 additional headers, as shown in Table 12: 17.4.1.2p3

Common Implementations

The location of tabulation positions on a line are usually controlled by the display device. There may be a limited number that can be configured on a line. Configuring a horizontal tab position every eight active positions from the start of the line is a common default. Many hosts allow the default setting to be changed, and some users actively make use of this configuration option.

Coding Guidelines

A commonly seen application problem is the assumption, by the developer, of where the horizontal tabulation positions occur on a display device. However, the handling display devices are outside the scope of these coding guidelines.

---

264 If the active position is at or past the last defined horizontal tabulation position, the behavior of the display device is unspecified.

Commentary

The standard does not specify how many horizontal tabulation positions must be supported by an implementation, if any.

C90

If the active position is at or past the last defined horizontal tabulation position, the behavior is unspecified.

Common Implementations

Some implementations do not move the active position when the last defined horizontal tabulation position has been reached; others treat writing such a character as being equivalent to writing a single white-space character at this position. In some cases the behavior is to move the active position to the first horizontal tabulation position on the next line.

vertical tab escape sequence

\v (*vertical tab*) Moves the active position to the initial position of the next vertical tabulation position. 265

Commentary

Although the standard recognizes that the direction of writing is locale-specific, it says nothing about the order in which lines are organized. The vertical tab (and new line) escape sequence move the active position in the same line direction. There is no escape sequence for moving the active position in the opposite direction, similar to backspace for movement within a line.

page 260 logical

The concept of vertical tabulation implicitly invokes the concept of *current page*. This concept is primarily applied to printers, while the dimensions of a page might be less variable than a terminal. Before laser printers were invented, it was very important to ensure that output occurred in a controlled, top-down fashion.

C++

Vertical tab appears in Table 5, 2.13.2p3. There is no other description of this escape sequence, although the C behavior might be implied from the following wording:

17.4.1.2p3 *The facilities of the Standard C Library are provided in 18 additional headers, as shown in Table 12:*

Common Implementations

In most implementations a vertical tab moves the active position to the next line, with the relative position within the line staying the same.

If the active position is at or past the last defined vertical tabulation position, the behavior of the display device is unspecified. 266

Commentary

The intended behavior is likely to vary between terminals and printers.

C90

If the active position is at or past the last defined vertical tabulation position, the behavior is unspecified.

Common Implementations

Many display devices do not define vertical tabulation positions; this escape sequence simply causes the active position to move to the next line. The behavior is the same as when a new line escape sequence is written at the end of a page, or screen.

---

escape sequence fit in char object

Each of these escape sequences shall produce a unique implementation-defined value which can be stored in a single **char** object. 267

Commentary

basic execution character set 221
basic character set fit in a byte 222

These escape sequences are defined to be members of the basic execution character set and also to fit in a byte.

The mapping to this implementation-defined value occurs at translation time. The execution time value actually received by the display device is outside the scope of the standard. The library function `fputc` could map the value represented by these single **char** object into any sequence of bytes necessary.

C++

This requirement can be deduced from 2.2p3.

Other Languages

Java explicitly defines the values of the escape sequences it specifies.

Common Implementations

The specified escape sequences are available in the Ascii character set (and thus also in ISO 10646). 28 ISO 10646

268 The external representations in a text file need not be identical to the internal representations, and are outside the scope of this International Standard.

Commentary

The Committee recognizes that host file systems may use a representation for text files that is different from that used for binary files. The output functions will know the mode with which a stream was opened and can process the bytes written appropriately. There is a guarantee for binary files, which does not hold for text files, that the bytes written out shall compare equal to the same bytes read back in again.

C++

The C++ Standard does not get involved in such details.

Common Implementations

The external representation of a text file is usually the same as that used to hold a C source file. The representation of the new line escape sequence is usually the same as that for end-of-line, which is not always a single character. 224 end-of-line representation

From an executing program's point of view, on hosts that support output redirection, there may be no distinction made between a display device and a text file. However, the driver for a display device may respond differently for some characters.

269 **Forward references:** the **isprint** function (7.4.1.8), the **fputc** function (7.19.7.3).

5.2.3 Signals and interrupts

270 **Commentary**

signal

Signals are difficult to specify in a system-independent way. The C89 Committee concluded that about the only thing a strictly conforming program can do in a signal handler is to assign a value to a volatile static variable which can be written uninterruptedly and promptly return. Rationale

. . .

A second signal for the same handler could occur before the first is processed, and the Standard makes no guarantees as to what happens to the second signal.

A pole exception is the same as a divide-by-zero exception: a finite non-zero floating-point number divided by a zero floating-point number. WG14/N748

Currently, various standards define the following exceptions for the indicated sample floating-point operations. For LIA–2, there are other operations that produce the same exceptions.

LIA	<---------- Standard ---------->			IEEE
Exception	LIA-1	LIA-2	IEEE-754/IEC-559	Exception
undefined	0.0 / 0.0	sqrt(-1.0)	0.0 / 0.0	invalid
	1.0 / 0.0	log(-1.0)	infinity / infinity	
			infinity - infinity	
			0.0 * infinity	

			sqrt(-1.0)	
pole	(not yet)	log(0.0)	1.0 / 0.0	division by zero
floating_ overflow	max * max	exp(max)	max * max	overflow
	max / min		max / min	
	max + max		max + max	
underflow	min * min	exp(-max)	min * min	underflow
	min / max		min / max	

In the above table, 1.0/0.0 is a shorthand notation for any non-zero finite floating-point number divided by a zero floating-point number; max is the maximum floating-point number (FLT_MAX, DBL_MAX, LDBL_MAX); min is the minimum floating-point number (FLT_MIN, DBL_MIN, LDBL_MIN); log() and exp() are mathematical library routines.

We believe that LIA–1 should be revised to match LIA-2, IEC-559 and IEEE-754 in that 1.0/0.0 should be a pole exception and 0.0/0.0 should be an undefined exception.

C++

The C++ Standard specifies, Clause 15 Exception handling, a much richer set of functionality for dealing with exceptional behaviors. While it does not go into the details contained in this C subclause, they are likely, of necessity, to be followed by a C++ implementation.

Other Languages

Some languages (e.g., Ada, Java, and PL/1) define statements that can be used to control how exceptions and signals are to be handled. After over 30 years floating point exception handling has finally been specified in the Fortran Standard.[651] A few languages include functionality for handling signals and interrupts, but most ignore these issues.

Common Implementations

Implementations are completely at the mercy of what signals are supported by the host environment and what interrupts are generated by the processor. Gould (Encore) PowerNode treated both floating-point and integer overflow as being the same.

Coding Guidelines

This subclause lists those minimum characteristics of a program image needed to support signals and interrupts. Such support by the implementations is only half of the story. A program that makes use of signals has to organize its behavior appropriately. Techniques for writing programs to handle signals, or even ensuring that they are thread-safe are outside the scope of these coding guidelines.

Functions shall be implemented such that they may be interrupted at any time by a signal, or may be called by a signal handler, or both, with no alteration to earlier, but still active, invocations' control flow (after the interruption), function return values, or objects with automatic storage duration. 271

Commentary

This is a requirement on the implementation. An implementation may provide a mechanism for the developer to switch off interrupts within time-critical functions. Although such usage is an extension to the standard, it cannot be detected in a strictly conforming program.

How could an implementation's conformance to this requirement be measured? A program running under an implementation that supports some form of external interrupt, for instance SIGINT, might be executed a large number of times, the signal handler recording where the program was interrupted (this would require functionality not defined in the standard). Given sufficient measurements, a statistical argument could be used to show that an implementation did not support this requirement. A nonprogrammatic approach would be to verify the requirement by understanding how the generated machine code interacted with the host processor and the characteristics of that processor.

This wording is not as restrictive on the implementation as it first looks. The only signal that an implementation is required to support is the one caused by a call to the `raise` function. Requiring that any developer-written functions be callable from a signal handler restricts the calling conventions that may be used in such a handler to be compatible with the general conventions used by an implementation. This simplifies the implementation, but places a burden on time-critical applications where the calling overhead may be excessive.

C++

This implementation requirement is not specified in the C++ Standard (1.9p9).

Other Languages

Most languages don't explicitly say anything about the interruptibility of a function.

Common Implementations

Few if any host processors allow execution of instructions to be interrupted. The boundary at the completion of one instruction and starting another is where interrupts are usually responded to. In the case of pipelined processors, there are two commonly seen behaviors. Some processors wait until the instructions currently in the pipeline have completed execution, while others flush the instructions currently in the pipeline. An example of an instruction that causes an interrupt to be raised after it has only partially completed is one that accesses storage, if the access causes a page fault (causing the instruction to be suspended while the accessed page is swapped into storage). Another case is performing an access to storage using a misaligned address, or an invalid address. In these cases the instruction may never successfully complete.

External, nonprocessor-based interrupts are usually only processed once execution of the current instruction is complete. Some processors have instructions that can take a relatively long time to execute, for instance, instructions that copy large numbers of bytes between two blocks of memory. Depending on the design requirements on interrupt latency, some processors allow these instructions to be interrupted, while others do not.

Some implementations[1340] require that functions called by a signal handler preserve information about the state of the execution environment, such as register contents. Developers are required to specify (often by using a keyword in the declaration, such as **`interrupt`**) which functions must save (and restore on return) this information.

---

272 All such objects shall be maintained outside the *function image* (the instructions that compose the executable representation of a function) on a per-invocation basis.

object storage outside function image

Commentary

This is a requirement on the implementation (although the as-if rule might be invoked). The model being described is effectively a stack-based approach to the calling of functions and the handling of storage for objects they define (the actual storage allocation could use a real stack or simulate one using allocated storage).

Storing objects in the function image, or simply having a preallocated area of storage for them, would prevent a function from being called recursively (having more than one call to a function in the process of being executed at the same time is a recursive invocation, however the invocation occurred). An implementation is required to support recursive function calls. This requirement prevents implementations using a technique that was once commonly used (primarily by implementations of other languages), but can have different execution time semantics when recursive calls are made.

1026 function call recursive

C++

The C++ Standard does not contain this requirement.

Other Languages

Most languages require support for recursive function calls, implying this requirement.

1026 function call recursive

Common Implementations

Modern processors try to separate code (function image) and data (object definitions). Accesses to the two have different characteristics, which affects the design of caches for them (often implemented as two separate cache areas on the chip). Independently of processor support, the host environment (operating system) may mark certain areas of storage as having execute-only permission. Attempts to read or write to such storage, from an executing program, often leads to a signal being raised.

Applications targeted at a freestanding environment rarely involve recursive function calls. Storage may also be at a premium and hardware stack support limited (the Intel 8051[625] is limited to a 128-byte stack). Some hosts allocate fixed areas, in static storage, for objects local to functions. A call tree, built at link-time, can be used to work out which storage areas can be shared by overlaying those objects whose lifetimes do not overlap, reducing the fixed execution time memory overhead associated with such a design.

Many processors have span-dependent load and store instructions. That is, a short-form (measured in number of bytes) that can only load (or store) from/to storage locations whose address has a small offset relative to a base address, while a long-form supports larger offsets. When storage usage needs to be minimized, it may be possible to use a short-form instruction to access storage locations in the function image. The usual technique used is to reserve storage for objects after an unconditional branch instruction, which is accessed by the instructions close (within the range supported by the short-form instruction) to those locations.[1174]

Coding Guidelines

While implementations might be required to allocate objects outside of a function image, developers have been known to write code to store values in a program image. In those few cases where values are stored in this way, the developers involved are very aware of what they are doing. A guideline recommendation serves no purpose.

Example

The following is one possible method that might be used to store data in a program image.

```
#include <stdio.h>

extern int always_zero = 0;
static int *code_ptr;

void f(void)
{
/*
 * No static object declarations in this function ;-)
 */
if (always_zero == 1) /* create some dead code */
   {
   /*
    * Pad out with enough code to create storage for an int.
    * A smart optimizer is the last thing we need here.
    */
   always_zero++;
   always_zero++;
   }

(*code_ptr)++;
printf("This function has been called %d times.\n", *code_ptr);
}

void init(void)
{
/*
 * The value 16 is the offset of the dead code from the start of the
 * function.  Change to suit your local instruction sizes (this works
```

```
 * for gcc on an Intel x86).  We also need to make sure that the
 * pointer to int is correctly aligned.  A reliable guess is that
 * the alignment is a multiple of the object size.
 */
code_ptr=(int *)((((int)(char *)f) + 16) & ~(sizeof(int)-1));
*code_ptr=0;
}

int main(void)
{
init();
for (int index=0; index < 10; index++)
   f();
}
```

5.2.4 Environmental limits

273 Both the translation and execution environments constrain the implementation of language translators and libraries.

environmental limits

Commentary

In the past the available storage capacity of the translation environment has been an implementation design consideration for translator vendors. Translating programs containing large numbers of some constructs sometimes exceeded the available host capacity. This is rarely the case today.

In some environments, particularly freestanding ones, there can be severe constraints on the execution environment.

C++

There is an informative annex which states:

> *Because computers are finite, C++ implementations are inevitably limited in the size of the programs they can successfully process.*

Annex Bp1

Common Implementations

While it might be theoretically possible to create a translator that is not affected by its own environment, the cost is likely to outweigh the benefits.

Coding Guidelines

Some limits, imposed by the translation environment, are best dealt with as they are encountered. The cost of structuring a program to deal with all lowest common denominators is rarely recouped in future savings (in reduced porting costs). Programs are often targeted at a particular class of environments (e.g., workstations or hand-held devices). Execution time constraints can have a large impact and may affect the choice of algorithms as well as how the source is structured. Both of these issues are dealt with, by these coding guidelines, as they are encountered in the C Standard wording.

274 The following summarizes the language-related environmental limits on a conforming implementation;

Commentary

The intent is that these are base limits and commercial pressure will encourage vendors to create implementations that improve on them. By specifying such limits the Committee is providing a guide as to what can be expected, by a developer, of an implementation.

C++

There is an informative annex which states:

Annex Bp2 *The bracketed number following each quantity is recommended as the minimum for that quantity. However, these quantities are only guidelines and do not determine conformance.*

Other Languages

Most language standards are silent on the subject of environmental limits and provide no guide on the number of constructs that a translator might be expected to handle. The Modula-2 Standard specifies minimum translator limits for many of the language constructs covered by the C Standard (Pronk[1127] tests the minimum values supported by a number of translators).

Common Implementations

Most translators allocate space for the symbol table and other information, dynamically as the source code is processed. This choice of implementation technique does not remove the limit on the total amount of memory available to a translator, but it does provide flexibility. There are a few cases where limits may be imposed because an implementation has chosen to use fixed-size data structures.

macro replacement

One limit not mentioned in the standard is the maximum number of characters in a macro, during expansion. Several implementations have limits in this area, sometimes as low as 256. The limit for macro definitions is covered by the logical line length.

limit characters on line 292

Coding Guidelines

Exceeding any defined minimum limits is a calculated risk. Some of the limits may be hard to design around; for instance, the number of identifiers with external linkage. What is the cost, both in developer effort and loss of design integrity, of adapting a program to fit within these limits? What is the likelihood of encountering a translator that cannot process a source file that exceeds some limit? Is it worth paying the cost to be certain of having source that is translatable by such translators? While the environments where translators are resource-limited are becoming rare, many translators continue to contain some of their own, internal, fixed limits.

A translator may have other limits that are not described in the C Standard. These will have to be dealt with, by developers, as they are encountered.

---

the library-related limits are discussed in clause 7. 275

C++

Clause 18.2 contains an *Implementation Limits:*.

5.2.4.1 Translation limits

---

translation limits

The implementation shall be able to translate and execute at least one program that contains at least one instance of every one of the following limits:[13)] 276

Commentary

This is a requirement on the implementation (a single preprocessing translation unit containing all of the constructs given here, to the limits specified). The topic of a perverse implementation, one that can successfully translate a single program containing all of these limits but no other program, crops up from time to time. Although of theoretical interest, this discussion is of little practical interest, because writing a translator that only handled a single program would probably require more effort than writing one that handled programs in general.

The values for these limits were not obtained by measuring how often each construct appeared within existing source code. There is no claim that a program containing an instance of all such constructs is in any way representative of a typical program.

Some of the limits chosen represent interesting compromises. The goal was to allow reasonably large portable programs to be written, without placing excessive burdens on reasonably small implementations, some of which might run on machines with only 64 K of memory. In C99, the minimum amount of memory for the target machine was raised to 512 K. In addition, the Committee recognized that smaller machines rarely serve as a host for a C compiler: programs for embedded systems or small machines are almost always developed using a cross compiler running on a personal computer or workstation. This allows for a great increase in some of the translation limits.

A program containing an instance of all such limits is one of the tests included in the commercially available C validation suites that used to be used by NIST and BSI.

C++

However, these quantities are only guidelines and do not determine conformance. Annex Bp2

This wording appears in an informative annex, which itself has no formal status.

Other Languages

Many language definitions specify some minimum value for some constructs that implementations are required to support. The Modula-2 Standard contains what it called *limit-specification generators*. These are a set of Modula-2 programs, which when executed generate a set of Modula-2 programs that an implementation must be capable of translating and executing.

Common Implementations

Some implementations provide a translator option that allows the developer to control the amount of storage allocated to various internal data structures; for instance, the option `-xs1234` might specify a symbol table capable of holding 1,234 symbols. For large programs it can take several attempts before the various options are tuned (enabling the source to be translated within the available storage). Such implementation options may still be provided today, as part of a backwards compatibility mode.

Coding Guidelines

Most of the limit values are sufficiently generous that few of them are likely to be exceeded. But within these coding guidelines, we are not just interested in translator limitations, we are also interested in developer limitations. There may be readability, comprehensibility, or complexity issues associated with multiple occurrences of some constructs. A program that contains an excessive number of any particular construct could be poorly structured or simply a large program.

In the case of nested constructs, it is often claimed that developers have problems remembering the information if the nesting is too deep. The fact that developers experience problems remembering information on nested constructs suggests they are using short-term memory to hold this information. The capacity limits of short-term memory are only one of the issues involved in comprehending nested constructs. How developers organize information presented to them (from the source code), knowledge held in their long-term memories (about how a program works or memories of previous code readings), and the extent to which information from different nesting levels is related all need to be considered.

0 memory developer

1821 coupling and cohesion

It is also important to consider the bigger picture of particular nested constructs. Are the alternatives any better? Some coding guideline documents specify a value for the maximum nesting level of particular constructs[941,942] (sometimes giving a rationale based on the famous 7±2 paper). These coding guidelines resist the attractions of providing a single, easy-to-calculate, maximum nesting limit. The issues are discussed in more detail within each nested construct.

0 Miller 7±2

277— 127 nesting levels of blocks

limit block nesting

Commentary

block 1710 compound 1729 statement syntax

Blocks are created by a number of different kinds of statements. The one most commonly thought of is a compound statement. There is no dependency on the kinds of statement that cause a block to be created. There could be any combination of **`if`**/**`while`**/**`for`**/**`switch`** or simply a compound statement with no associated header.

This limit might be reached in automatically generated code, but it would be considered an extreme case.

C90

15 nesting levels of compound statements, iteration control structures, and selection control structures

block 1741 selection statement block 1742 selection sub-statement block 1768 iteration statement block 1769 loop body

The number of constructs that could create a block increased between C90 and C99, including selection statements and their associated substatements, and iteration statements and their associated bodies. Although use of these constructs doubles the number of blocks created in C99, the limit on the nesting of blocks has increased by a factor of four. So, the conformance status of a program will not be adversely affected.

C++

The following is a non-normative specification.

Annex Bp2 *Nesting levels of compound statements, iteration control structures, and selection control structures [256]*

Common Implementations

Nesting of blocks is part of the language syntax and is usually implemented with a table-driven syntax analyzer. Table-driven syntax analyzers maintain their own stack, often a predefined fixed size, of information. A very large number of nested blocks is likely to cause this parser table to overflow.

Coding Guidelines

In human-written code a significantly lower limit on the nesting of blocks is often recommended. Working purely on the basis of some form of line indentation, for every new block opened, more than five nested levels would lead to a visually difficult to follow, on a display device, source file. Blocks opened and closed within a macro definition would not affect the visual appearance of source, at the point of macro invocation. This kind of nesting would not be counted in the five recommendation.

— 63 nesting levels of conditional inclusion 278

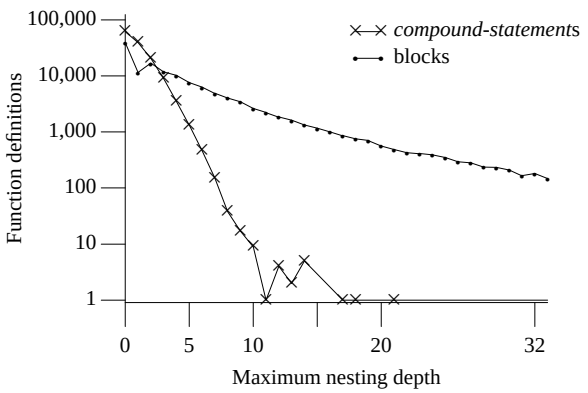

Figure 277.1: Number of functions containing blocks and *`compound-statement`*s nested to the given maximum nesting level. Based on the visible form of the `.c` files.

Commentary

Conditional inclusion is performed as part of preprocessing. As such, it is independent of the syntax processing performed by subsequent translation phases and is given its own limit. conditional inclusion

The value of this limit is consistent with other limit values. It is something of a fortunate coincidence, because the same ratios applied in C90, where the following rationale did not apply. The value is half the limit value for nesting of blocks. This difference occurs because the C **if** statement is defined to create two blocks. Nesting **if** statements 64 deep would be sufficient to exceed the block limit, and 64 nested **#if** directives would exceed the above limit. 277 limit block nesting 1741 block selection statement

C90

8 nesting levels of conditional inclusion

C++

The following is a non-normative specification.

Nesting levels of conditional inclusion [256] Annex Bp2

Common Implementations

Several different techniques are used to write preprocessors. Given the relatively simple C preprocessor syntax, many have a *flat* view of the nesting of these constructs. They simply maintain a count of the current nesting level. A full parser/syntax-based approach faces the same type of problems found in handling the C syntax limits discussed here. But, such an approach is rarely seen in C preprocessor implementations.

This limit may be reached in automatically generated code.

Coding Guidelines

Conditional inclusion differs from selection statements in that it is not possible to prevent deep nesting by moving directives to separate functions (although they could be moved to a separate source file and accessed via a **#include** directive, or the design of the configuration control implied by the nested directives could be changed). 1739 selection statement syntax

The human factors issues might be thought to be the same as those for the nesting of selection statements. However, developers generally do not visually indent nested conditional inclusion directives (see Figure 1854.1) a practice that is commonly used for selection (and other) statements.

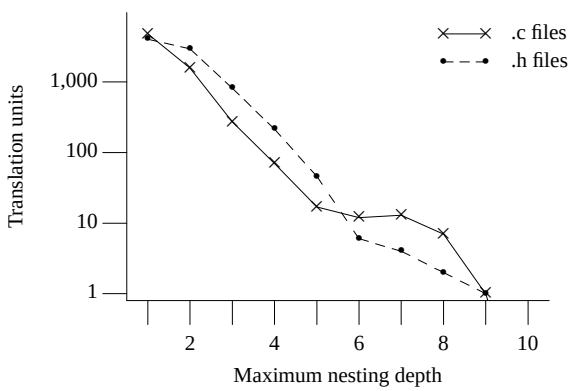

Figure 278.1: Number of translation units containing conditional inclusion directives nested to the given maximum nesting level. Based on the visible form of the `.c` and `.h` files.

limit type complexity

— 12 pointer, array, and function declarators (in any combinations) modifying an arithmetic, structure, union, or incomplete type in a declaration 279

Commentary

This limit is based on a particular encoding of type information within 32 bits, which was used in some early translators. Eight bits were used to encode the base type and up to 12 lots of 2 bits representing pointer-to, array-of, or function-of. Another consideration was that Fortran originally supported a maximum of seven subscripts in an array declaration. The committee recognized that Fortran to C translations needed to be able to support this number of nested array declarations.

limit 279 type complexity

Wording that appears elsewhere specifies that types defined via typedef names need to be included in the count.

C++

The following is a non-normative specification.

Annex Bp2

Pointer, array, and function declarators (in any combinations) modifying an arithmetic, structure, union, or incomplete type in a declaration [256]

Common Implementations

Some implementations continue to use the K&R technique. Many others use a dynamic data structure relevant to the type being defined and have no internal limits on the complexity supported.

Coding Guidelines

Data structures need to mimic the application domain being addressed. If a deep nesting of pointers, arrays, or function declarators is called for, there may be little benefit in arbitrarily splitting the declaration into smaller components, unless these subcomponents have semantic meaning within the application domain.

Example

```
1  char ************p_12;
2  short a_12[1][1][1][1][1][1][1][1][1][1][12];
3  void (* (* (* (* (* (* (* (* (* (* (*p)
4     (void))(void))(void))(void))(void))(void))(void))(void))(void))(void))(void);
```

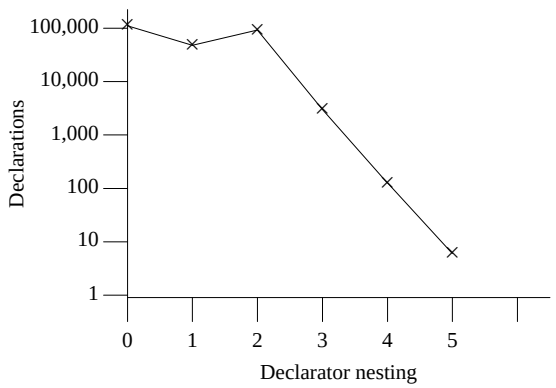

Figure 279.1: Number of full declarators containing a given number of modifiers. Based on the translated form of this book's benchmark programs.

280 — 63 nesting levels of parenthesized declarators within a full declarator

limit declarator parentheses

Commentary

The limit of 12 modifiers on a declaration is likely to be reached before this limit of 63 is reached on a full declarator (unless redundant ( ) are used, or some very rarely seen structure declarations). This limit is unlikely to be reached, even in automatically generated code. 1549 full declarator

```
1  struct {
2          (struct {
3                  (struct {
4                          ...
5                  } *p)[2];
6          } *q)[1];
7  };
```

C90

31 nesting levels of parenthesized declarators within a full declarator

C++

The C++ Standard does not discuss declarator parentheses nesting limits.

Common Implementations

Nesting of parentheses is part of the language syntax and is usually implemented with a table-driven syntax analyzer. The same implementation details as nesting of blocks applies. The nesting of parentheses can occur within a nested block, slightly increasing the chances of reaching an internal implementation limit. 277 limit block nesting

281 — 63 nesting levels of parenthesized expressions within a full expression

parenthesized expression nesting levels

Commentary

While it is possible to keep within this limit in an expression containing one instance of every operator (C contains 47 unique operators), an expression containing more than one instance of two operators may need to exceed this limit— for instance, `(((((a0/x+a1)/x+a2)/x+a3)/x+a4)/x+a5)/x+...`.

This limit is rarely reached except in automatically generated code. Even then it is rare.

C90

31 nesting levels of parenthesized expressions within a full expression

C++

The following is a non-normative specification.

Nesting levels of parenthesized expressions within a full expression [256] Annex Bp2

Common Implementations

The same implementation details as nesting of declarators applies, with the difference that nesting of expressions is more common and likely to be deeper. 280 limit declarator parentheses

Coding Guidelines

memory 0 chunking

Although some uses of parentheses may be technically redundant, they may be used to simplify the visual appearance of an expression, or to divide an expression into meaningful chunks. While minimizing the number of parentheses in an expression may be an interesting mathematical problem, minimization is not a desirable goal when writing source code. The top priority when considering the use of parentheses should always be comprehensibility of the resulting expression.

```
1  (((((a0 * x + a1) * x + a2) * x + a3) * x + a4) * x + a5) * x + a6
2
3  a * (b + (c << (d > (e == (f & (g ^ (h | (i && (j || (k_1 ? k_2 : (L = (m , n ))))))))))));
```

expressions 940 The issue of expression complexity is discussed elsewhere.

---

internal identifier significant characters

— 63 significant initial characters in an internal identifier or a macro name (each universal character name or extended source character is considered a single character) 282

Commentary

An internal identifier is one whose name is never visible outside of the source file in which it is declared. Because it is not necessary to worry about external representation issues, it is possible to count one UCN as one character.

significant 2036 characters future language directions

This limit may be reached in automatically generated code.

This minimum limit may be increased in a future revision of the standard.

C90

31 significant initial characters in an internal identifier or a macro name

C++

2.10p1 *All characters are significant.*[20)]

C identifiers that differ after the last significant character will cause a diagnostic to be generated by a C++ translator.

The following is a non-normative specification.

Annex Bp2

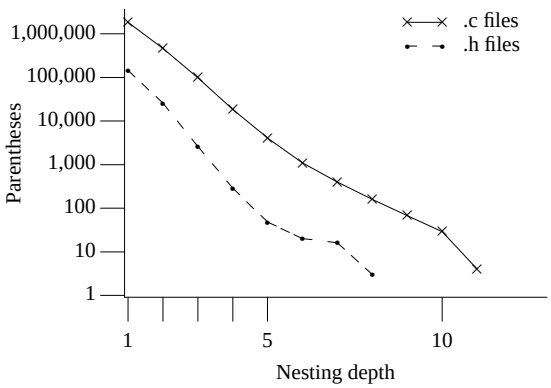

Figure 281.1: Nesting of all occurrences of parentheses. Based on the visible form of the `.c` and `.h` files.

Number of initial characters in an internal identifier or a macro name [1024]

Other Languages

Some languages are silent on the number of significant characters in an internal identifier; others specify the same limit as external identifiers.

Common Implementations

This is one area where translators are likely to use a fixed-size data structure (usually an array). Using a linked list of characters to represent an identifier name would be a significant overhead. Having a fixed-size data structure that grows once the available free space is filled is an alternative used by some implementations.

Coding Guidelines

The issue of identifier length is discussed elsewhere.

792 identifier number of characters

Usage

Very few identifiers approach the C99 translation limit (see Figure 792.7).

---

283 — 31 significant initial characters in an external identifier (each universal character name specifying a short identifier of 0000FFFF or less is considered 6 characters, each universal character name specifying a short identifier of 00010000 or more is considered 10 characters, and each extended source character is considered the same number of characters as the corresponding universal character name, if any)[14)]

external identifier significant characters

Commentary

Information on externally visible identifiers needs to be stored in the files (usually object files) created by a translator. This information is compared against identifiers declared in other translation units when linking to build a program image. The predefined format of such files (not always within the control of the translator writer) may have limitations on what characters are acceptable in an identifier.

141 program image

The values of 6 and 10 were chosen so that the encodings *\u1234* and *\U12345678* could be used.

C90

6 significant initial characters in an external identifier

C++

All characters are significant.[20)]

2.10p1

C identifiers that differ after the last significant character will cause a diagnostic to be generated by a C++ translator.

The following is a non-Normative specification.

Number of initial characters in an external identifier [1024]

Annex Bp2

Other Languages

The Fortran significant character limit of six was followed by many suppliers of linkers for a long time. The need for longer identifiers to support name mangling in C++ ensured that most modern linkers support many more significant characters in an external identifier.

Common Implementations

Historically, the number of significant characters in an external identifier was driven by the behavior of the host vendor-supplied linker. Only since the success of MS-DOS have developers become used to translator vendors supplying their own linker. Previously, most linkers tended to be supplied by the hardware vendor.

The mainframe world tended to be driven by the requirements of Fortran, which had six significant characters in an internal or external identifier. In this environment it was not always possible to replace the system linker by one supporting more significant characters. The importance of the mainframe environment waned in the 1990s. In modern environments it is very often possible to obtain alternative linkers.

Coding Guidelines

The number of significant characters should not affect the choice of a meaningful name. One coding technique is to continue to use the original (meaningful name) and to use macros to map to a different external name.

```
1  #define comms_inport_1 E1234
2  #define comms_inport_2 E1235
```

This approach suffers from the problem that there are two names associated with every object, not a good state of affairs from a program maintenance point of view. So, care needs to be taken that the alternative macro-derived names are not used directly.

C90 had a six character limit. Such a limit is very low and is an ideal that only a few, ultra-portable programs should still aspire to. However, it is possible that some C90 translators never migrate to the C99 limit (it being uneconomical to upgrade them).

identifier 792 number of characters

The issue of identifier length is discussed more fully elsewhere.

---

footnote 13

13) Implementations should avoid imposing fixed translation limits whenever possible. 284

Commentary

This is only a suggestion to implementors, not a requirement. It implies that implementations ought to use dynamically allocated data structures, rather than fixed-size ones.

Common Implementations

Most implementations dynamically allocate data structures for most constructs. The developer's desire for translators that translate at reasonable rates means that there are trade-offs associated with the use of fixed-size data structures in some areas.

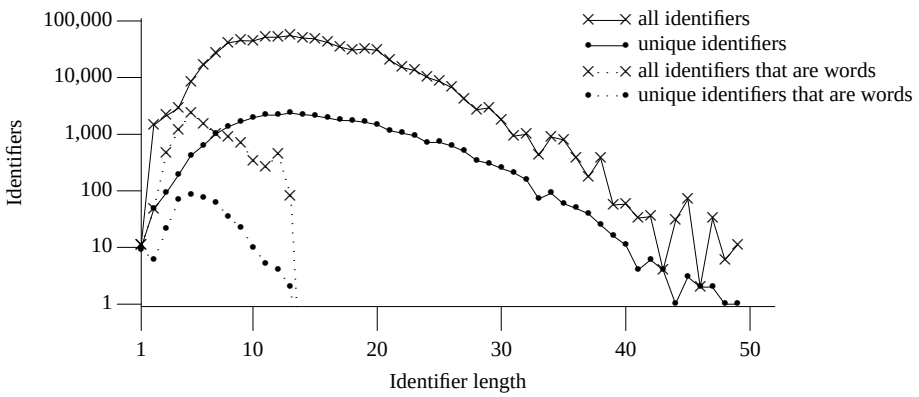

Figure 283.1: Number of identifiers, with external linkage, having a given length. Based on the translated form of this book's benchmark programs. Information on the length of all identifiers in the visible source is given elsewhere (see Figure 792.7).

Coding Guidelines

The developer has no control over the design of an implementation. Although implementations do not go out of their way to make inefficient use of host resources, there is not always the commercial incentive, on some hosts, to improve the quality of a translator.

---

285 — 4095 external identifiers in one translation unit

limit external identifiers

Commentary

This limit may appear to be generous. But, it includes identifiers declared both by the developer and the implementation (when a system header is included). This limit may be reached in automatically generated code. The standard does not define a per program limit. This is mainly because some linkers are not provided by the translator vendor and are in many ways outside of these vendors' control.

C90

511 external identifiers in one translation unit

C++

The following is a non-normative specification.

External identifiers in one translation unit [65536] Annex Bp2

Common Implementations

Most vendors include a large number of identifiers in their system headers. This is particularly true on workstations where the total number of identifiers declared in system headers can exceed 15,000 (see Table 1897.1). Developers have no control over the contents of these headers.

Usage

External declaration usage information is given elsewhere (see Figure 1810.1).

Table 285.1: Number of identifiers with external linkage (total 487), and total number of identifiers (total 810), implementations are required to declare in the standard headers.

Header	External Identifiers	Total Identifiers	Header	External Identifiers	Total Identifiers
<assert.h>	1	2	<signal.h>	2	12
<complex.h>	66	71	<stdarg.h>	3	5
<ctype.h>	15	15	<stdbool.h>	0	4
<errno.h>	1	4	<stddef.h>	0	5
<fenv.h>	11	24	<stdint.h>	0	38
<float.h>	0	31	<stdio.h>	49	65
<inttypes.h>	6	62	<stdlib.h>	36	37
<iso646.h>	0	11	<string.h>	22	24
<limits.h>	0	19	<tgmath.h>	0	60
<locale.h>	2	10	<time.h>	9	15
<math.h>	184	203	<wchar.h>	59	68
<setjmp.h>	2	3	<wctype.h>	18	22

---

286 — 511 identifiers with block scope declared in one block

identifiers number in block scope

Commentary

This limit may be reached in automatically generated code. In human-written code more than 10 identifiers declared in block scope is uncommon.

C90

127 identifiers with block scope declared in one block

C++

The following is a non-normative specification.

Annex Bp2 *Identifiers with block scope declared in one block [1024]*

Common Implementations

Most implementations take advantage of the scoping nature of blocks to create symbol table information when the declaration is encountered and to remove it (freeing up the storage used) when the block scope terminates. For implementations that operate in a single pass, generating machine code on a basic block basis, this can result in considerable storage savings. High-powered optimizing translators may still generate machine code in a single pass, but they usually build a tree representing all of the statements and expressions within each function. This means that information on block scope declarations cannot be freed up at the end of the block in which they occur.

Coding Guidelines

Having a large number of objects defined in the same block may be an indicator that a function definition has grown too large and needs to be split up, or an indicator that a structure type needs to be created. Although this is a design issue, there is a potential impact on comprehension effort. However, your author knows of no method of comparing the comprehension effort required for the various cases and so is silent on the subject.

Usage

The 53,630 function definitions in the translated form of this book's benchmark programs contained: definitions of 76 structure, union or enumeration types that included a tag; 6 **`typedef`** definitions; and definitions of 70 enumeration constants.

---

limit
macro definitions — 4095 macro identifiers simultaneously defined in one preprocessing translation unit 287

Commentary

This limit may appear to be generous. But, it includes macro identifiers declared both by the developer and the implementation (when a system header is included). The standard does not specify limits on the bodies of macro definitions. This is something that usually occupies much more storage than the identifier itself.

This limit may be reached in automatically generated code.

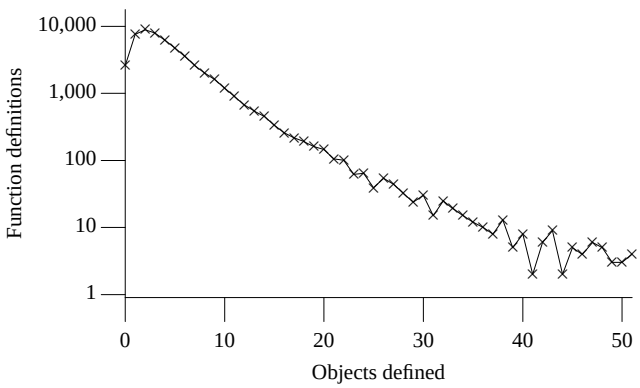

Figure 286.1: Number of function definitions containing a given number of definitions of identifiers as objects. Based on the translated form of this book's benchmark programs.

C90

1024 macro identifiers simultaneously defined in one translation unit

C++

The following is a non-normative specification.

Macro identifiers simultaneously defined in one translation unit [65536] Annex Bp2

Common Implementations

Most vendors include a large number of identifiers in their system headers. This is particularly true on workstations where the total number of identifiers declared in system headers can exceed 15,000 (see Table 1897.1). Developers have no control over the contents of these headers. It would not be uncommon for the total number of macros in a translation unit to exceed this limit (assuming an appropriate number of system headers are included). [98] footnote 3

There are several public domain preprocessors that might be of use if this translator limit on number of macro identifiers is encountered. However, if the problem is caused by lack of storage on the host where the translation is performed, such a tool may not be of practical use. Using a different preprocessor, from the one provided as part of the implementation also introduces the problem of ensuring that any predefined, by one preprocessor, macro names are also defined with the same bodies when another preprocessor is used.

---

288 — 127 parameters in one function definition

limit parameters in definition

Commentary

This limit is rarely reached except in automatically generated code, even then it is rare.

C90

31 parameters in one function definition

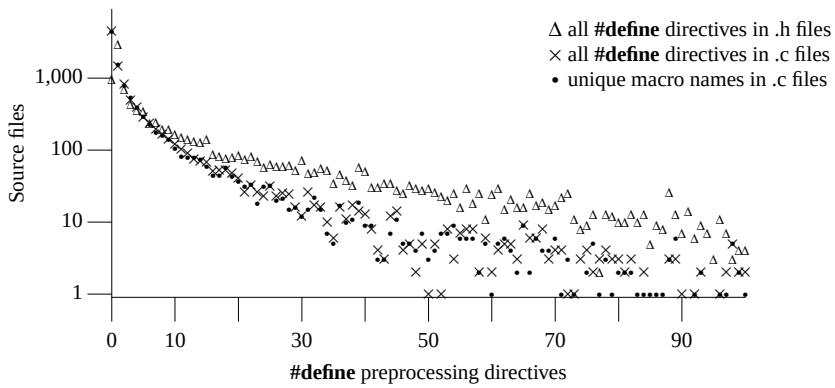

Figure 287.1: Number of source files containing a given number of identifiers defined as macro names in **`#define`** preprocessing directives. Unique macro name counts an identifier once, irrespective of the number of **`#define`** directives it appears in. Based on the visible form of the `.c` and `.h` files.

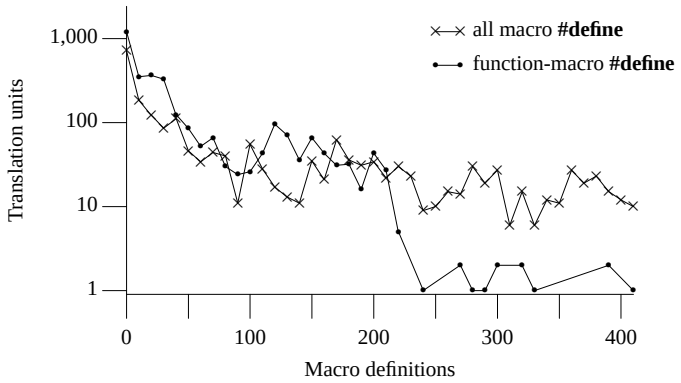

Figure 287.2: Number of translation units containing a given number of evaluations of **#define** preprocessing directives, excluding the contents of system headers, during translation of this book's benchmark programs (there were a total of 1,432,735 macros defined, of which 313,620 were function-like macros).

C++

The following is a non-normative specification.

Annex Bp2 *Parameters in one function definition [256]*

Common Implementations

Few hosted implementations place restrictions on the number of parameters in a function definition. Having one parameter on a stack is much the same as having 100. However, storage-limited execution environments (invariably freestanding) often limit the maximum number of parameters in a function definition.

The C binding for the GKS Standard[643] did manage to exceed the C90 limit, but this is uncommon.

Coding Guidelines

file scope 407 Some coding guideline documents recommend that use of file scope objects be minimized.[1026] This has the consequence of increasing the number of parameters in function definitions. Other guideline documents recommend keeping the number of parameters below a certain limit to reduce the possibility of developers making mistakes (by passing arguments in the incorrect order). Possible alternatives include the following:

- *Relying on file scope objects.* Out of sight, out of mind— developers could easily forget to assign to these objects. Alternatively, once an object has file scope, any number of unexpected functions might also reference it, creating unintended dependencies.
- *Declaring a structure to hold the parameter values.* The arguments now need to be assigned to the members of the structure. The names of these members, if well chosen, could provide a useful reminder of the appropriate value to assign. The disadvantage is that there is no automatic checking when new parameters, in the form of new members, are added, potentially resulting in the new parameters being passed in existing invocations as uninitialized members.
- *Passing as much information as possible through parameters.*

There have been no empirically based studies whose results might be used as the basis for calculating which information-passing method has the optimal cost/benefit.

---

function call number of arguments — 127 arguments in one function call 289

Commentary

limit 288 parameters in definition Functions declared using the ellipsis notation can be called with arguments that exceed this limit, while their definitions do not exceed the limit on the number of parameters.

This limit is rarely reached except in automatically generated code, even then it is rare.

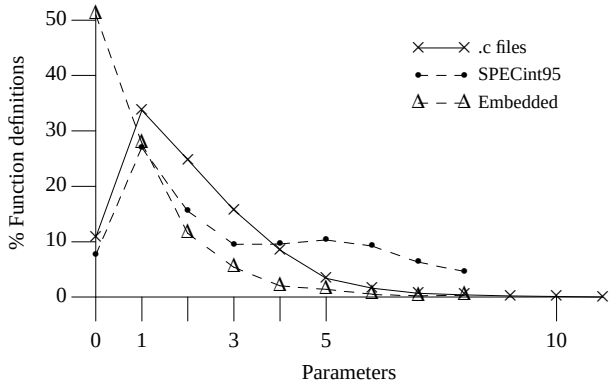

Figure 288.1: Percentage of function definitions appearing in the source of embedded applications (5,597 function definitions), the SPECint95 benchmark (2,713 function definitions), and the translated form of this book's benchmark programs (53,719 function definitions) declared to have a given number of parameters. The embedded and SPECint95 figures are from Engblom.[390]

C90

31 arguments in one function call

C++

The following is a non-normative specification.

Arguments in one function call [256] Annex Bp2

Common Implementations

Few hosted implementations place restrictions on the number of arguments passed in one function call. However, storage-limited execution environments (invariably freestanding) sometimes have limits on the number of bytes available on the function call stack.

290 — 127 parameters in one macro definition limit macro parameters

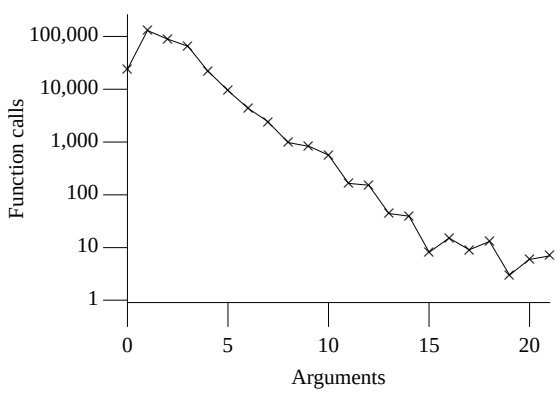

Figure 289.1: Number of function calls containing a given number of arguments. Based on the translated form of this book's benchmark programs.

Commentary

macro 1933 function-like

Function-like macro definitions are sometimes used to provide an alternative to an actual function call. These limits ensure that such definitions can handle at least as many parameters as function definitions.

C90

31 parameters in one macro definition

C++

The following is a non-normative specification.

Annex Bp2

Parameters in one macro definition [256]

Common Implementations

A few implementations used fixed-size data structures for macro definitions. The extent to which these will be increased to support the new C99 limit is not known.

Coding Guidelines

In the case where the macro body is not syntactically a function body, a large number of parameters may be the most reliable method of ensuring that the intended objects are accessed. Because macro bodies are expanded at the point of reference, the objects visible at that point (not the point of definition) are accessed.

---

limit arguments in macro invocation

— 127 arguments in one macro invocation

Commentary

... arguments 1923 macro

It is now possible, in C99, to define macros taking a variable number of arguments, using a similar principle to that used in function definitions. Although the arguments corresponding to the `...` notation are treated as a single parameter, inside the body of the macro definition, not individual ones.

C90

31 arguments in one macro invocation

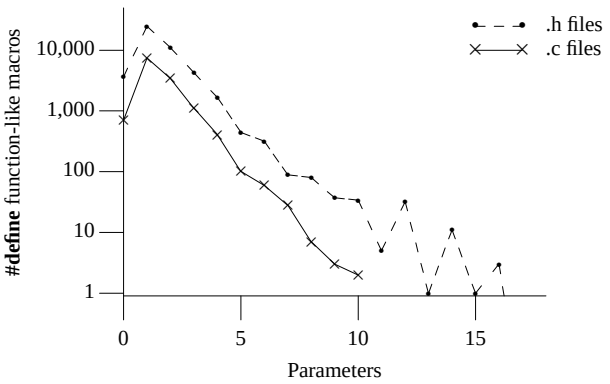

Figure 290.1: Number of function-like macro definitions having a given number of parameter declarations. Based on the visible form of the `.c` and `.h` files.

C++

The following is a non-normative specification.

Arguments in one macro invocation [256] Annex Bp2

Common Implementations

Some implementations limit the size (e.g., the number of characters) of an argument (an early version of Microsoft C[932] had a 256-character limit).

292 — 4095 characters in a logical source line

limit characters on line

Commentary

A logical line is created from a physical line after any line splicing has taken place in translation phase 2. Line splicing is only really needed in macro definitions. This limit can really be thought of as applying to the number of characters in a macro definition.

118 translation phase 2

Note that this limit does not apply to the result of any macro expansion. The C Standard defines a token-based preprocessor; characters and line length need not enter into the macro expansion process.

macro replacement

This limit may, rarely, be reached in automatically generated code.

C90

509 characters in a logical source line

C++

The following is a non-normative specification.

Characters in a logical source line [65536] Annex Bp2

Other Languages

Fortran (prior to Fortran 90) had a limit of 80 characters— the width of an IBM punched card.

Common Implementations

Some implementations use a fixed-length buffer for handling single logical source lines. Others use a fixed-length buffer and handle those situations where the length of a logical line exceeds the length of that buffer as a special case. The environmental limit on the minimum number of characters that may be supported on a physical line may affect translators written in C.

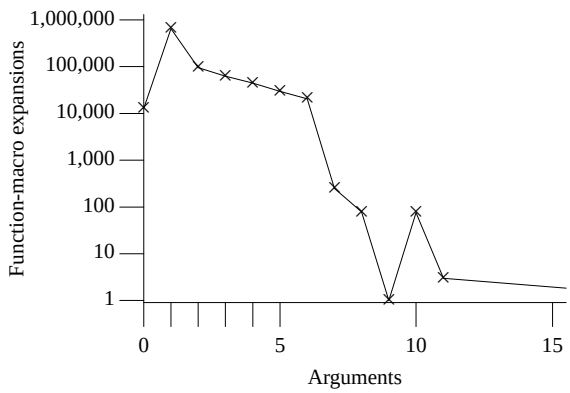

Figure 291.1: Number of function-like macro expansions containing a given number of arguments, excluding expansions that occurred while processing system headers, during translation of this book's benchmark programs.

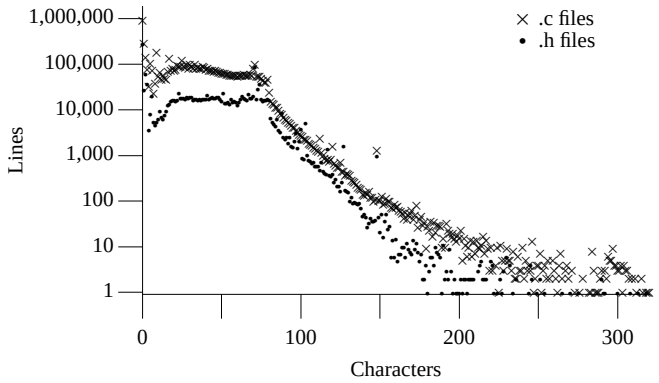

Figure 292.1: Number of physical lines containing a given number of characters. Based on the visible form of the `.c` and `.h` files.

limit string literal

— 4095 characters in a character string literal or wide string literal (after concatenation) 293

Commentary

translation phase 135 6

limit characters on line 292

This limit applies after translation phase 6. If the limit on the number of characters in a logical line is taken into account then, allowing for the delimiting quote characters, the only way of reaching or exceeding this limit without exceeding any other limits is via concatenation. Longer strings, than this limit, can be created by copying character values into object storage. But, these would not be string literals.

C90

509 characters in a character string literal or wide string literal (after concatenation)

C++

The following is a non-normative specification.

Annex Bp2 *Characters in a character string literal or wide string literal (after concatenation) [65536]*

Common Implementations

Some implementations use a fixed-length buffer to hold the characters making up a preprocessing token (in this case a string literal). The characters forming the string literal are rarely held on a linked list. Other implementations use a string-handling package to look after the details of manipulating variable-length string literals and have no internal length restrictions.

Coding Guidelines

If a very long string literal is needed by the application, it makes sense to try to create it as a single entity. String literals containing more than a few hundred characters are rare enough not to be worth a coding guideline.

limit minimum object size

— 65535 bytes in an object (in a hosted environment only) 294

Commentary

Many CISC processors have an efficient 16-bit addressing mode to access objects. It is often possible to create and access objects that exceed this addressing range, but the implementation and execution time overhead can be much higher. In many ways this limit can be seen as giving permission for implementations to stay within the natural addressing structure of their target processor (should it be a 16-bit one).

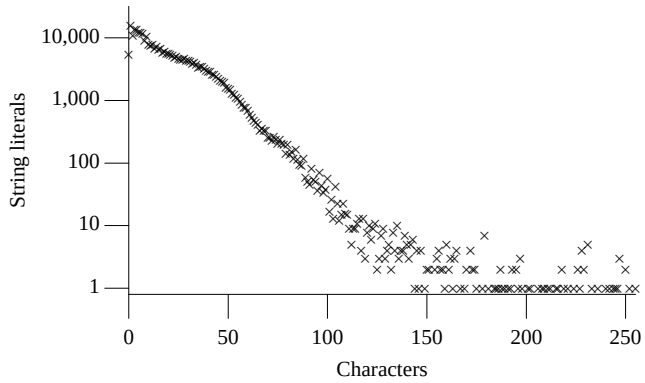

Figure 293.1: Number of character string literals containing a given number of characters (i.e., their length). Based on the visible form of the `.c` files.

The standard does not say anything about the storage duration of objects of this size; does it apply to all of them or at least one of them? There is no specification requiring that it be possible to define more than one of these objects, or for several smaller objects whose total size is 65,535 bytes to be supported.

This limit matches the corresponding minimum limits for `size_t` and `ptrdiff_t`. This limit means that for a translator where the type **`int`** is represented in 16 bits, the typedefs `size_t` and `ptrdiff_t` must have ranks at least equal to the type **`long`**.

Many freestanding environments don't even have 64 K bytes of memory in total. However, the standard does not specify a minimum object size that must be supported in these environments.

Committee Discussion DR #266

Translation limits do not apply to objects whose size is determined at runtime.

C90

32767 bytes in an object (in a hosted environment only)

C++

The following is a non-normative specification.

Size of an object [262144] Annex Bp2

Common Implementations

The maximum size of an object that can be defined may depend on its storage duration. On the basis that most function definitions only use a small amount of local data, some processor designers choose to ignore the relatively rare case of large amounts of local storage being required. The addressing modes needed to access large local objects, with a few instructions, may not be available (instead, relatively long sequences of instructions need to be used). These processor-based limitations can lead to translator vendors deciding not to go to the trouble of supporting very large objects having automatic storage duration.

If support for objects larger than 64 K is needed, it is most likely to be available via allocated storage. However, in some cases there may be limitations caused by host environment restrictions on the amount of storage that can be dynamically allocated in one contiguous storage area.

Linkers sometimes place restrictions on the maximum size of an object that can be statically allocated. This will affect objects with static storage duration.

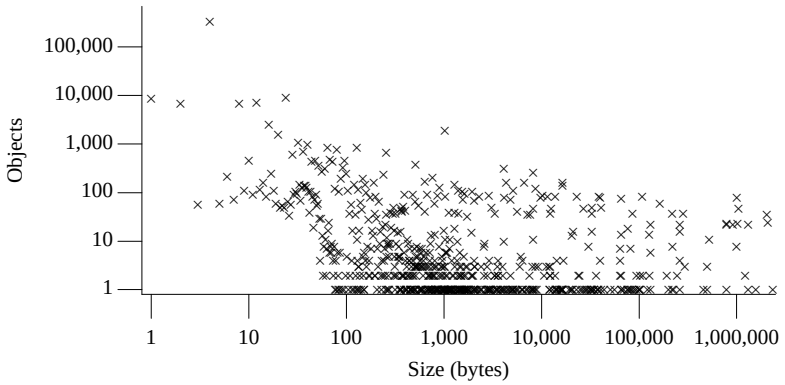

Figure 294.1: Number of objects requiring the specified amount of storage. Based on the translated form of this book's benchmark programs, using integer types whose sizes were: `sizeof(short) == 2`, `sizeof(int) == 4`, and `sizeof(long) == 4`; and alignment requirements that were a multiple of a types size.

Coding Guidelines

Although the standard may require that it be possible to define an object of the specified size, it is silent on the circumstances in which a program containing such a definition must be capable of executing. The standard does not provide any mechanism for verifying that a particular function invocation will successfully start to execute (i.e., not generate a stack overflow). In the case of static storage allocation, the program will either start to execute, or fail to start executing.

Use of dynamic allocation for objects does provide a degree of developer control of the situation where the allocation request fails. The disadvantage of such allocation methods is that it puts more responsibility for getting things right onto the developers' shoulders. Handling execution environment object storage limitations is a design and algorithmic issue that is outside the scope of these coding guidelines.

---

limit #include nesting

— 15 nesting levels for **`#include`**d files 295

Commentary

This limit makes no distinction between system headers and developer-written header files. However, an implementation is required to support its own system headers whose contents are defined by the standard. If a particular implementation chooses to use nested **`#include`**s, then it is responsible for ensuring that these do not prevent a translator from meeting its obligations with regard to this limit.

Use of nested **`#include`**s requires that the source file containing each of the **`#include`** directive be kept open, while the included file is processed. Supporting 15 nesting levels invariably requires keeping at least 17 (the top-level source file and the file holding the generated code also need to be counted) files open simultaneously. Using the `fsetpos` library function to record the current file position, at the point the **`#include`** occurs, and closing the current file before opening the nested include is possible; however, your author has never heard of an implementation that uses it.

C90

8 nesting levels for #included files

C++

The following is a non-normative specification.

Annex Bp2

Nesting levels for #included files [256]

Common Implementations

This limit is not just about data structures within the translator. Most environments have limits on the number of files that a process can have open simultaneously. This limit may be soft in the sense that the developer can modify it, or hard in that the limit is built into the OS (requiring a kernel rebuild to change it).

Coding Guidelines

Developers have no control over the nesting used by system headers. These headers are essentially black boxes, so it is permissible to ignore any nesting that occurs within them, from the point of view of calculating the maximum **#include** nesting level.

Does the depth of nesting of **#include** files affect the cost of ownership of source code?

Headers that only contain information specific to a particular application area, or even data type, would seem to be following the principles of information-hiding. The nesting of headers might be mapped to the corresponding nesting of application data structures. A practical problem associated with information-hiding in headers is locating the header that contains a particular identifier declaration. Program development environments rarely provide tools for handling headers in a structured fashion.

In a traditional development environment the source code editor does not usually have any knowledge of the character sequences it is displaying, although some editors do support a tags facility (enabling a database of identifier tags and the files that reference them to be built). Syntax highlighting is also becoming common and C++ style class browsers are growing in popularity, but structured support for displaying header file contents is still uncommon.

Given the support tools that are likely to be available to a developer, a limit on the nesting of **#include** directives could provide a benefit by reducing developer effort when browsing the source of various header files. However, limiting the nesting to which **#include** directives can occur could increase configuration-management costs, or result in poorly structured source files. The cost/benefit issues are complex and these coding guidelines say nothing more on the issue.

---

296 — 1023 **case** labels for a **switch** statement (excluding those for any nested **switch** statements)

limit
case labels

Commentary

The limit chosen in C90 had a rationale behind it. The value used for C99 has been increased in line with the percentage increases seen in other limits.

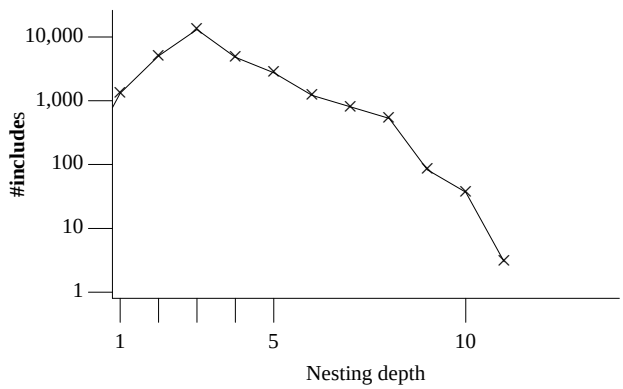

Figure 295.1: Number of **#include** preprocessor directives, that contain the quote-delimited form of header name (occurrences of the < > delimited form were not counted), having a given nesting depth. Based on the translated form of this book's benchmark programs.

C90

*257 case labels for a **switch** statement (excluding those for any nested **switch** statements)*

switch statement 1748 The intent here was to support **switch** statements that included 256 unsigned character values plus EOF (usually implemented as -1).

C++

The following is a non-normative specification.

Annex Bp2 *Case labels for a **switch** statement (excluding those for any nested **switch** statements) [16384]*

Common Implementations

selection statement syntax 1739 The number of **case** labels in a **switch** statement may affect the generated code. For instance, a processor instruction designed to indirectly jump based on an index into a jump table may have a 256 (bytes or addresses) limit on the size of jump table supported.

Coding Guidelines

The number of **case** labels in a **switch** statement is an indication of the complexity of the application, or the algorithm. Splitting a **switch** statement into two or more **switch** statements solely for the purpose of reducing the number of **case** labels within an individual **switch** statement has costs and benefits. The following are some of the issues:

- The size of a large **switch** statement, in the visible source, can affect the ease of navigation of the function containing it.
- In some environments (e.g., freestanding environments) there may be resource limitations (these may occur as a result of processor architecture or internal limits of the translator used); for instance, generating to case tables when there are large ranges of unused case values may make inefficient use of storage, or mapping to if/else pairs may cause a critical section of code to execute too slowly.
- The code complexity is increased (e.g., a conditional test that did not previously exist needs to be introduced).
- There may not be semantically meaningful disjoint sets of **case** labels that can form a natural division into separate **switch** statements.

---

limit members in struct/union — 1023 members in a single structure or union 297

Commentary

This limit does not include the members of structure tags, or typedef names, that have been defined elsewhere and are referenced in a structure or union definition.

This limit may be reached in automatically generated code.

C90

127 members in a single structure or union

C++

The following is a non-normative specification.

Annex Bp2

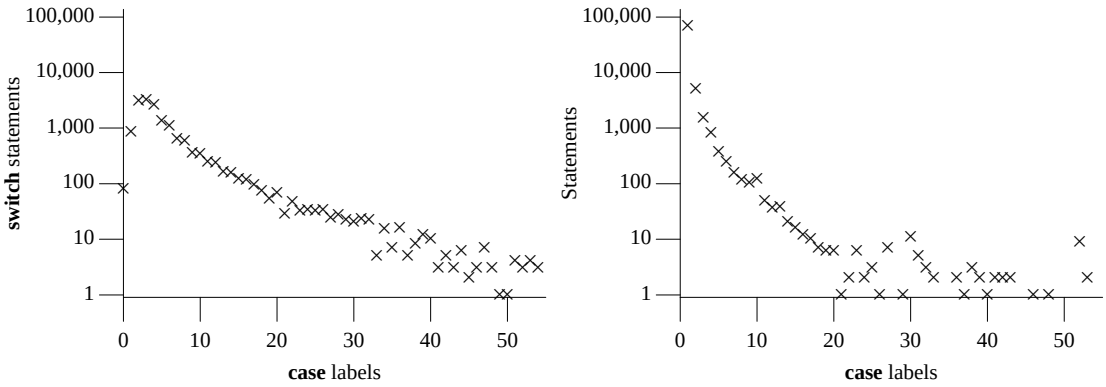

Figure 296.1: Number of **switch** statements containing the given number of **case** labels (left) and number of individual statements labeled by a given number of **case** labels (right). Based on the visible form of the `.c` files. Note that counts do not include occurrences of the **default** label.

Data members in a single class, structure or union [16384]

Coding Guidelines

The organization of the contents of data structures is generally determined by the application and algorithms used. While it may be difficult to imagine a structure definition containing a large number of members without some subset sharing a common characteristic, which enables them to be split into separate definitions; this does not mean that structures with large numbers of members cannot occur for a good reason. This issue is discussed in more detail elsewhere.

299 limit struct/union nesting

It is unlikely that a, human-written, union definition would ever contain a large number of members.

Usage

Measurements of classes,[1455] in large Java programs, have found that the number of members follows the same pattern as that in C (see Figure 297.1).

---

298 — 1023 enumeration constants in a single enumeration

limit enumeration constants

Commentary

This C99 limit has a value comparable to the increased limits of other constructs sharing the same C90 limit.

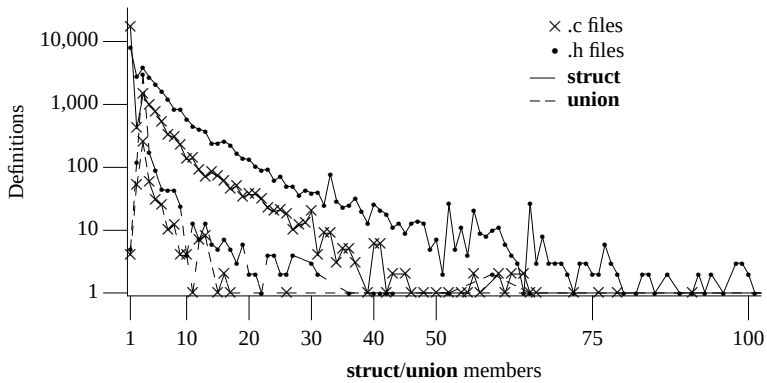

Figure 297.1: Number of structure and union type definitions containing the given number of members (members in any nested definitions are not included in the count of members of the outer definition). Based on the visible form of the `.c` and `.h` files.

C90

127 enumeration constants in a single enumeration

C++

The following is a non-normative specification.

Annex Bp2 *Enumeration constants in a single enumeration [4096]*

Common Implementations

The only known implementation restrictions on enumeration constants in an enumeration is the amount of available memory.

Coding Guidelines

Enumerators are unstructured in the sense that it is not possible to break down an enumerator into component parts to be included in some higher-level enumerator.

Would an application ever demand a large number of enumeration constants in a single enumerator? There are some cases where a large number do occur; for instance, specifying the tokens in the SQL/2 grammar requires 318 enumeration constants. Limiting the number of enumeration constants in an enumeration would not appear to offer any benefits, especially since there is no mechanism (like there is for structure members) for creating hierarchies of enumeration constants.

---

limit struct/union nesting — 63 levels of nested structure or union definitions in a single struct-declaration-list

Commentary

The specification of definitions, rather than types, suggests that this limit does not include nested structures and unions that occur via the use of typedef names.

C90

15 levels of nested structure or union definitions in a single struct-declaration-list

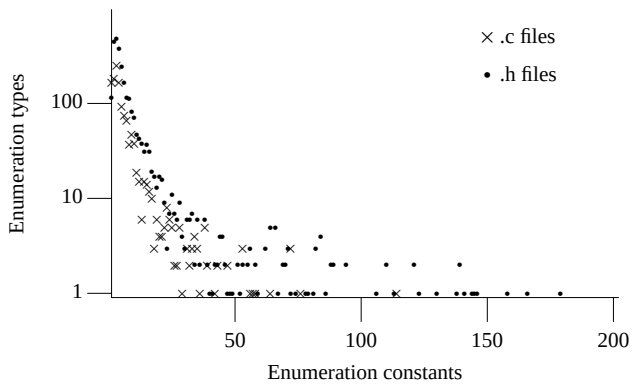

Figure 298.1: Number of enumeration types containing a given number of enumeration constants. Based on the visible form of the `.c` and `.h` files (also see Figure 1439.1).

C++

The following is a non-normative specification.

Levels of nested class, structure, or union definitions in a single `struct-declaration-list` *[256]* Annex Bp2

Other Languages

Fortran 90 and Common Lisp do not support the lexical nesting of record declarations.

Common Implementations

Nesting of definitions is part of the language syntax and usually implemented using a table-driven syntax analyzer. Most nested structure and union definitions occur at file scope; that is, they are not nested within other constructs. However, even if a declaration occurs in block scope, it is likely that any internal table limits will not be exceeded by a definition nested to 63 levels. This limit is only half that of nested block levels, even if creating a new level of structure nesting consumes 2 to 3 times as many table entries as a new level of nested block, there is likely to be sufficient table entries remaining to handle a deeply nested structure definition.

Coding Guidelines

Textual nesting of structure and union definitions is not necessary. C contains a mechanism (typedef names or tags) that removes the need for any textual nesting within structure or union definitions. Is there some optimal level of nesting, or can developers simply create whatever declarations suit them at the time?

The following are some of the benefits of using textually nested definitions:

- Having a definition nested within the structure of which it is a subcomponent highlights, to readers, the close association between the two types.
- Nested definitions may reduce reader effort (e.g., source code scanning) in locating a needed definition (e.g., the type of a member will be visible in the source next to where the member appears).
- If a single instance of a definition is needed, there is no need to create a tag name for it.

Some of the costs of using textually nested definitions include:

- Given the typical source code indentation strategies used for nested definitions, it is likely that deeply nested definitions will cause the same layout problems as deeply nested blocks (this issue is discussed elsewhere). 277 limit block nesting
- There is a reader expectation that a reference to a tag name, either refers to a definition nested within the current definition or that is not nested within any other definition. Such an expectation increases search costs (because the search is performed visually rather than via, say, an editor search command).
- C++ compatibility— a structure/union definition is treated as a scope in C++, which means that names defined within it are not visible outside of it. Any references to tags nested within other definitions will cause a C++ translator to issue a diagnostic and the definition will have to be unnested before these references will be acceptable to a C++ translator. 402 scope kinds of

There are also costs and benefits associated with nested definitions, whether such definitions are created through textual occurrence in the source or the use of tag or typedef names. The alternative to using nested definitions is to have a single level of definition (i.e., all structure or union members have a scalar or array type).

The issues involved in deciding the extent to which members having a shared semantic association should be contained in a single structure definition (i.e., used whenever that member is required, sometimes creating a nested structure) or duplicated in more than one structure definition (which does not require a nested structure to be created) include:

member selection 1031

- References (e.g., as an operand in an expression) to members nested within other definitions requires a sequence of member-selection operators (it may be possible to visually hide these behind a macro invocation). The visible source needed for accessing deeply nested members may impact the layout of the containing expression (e.g., a line break may be needed).
- As source code evolves, the information represented by a member that was once unique to one structure definition may need to be represented in other structure definitions. Creating a new type containing the related members may have many benefits (moving a member to such a definition changes what was a nonnested member into a nested member). However, the cost of adding a nesting level to an existing type definition can be high. The editing effort will be proportional to the number of occurrences of the moved members in the existing code, which requires the appropriate additional member-selection operation to be added.

categorization 0

- Type definitions are not always based on the categorization attributes of the application or algorithm. How a source code manipulates that information also needs to be considered. For instance, if some function needs to access particular information and takes as an argument a structure object that might reasonably contain a member holding that information, it might be decided to define the member holding that information in that structure type rather than another one.

developers organized knowledge 0

- The advantages of organizing information according to shared attributes is discussed in the introduction.

At the time of this writing algorithmic methods for optimally, or even approximately optimal, selecting structure type hierarchies are not known. Some of the considerations such an algorithm would need to take into account: the effort needed by readers to recall which structure type included which member, the effort needed to modify the types as the source evolved over time, and the structuring requirements caused by the need to pass arguments or create pointers to members.

Example

```
1  struct R {
2            struct {
3                   int mem_1;
4                   } mem_2;
5            };
6  struct S {
7            /*
8             * A tag is only needed if the structure type is referred to.
9             */
10           struct T {
11                    int mem_1;
12                    } mem_2;
13           };
14
15 struct U {
16           int mem_1;
17           };
18 struct V {
19           struct U mem_2;
20           };
```

5.2.4.2 Numerical limits

numerical limits

An implementation is required to document all the limits specified in this subclause, which are specified in the headers **<limits.h>** and **<float.h>**. 300

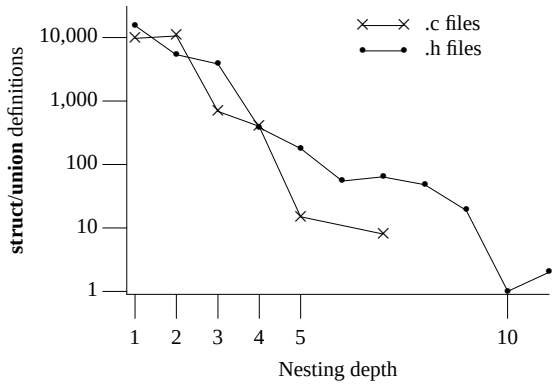

Figure 299.1: Number of structure and union type definitions containing the given number nested members that are textually structure and union type definitions (i.e., definitions using **{ }** not typedef names). Based on the visible form of the `.c` and `.h` files.

Commentary

Telling developers to look at the contents of the headers **<limits.h>** and **<float.h>** could well suffice as documentation.

C90

A conforming implementation shall document all the limits specified in this subclause, which are specified in the headers ***<limits.h>*** *and* ***<float.h>****.*

C++

Header ***<climits>*** *(Table 16): . . . The contents are the same as the Standard C library header* ***<limits.h>****.* 18.2.2p2

Header ***<cfloat>*** *(Table 17): . . . The contents are the same as the Standard C library header* ***<float.h>****.* 18.2.2p4

Other Languages

Many languages provide no means of obtaining such information about an implementation. The size of all scalar data types is predefined in Java. There are no implementation decisions to be made. The Java classes—`java.lang.Character`, `java.lang.Integer` and `java.lang.Long`— contain members giving minimum and maximum values of those types. There is no such class for the type **short**.

Common Implementations

There are two main kinds of implementations. Those in which **int** is 16 bits and those in which **int** is 32 bits. A third kind might be added, those in which **int** is not one of these two values (24 and 40 have been used). Processors supporting 128-bit integer types, where **int** might naturally be 64 bits, are beginning to appear.[27]

---

301 Additional limits are specified in **<stdint.h>**.

Commentary

This header contains declarations of integer types having specified widths, along with corresponding limits macros.

C90

Support for these limits and the header that contains them is new in C99.

C++

Support for these limits and the header that contains them is new in C99 and is not available in C++.

Forward references: integer types <stdint.h> (7.18). 302

5.2.4.2.1 Sizes of integer types <limits.h>

---

integer types sizes

303 The values given below shall be replaced by constant expressions suitable for use in **#if** preprocessing directives.

Commentary

macro object-like 1931 In other words they represent object-like macros. The difference between this statement and one requiring that the values be integral constant expressions is that the **sizeof** and cast operators cannot appear in a **#if** preprocessing directive (or to be more exact, a sequence of preprocessing tokens in this context is not converted to tokens and **sizeof** or type names are not treated as such).

These macros were created to give names to values that developers are invariably aware of, may make use of, and for which they may have defined their own macros had the standard not provided any.

C++

17.4.4.2p2 *All object-like macros defined by the Standard C library and described in this clause as expanding to integral constant expressions are also suitable for use in* ***#if*** *preprocessing directives, unless explicitly stated otherwise.*

18.2.2p2 *Header* ***<climits>*** *(Table 16): . . . The contents are the same as the Standard C library header* ***<limits.h>***

Other Languages

The equivalent identifiers in Java contain constant values. Ada and Fortran (90) use a function notation for returning representation properties of types and objects.

Common Implementations

These values can all be implemented using strictly conforming C constructs (although the numerical values used may vary between implementations). That is not to say that all vendors' implementations do it in this way. For some of these macros it is possible to use the same definition in all environments (without affecting the existing conformance status of programs). However, this usage is not very informative:

```
#define UINT_MAX (-1U)
#define ULONG_MAX (-1UL)
#define ULLONG_MAX (-1ULL)
```

The definition of the macros for the signed types always depends on implementation-defined characteristics. For instance,

```
#define INT_MAX 32767        /* 16 bits */
#define INT_MIN (-32767-1)
```

Coding Guidelines

The standard specifies values, not the form the expression returning those values takes. For instance, the replacement for INT_MIN is not always the sequence of digits denoting the actual value returned.

317 int minimum value

Table 303.1: Number of identifiers defined as macros in **<limits.h>** (see Table 770.3 for information on the number of identifiers appearing in the source) appearing in the visible form of the .c and .h files.

Name	.c file	.h file	Name	.c file	.h file	Name	.c file	.h file
LONG_MAX	47	28	CHAR_MAX	15	8	CHAR_BIT	36	3
INT_MAX	106	17	INT_MIN	17	7	SCHAR_MIN	12	2
UINT_MAX	30	14	UCHAR_MAX	16	5	LLONG_MAX	0	1
SHRT_MAX	20	13	CHAR_MIN	9	5	ULLONG_MAX	0	0
SHRT_MIN	19	12	SCHAR_MAX	13	4	LLONG_MIN	0	0
USHRT_MAX	12	11	MB_LEN_MAX	15	4			
ULONG_MAX	85	10	LONG_MIN	23	3			

304 Moreover, except for **CHAR_BIT** and **MB_LEN_MAX**, the following shall be replaced by expressions that have the same type as would an expression that is an object of the corresponding type converted according to the integer promotions.

*_MAX same type as *_MIN same type as

Commentary

CHAR_BIT and MB_LEN_MAX have no implied integer type. This requirement maintains the implicit assumption that use of one of these identifiers should not cause any surprises to a developer. There could be some surprises if promotions occurred; for instance, if the constants had type **unsigned long long**. There is no literal suffix to indicate a character or **short** type, so the type can only be the promoted type.

Common Implementations

Suffixes are generally used, rather than hexadecimal notation, to specify unsigned types.

305 Their implementation-defined values shall be equal or greater in magnitude (absolute value) to those shown, with the same sign.

Commentary

The C Standard does not specify the number of bits in a type. It specifies the minimum and maximum values that an object of that type can represent. An implementation is at liberty to exceed the limits specified here. It cannot fail to meet them. Except for the character types, a type may also contain more bits in its object representation than in its value representation.

494 integer types relative ranges
574 object representation
595 value representation

Common Implementations

The values that are most often greater than the ones shown next are those that apply to the type **int**. On hosted implementations they are often the same as the corresponding values for the type **long**. On a freestanding implementation the processors' efficiency issues usually dictate the use of smaller numeric ranges, so the minimum values shown here are usually used. The values used for the corresponding character, **short**, **long**, and **long long** types are usually the same as the ones given in the standard.

The Unisys A Series[1390] is unusual in not only using sign magnitude, but having a single size (six bytes) for all non-character integer types (the type **long long** is not yet supported by this vendor's implementation).

```
#define SHRT_MIN        (-549755813887)
#define SHRT_MAX          549755813887
#define USHRT_MAX         549755813887U
#define INT_MIN         (-549755813887)
#define INT_MAX           549755813887
#define UINT_MAX          549755813887U
#define LONG_MIN        (-549755813887L)
```

```
#define LONG_MAX          549755813887L
#define ULONG_MAX         549755813887UL
```

The character type use two's complement notation and occupies a single byte.

The C compiler for the Unisys e-@ction Application Development Solutions (formerly known as the Universal Compiling System, UCS)[1391] has 9-bit character types— 18-bit **short**, 36-bit **int** and **long**, and 72-bit **long long**.

Coding Guidelines

Some applications may require that implementations support a greater range of values than the minimum requirements specified by the standard. It is the developer's responsibility to select an implementation that meets the application requirements in this area.

symbolic name 822

These, and other, macro names defined by the standard provide symbolic names for the quantities they represent. The contexts in which these identifiers (usually macros) might be expected to occur (e.g., as operands of certain operators) are discussed in subsections associated with the C sentence that specifies them.

Example

Whether an occurrence of a symbolic name is making use of representation information is not always clear-cut.

```
#include <limits.h>

extern _Bool overflow;
extern int total;

void f(int next_digit_val)
{
/*
 * Check that the calculation will probably not overflow.  Perform
 * arithmetic on INT_MAX, but use a property (being a factor of
 * ten-less-than), not any specific numeric value.  The symbolic
 * name  is still being treated as the maximum representable int value.
 */
if (total < (INT_MAX / 10))
   total = (total * 10) + next_digit_val;
else
   overflow = 1;
}

unsigned int g(unsigned long some_val)
{
/*
 * While the internal representation of the value of UINT_MAX
 * is required to have all bits set, this might be considered
 * incidental to the property it is defined to represent.
 */
return (unsigned int)(some_val & UINT_MAX);
}

void h(int *characteristic)
{
/*
 * Comparing symbolic names against individual literal values is often
 * an indication that use is being made of representation details.  If
 * the comparisons occur together, as a set, it might be claimed that an
 * alternative representation of the characteristics of an implementation
 * are being deduced.  The usage below falls into the trap of overlooking
 * an undefined behavior (unless a translator has certain properties).
 */
switch (INT_MIN)
```

```
41      {
42      case -32767: *characteristic=1;
43                   break;
44
45      case -32768: *characteristic=2;
46                   break;
47
48      case -2147483647: *characteristic=3;
49                   break;
50
51      default: *characteristic=4;
52               break;
53      }
54  }
```

306 14) See "future language directions" (6.11.3). footnote 14

307 — number of bits for smallest object that is not a bit-field (byte) CHAR_BIT macro

CHAR_BIT 8

Commentary

C is not wedded to an 8-bit byte, although this value is implicit in a large percentage of source written in it.

Common Implementations

On most implementations a byte occupies 8 bits. The POSIX Standard requires that CHAR_BIT have a value of 8. The Digital DEC 10 and Honeywell/Multics[179] used a 36-bit word with the underlying storage organization based on 9-bit bytes. Some DSP chips have a 16- or 32-bit character type (this often has more to do with addressability issues than character set sizes).

Coding Guidelines

A value of 8, for this quantity, is welded into many developers' mind-set. Is a guideline worthwhile, just to handle those cases where it does not hold? Developers porting programs from an environment where CHAR_BIT is 8, to an environment where it is not 8 are likely to uncover many algorithmic dependencies. In many application domains the cost of ensuring that programs don't have any design, or algorithmic, dependencies on the number of bits in a byte is likely to be less than the benefit (reduced costs should a port to such an environment be undertaken).

A literal appearing within source code conveys no information on what it represents. If the number of bits in a byte is part of a calculation, use of a name, which has been defined, by the implementation to represent that quantity (even if it is not expected that the program will ever be translated in an environment where the value differs from 8) provides immediate semantic information to the developer reading the source (saving the effort of deducing it).

The CHAR_BIT is both a numeric quantity and represents bit-level information.

Example

In the first function assume a byte contains 8 bits. The second function has replaced the literal that explicitly contains this information, but not the literal that implicitly contains it. The third function contains an implicit assumption about the undefined behavior that occurs if `sizeof(int) == sizeof(char)`.

```
1  #include <limits.h>
2
3  unsigned char second_byte_1(unsigned int valu)
4  {
5  return ((valu >> 8) & 0xff);
```

```
6   }
7
8   unsigned char second_byte_2(unsigned int valu)
9   {
10  return ((valu >> CHAR_BIT) & 0xff);
11  }
12
13  unsigned char second_byte_3(unsigned int valu)
14  {
15  return ((valu >> CHAR_BIT) & ((0x01 << CHAR_BIT) - 1));
16  }
```

SCHAR_MIN value — minimum value for an object of type **signed char** 308

SCHAR_MIN -127 // $-(2^7-1)$

Commentary

The minimum value an 8-bit, one's complement or sign magnitude representation can support.

Common Implementations

A value of -128 is invariably used in a two's complement representation.

Coding Guidelines

two's complement minimum value

Because almost all implementations use two's complement, this value is often assumed to be -128. Porting to processors that use a different integer representation is likely to be very rare event. Designing code to handle both cases increases cost and complexity (leading to faults) for a future benefit that is unlikely to be cashed in. Ignoring the additional value available in two's complement implementations, on the grounds of symmetry or strict standard's conformance, can lead to complications if this value can ever be created (e.g., by a cast from a value having greater rank).

— maximum value for an object of type **signed char** 309

SCHAR_MAX +127 // 2^7-1

UCHAR_MAX — maximum value for an object of type **unsigned char** 310

UCHAR_MAX 255 // 2^8-1

Commentary

Because there are two representations of zero in one's complement and signed magnitude the relation `(SCHAR_MAX-SCHAR_MIN) < UCHAR_MAX` is true for all implementations targeting such environments.

In the case of two's complement the equality `(SCHAR_MAX-SCHAR_MIN) == UCHAR_MAX` is true, provided there are no padding bits in the representation of the type **signed char** (padding bits are never permitted in the representation of the type **unsigned char**, and no implementations known to your author use padding bits in the type **signed char**).

unsigned char 571 pure binary

unsigned char 571 pure binary 316 USHRT_MAX UINT_MAX 319 byte 53 addressable unit

There is a requirement that `UCHAR_MAX` equals $2^{\texttt{CHAR\_BIT}} - 1$. Equivalent requirements do not hold for `USHRT_MAX` or `UINT_MAX`

A byte is commonly thought of as taking on the range of values between zero and `UCHAR_MAX` and occupying `CHAR_BIT` bits. In other words it is treated as an unsigned type.

Other Languages

The Java class `java.lang.Character` contains the member:

```
1   public static final char MAX_VALUE = '\uffff';
```

Coding Guidelines

The macro `UCHAR_MAX` has a value that has an arithmetic property. It also has a bitwise property— all bits set to one. The property of all bits set to one is often seen in code that performs bit manipulation (the issue of replacing numeric literals with meaningful identifiers is dealt with elsewhere).

all bits one

822 symbolic name

---

311 — minimum value for an object of type **char**

char minimum value CHAR_MIN

CHAR_MIN *see below*

Commentary

The variability in the value of this macro follows the variability of the choice of representation for the type **char**. It depends on whether **char** is treated as a signed or unsigned type. There is an equivalent set of macros for wide characters.

326 char if treated as signed integer

Other Languages

`java.lang.Character` contains the member:

```
1   public static final char MIN_VALUE = '\u0000';
```

Common Implementations

The value used is often translation-time selectable, via a conditional inclusion in the **<limits.h>** header. The translator using a developer-accessible option to control the choice of type.

---

312 — maximum value for an object of type **char**

CHAR_MAX

CHAR_MAX *see below*

Commentary

The commentary on `CHAR_MIN` is applicable here.

311 char minimum value

Other Languages

`java.lang.Character` contains the member:

```
1   public static final char MAX_VALUE = '\uffff';
```

---

313 — maximum number of bytes in a multibyte character, for any supported locale

MB_LEN_MAX

MB_LEN_MAX 1

Commentary

For the value of this macro to be a translation-time constant, it has to refer to the locales known to the translator. The value must be large enough to support the sequence of bytes needed to specify a change from any supported shift state, to any other supported shift state, for any character available in the later shift state. There is no requirement on the implementation to support redundant changes of shift state.

2017 footnote 152

Common Implementations

Many US- and European-based vendors use a value of 1. The GNU library uses a value of 16.

Coding Guidelines

Using this identifier as the size in the definition, of an array used to hold the bytes of a multibyte character, implies that the bytes stored will not contain any redundant shift sequences.

---

short minimum value — minimum value for an object of type **short int** 314

```
SHRT_MIN -32767 // -(2^15-1)
```

Commentary

The minimum value a 16-bit, one's complement or sign magnitude representation can support.

Other Languages

Java defines **short** as having the full range of a two's complement 16-bit value.

Common Implementations

Most implementations support a 16-bit **short** type.

The token - is a unary operator; it is not part of the integer constant token. The expression -32768 has type **long** (assuming a 16-bit **int** type), ((-32767)-1) has type **int** (assuming that two's complement notation is being used). A value of (-32767-1) is invariably used in a 16-bit two's complement representation.

— maximum value for an object of type **short int** 315

```
SHRT_MAX +32767 // 2^15-1
```

Commentary

short 314 minimum value The commentary on SHRT_MIN is applicable here.

USHRT_MAX — maximum value for an object of type **unsigned short int** 316

```
USHRT_MAX 65535 // 2^16-1
```

Commentary

object representation 574 There is no requirement that USHRT_MAX equals $2^{\texttt{sizeof(short)} \times CHAR\_BIT} - 1$.

Common Implementations

The standard does not prohibit an implementation giving USHRT_MAX the same value as SHRT_MAX (e.g., Unisys A Series[1390]). In practice the additional bit used to represent sign information, in a signed type, is invariably used to represent a greater range of positive values for unsigned types.

---

int minimum value — minimum value for an object of type **int** 317

```
INT_MIN -32767 // -(2^15-1)
```

Commentary

The minimum value a 16-bit, one's complement or sign magnitude representation can support.

Other Languages

Java defines **int** as holding the full range of a 32-bit two's complement value. java.lang.Integer contains the member:

```
1  public static final int MIN_VALUE = 0x80000000;
```

Common Implementations

On most implementations this macro is the same as either SHRT_MIN or LONG_MIN. A value of (-32767-1) is invariably used in a 16-bit two's complement representation, while a value of (-2147483647-1) is invariably used in a 32-bit two's complement representation. 314 short minimum value

A number of DSP processors use 24 bits to represent the type **int**.[970]

Coding Guidelines

Developers often make some fundamental assumptions about the representation of **int**. These assumptions may be true in the environment in which they spend most of their time developing code, but in general are always true. Coding to the minimum limit specified in the standard in a 32-bit environment can be very restrictive and costly. If a program is never going to be ported to a non-32-bit host the investment cost of writing code to the minimum requirements, guaranteed by the standard, may never reap a benefit. This is a decision that is outside the scope of these coding guidelines.

---

318 — maximum value for an object of type **int** INT_MAX

```
INT_MAX +32767 // 2^15-1
```

Other Languages

java.lang.Integer contains the member:

```
1   public static final int MAX_VALUE = 0x7fffffff;
```

Common Implementations

On most implementations this macro is the same as either SHRT_MAX or LONG_MAX.

---

319 — maximum value for an object of type **unsigned int** UINT_MAX

```
UINT_MAX 65535 // 2^16-1
```

Commentary

There is no requirement that UINT_MAX equal $2^{\texttt{sizeof(int)} \times CHAR\_BIT} - 1$. 574 object representation

Common Implementations

The standard does not prohibit an implementation giving UINT_MAX the same value as INT_MAX, which would entail increasing the value of INT_MAX (e.g., Unisys A Series[1390]). In practice the bit used to represent sign information, in a signed type, is invariably included in the value representation for unsigned types (enabling a greater range of positive values to be represented). On most implementations this macro is the same as either USHRT_MAX or ULONG_MAX.

Coding Guidelines

The term *word* has commonly been used in the past to refer to a unit of storage that is larger than a byte. The unit of storage chosen is usually the *natural* size for a processor, much like the suggestion for the size of an **int** object. Like a byte, a word is usually considered to be unsigned, taking on the range of values between zero and UINT_MAX. word range of values 485 int natural size

Like the UCHAR_MAX macro the UINT_MAX macro is sometimes treated as having the bitwise property of all bits set to one. 310 UCHAR_MAX 310 all bits one

---

320 — minimum value for an object of type **long int**

```
LONG_MIN -2147483647 // -(2^31-1)
```

Commentary

The minimum value a 32-bit, one's complement or sign magnitude representation can support.

Other Languages

`java.lang.Long` contains the member:

```
public static final long MIN_VALUE = 0x8000000000000000L;
```

Common Implementations

A value of `(-2147483647-1)` is invariably used in a 32-bit two's complement representation. Prior to the introduction of the type **`long long`** in C99, some implementations targeting 64-bit processors chose to use the value `(-9223372036854775807-1)`, while others extended the language to support a **`long long`** type and kept long at 32 bits.

The number of bits used to represent the type **`long`** is not always the same as, or an integer multiple of, the number of bits in the type **`int`**. The ability to represent a greater range of values (than is possible in the type **`int`**) may be required, but processor costs may also be a consideration. For instance, the Texas Instruments TMS320C6000,[1342] a DSP processor, uses 32 bits to represent the type **`int`** and 40 bits to represent the type **`long`** (this choice is not uncommon). Those processors (usually DSP) that use 24 bits to represent the type **`int`**,[970] often use 48 bits to represent the type **`long`**. The use of 24/48 bit integer type representations can be driven by application requirements where a 32/64-bit integer type representation are not cost effective.[962]

Coding Guidelines

Some developers assume that `LONG_MIN` is the most negative value that a program can generate. The introduction of **`long long`**, in C99, means that this assumption is no longer true.

widest type assumption 494

— maximum value for an object of type **`long int`** 321

`LONG_MAX +2147483647` `// 2^31-1`

Other Languages

`java.lang.Long` contains the member:

```
public static final long MAX_VALUE = 0x7fffffffffffffffL;
```

Common Implementations

The value given in the standard is the one almost always used by implementations.

— maximum value for an object of type **`unsigned long int`** 322

`ULONG_MAX 4294967295` `// 2^32-1`

Commentary

There is no requirement that `ULONG_MAX` equal $2^{\texttt{sizeof(long)} \times CHAR\_BIT} - 1$.

object representation 574

Common Implementations

The standard does not prohibit an implementation giving `ULONG_MAX` the same value as `LONG_MAX` (Unisys A Series[1390]). In practice the additional bit used to represent sign information, in a signed type, is invariably used to represent a greater range of positive values for unsigned types.

The value given in the standard is the one almost always used by implementations.

Coding Guidelines

Some developers assume that `ULONG_MAX` is the largest value that a program can generate. The introduction of the type **`long long`** means that this assumption is no longer true.

widest type assumption 494

323 — minimum value for an object of type **long long int**

LLONG_MIN -9223372036854775807 // $-(2^{63}-1)$

Commentary

The minimum value a 64-bit, one's complement or sign magnitude representation can support. This value is calculated in a way that is consistent with the other _MIN values. However, hardware support for 64-bit integer arithmetic is usually only available on modern hosts, all of which use two's complement (to the best of your author's knowledge).

C90

Support for the type **long long** and its associated macros is new in C99.

C++

The type **long long** is not available in C++ (although many implementations support it).

Other Languages

In Java the type **long** uses 64 bits; a **long long** type is not needed (unless support for 128-bit integers were added to the language).

Common Implementations

This macro was supported in those C90 implementations that had added support for **long long** as an extension.

Coding Guidelines

The **long long** data type is new in C99. It will be some time before it is widely supported. A source file that accesses this identifier will fail to translate with a C90 implementation. The issue encountered is likely to be one of nontranslation, not one of different behavior. Deciding to create programs that require at least a 64-bit data type is an application-based issue that is outside the scope of these coding guidelines.

324 — maximum value for an object of type **long long int**

LLONG_MAX +9223372036854775807 // $2^{63}-1$

C90

Support for the type **long long** and its associated macros is new in C99.

C++

The type **long long** is not available in C++ (although many implementations support it).

325 — maximum value for an object of type **unsigned long long int**

ULLONG_MAX 18446744073709551615 // $2^{64}-1$

Commentary

There is no requirement that ULLONG_MAX equals $2^{\texttt{sizeof(long long)} \times CHAR\_BIT} - 1$. 574 object representation

C90

Support for the type **unsigned long long** and its associated macros is new in C99.

C++

The type **unsigned long long** is not available in C++.

326 If the value of an object of type **char** is treated as a signed integer when used in an expression, the value of **CHAR_MIN** shall be the same as that of **SCHAR_MIN** and the value of **CHAR_MAX** shall be the same as that of **SCHAR_MAX**.

char if treated as signed integer

Commentary

integer promotions 675

In most implementations the value of objects of type **char** will promote to the type **signed int**. So the values of objects of type **char** are treated as a **signed integer**. It is only when an object of type **char** is treated as an lvalue, that its signedness becomes a consideration. For instance, on being assigned to, is modulo arithmetic or undefined behavior used for out-of-range values.

lvalue 721

Common Implementations

Most implementations provide a translation-time option that enables a developer to select how the type **char** is to be handled. This option usually causes the translator to internally predefine an object-like macro. The existence of this macro definition is tested inside the **<limits.h>** header to select between the two possible values of the CHAR_MIN and CHAR_MAX macros.

Coding Guidelines

A comparison of the value of CHAR_MIN against SCHAR_MIN (or CHAR_MAX against SCHAR_MAX) can be used to determine an implementation-defined behavior (whether the type **char** uses the same representation as **signed char** or **unsigned char**).

Example

```
#include <limits.h>
#include <stdio.h>

int main(void)
{
if (CHAR_MIN == SCHAR_MIN)
   {
   printf("char appears to be signed\n");
   if (CHAR_MAX != SCHAR_MAX)
      printf("nonconforming implementation\n");
   }
if (CHAR_MIN != SCHAR_MIN)
   printf("char does not appear to be signed\n");
}
```

Otherwise, the value of **CHAR_MIN** shall be 0 and the value of **CHAR_MAX** shall be the same as that of **UCHAR_MAX**.[15)] 327

Commentary

*_MIN 304 same type as

When the type **char** supports the same range of values as the type **unsigned int**, the type of CHAR_MIN must also be **unsigned int** (i.e., the body of its definition is likely to be 0u).

Coding Guidelines

The possibility that the expression (CHAR_MIN == 0) && (CHAR_MIN <= -1) can be true is likely to be surprising to developers. However, implementations where this macro has type **unsigned int** are not sufficiently common to warrant a guideline recommendation (e.g., perhaps suggesting that CHAR_MIN always be cast to type **int**, or that it not appear as the operand of a relational operator).

Example

```
#include <limits.h>
#include <stdio.h>

int main(void)
{
```

```
6   if (CHAR_MIN == 0)
7      {
8      printf("char appears to be unsigned\n");
9      if ((CHAR_MAX - UCHAR_MAX) != 0)
10        printf("nonconforming implementation\n");
11     }
12
13  if (((int)CHAR_MIN) <= -1) /* Handle the case #define CHAR_MIN 0U */
14     printf("char does not appear to be unsigned\n");
15  }
```

328 The value **UCHAR_MAX** shall equal $2^{\mathbf{CHAR\_BIT}} - 1$. UCHAR_MAX value

Commentary

Any unsigned character types are not allowed to have any hidden bits that are not used in the representation. Therefore UCHAR_MAX must equal $2^{\texttt{sizeof(char)} \times CHAR\_BIT} - 1$. Since `sizeof(char) == 1` by definition, the above C specification must hold.

571 unsigned char pure binary

1124 sizeof char defined to be 1

C90

This requirement was not explicitly specified in the C90 Standard.

C++

Like C90, this requirement is not explicitly specified in the C++ Standard.

Other Languages

Most languages do not get involved in specifying this level of detail.

329 **Forward references:** representations of types (6.2.6), conditional inclusion (6.10.1).

5.2.4.2.2 Characteristics of floating types <float.h>

330 The characteristics of floating types are defined in terms of a model that describes a representation of floating-point numbers and values that provide information about an implementation's floating-point arithmetic.[16)] floating types characteristics

Commentary

Floating-point types are an alternative to integer representation of numeric values. Some of the floating types occupy the same amount of storage as the larger integer types. Floating-point types trade-off some accuracy representation bits to hold an exponent value. This exponent is used to increase the range of values that can be represented at the cost of a reduced number of significant digits.

The C90 Standard made no mention of ISO/IEC 60599 floating-point arithmetic (although IEEE-754 is mentioned in an example). At that time this standard was only just emerging as the computer industry-wide model of choice. There were still other formats in widespread use. The usage of these formats continues to decline and is now limited to a small number of markets.

In at least one case, it is possible for a program to check which floating-point representation is being used. The __STDC_IEC_559__ macro has the value 1 if the implementation conforms to annex F (IEC 60559 floating-point arithmetic).

2015 __STDC_IEC_ macro

This model assumes its components have a fixed width during program execution. Models based on a variable number of bits in the exponent and significand (adjusted as the value represented gets larger or smaller) have been proposed.[1494] Such variable-width models have yet to be used by commercial processors.

Rationale

The characterization of floating point follows, with minor changes, that of the Fortran standardization Committee. The C89 Committee chose to follow the Fortran model in some part out of a concern for Fortran-to-C translation, and in large part out of deference to the Fortran Committee's greater experience with fine points of floating

point usage. Note that the floating point model adopted permits all common representations, including sign-magnitude and two's-complement, but precludes a logarithmic implementation.

The C89 Committee also endeavored to accommodate the IEEE 754 floating point standard by not adopting any constraints on floating point which were contrary to that standard. IEEE 754 is now an international standard, IEC 60559; and that is how it is referred to in C99.

C++

18.2.2p4 *Header* **<cfloat>** *(Table 17): . . . The contents are the same as the Standard C library header* **<float.h>**

Other Languages

Many languages contain floating-point types. Ada gets involved in very low-level details of the representation model. Fortran (90) contains inquiry functions that return values representing properties of the real types used by an implementation. Lisp defines a bignum package, allowing calculations to precisions greater than that supported by most C implementations **long double**. However, the performance is not as great. One of the design aims of the Java language was to ensure that the behavior of a program did not vary across implementations. While the Java language does specify support for a floating-point standard:

The Java types **float** *and* **double** *are IEEE 754 32-bit single-precision and 64-bit double-precision binary floating-point values, respectively.*

it is necessary to remember that this standard permits some degree of implementation leeway. The Java designers attempt to exactly specify how an implementation should follow the floating-point standard (in order to prevent differences in generated results) has met with some criticism.[701]

Common Implementations

Most implementations use the floating-point format supported by the processor on which the program is executed.

Writing a C translator does not require the use of floating-point types. A translator can output floating-point literals in some canonical representation, which is converted to the host representation on program startup (before control is transferred to `main`). However, many translators do make use of knowledge of the representation used at execution time and output, to object files, floating-point literals in this format.

The Unisys e-@ction Application Development Solutions (formerly known as the Universal Compiling System [UCS])[1391] (see Table 330.1) has a word size that is not an integer multiple of the types defined by IEC 60559.

Table 330.1: Range of representable floating-point values for the Unisys e-@ction Application Development Solutions Compiling System.

Type	Bits	Decimal Range
float	36	1.4693680E-39 . . . 1.7014118E+38
double	72	2.7813423E-309 . . . 8.9884657E+307
long double	72	2.7813423E-309 . . . 8.9884657E+307

Some implementations emulate the larger representations by joining together several smaller representations. For instance, the Apple numerics implementation on the PowerPC uses two doubles, each using 64 bits, to represent a **long double**, occupying 128 bits.[52] The PowerPC processor does not support operations on 128-bit floating-point types; they are implemented with some software support. The exponents are adjusted

so that the *least significant* component has an exponent that is at least 54 (representing a value of 2 to 54) less than the *most significant* component. This arrangement increases the precision of the significand (unless it is near the smallest normal value) but does not change the range of possible exponents. The original IBM 390 floating-point format[1207] (base 16) also used two doubles to represent a **long double**. In some cases the sequence of value bits, in the object representation, may be disjoint. For instance, the Motorola 68000 only uses 80 bits of the possible 96 bits in its double extended object representation.[968]

For those applications requiring even greater precision, use of four doubles (providing 212 bits of significand) has been proposed.[572]

Coding Guidelines

Goldberg[500] is frequently recommended reading for developers working with floating-point types. The following provides a rough-and-ready introduction to error analysis.

Assume alg represents the value returned by the C algorithm for the mathematically exact function f, the error is (for simplicity assume a single argument x):

$$error = alg(x) - f(x) \tag{330.1}$$

If alg is a good approximation to f, another way to look at this is to say the result returned by alg at x corresponds to the exact value at the point $x + e$, where e is a very small displacement from x:

$$alg(x) \approx f(x + e) \tag{330.2}$$

Taking the first two terms from a Taylor series expansion about x (assuming f does not contain any discontinuities):

$$f(x + e) \approx f(x) + e * f'(x) \tag{330.3}$$

Combining the preceding three equations we get:

$$\begin{aligned} error &= alg(x) - f(x) && (330.4)\\ &\approx f(x + e) - f(x) && (330.5)\\ &\approx f(x) + e * f'(x) - f(x) && (330.6)\\ &\approx e * f'(x) && (330.7) \end{aligned}$$

showing that the error is proportional to the derivative of the function. To within the approximations used, the algorithm used is not a factor in the error analysis; the mathematical function used to solve the application-domain problem is the important factor.

The formula given in mathematical textbooks usually assume infinite precision and are not well-behaved when less precision is used.[702] A well-known example is computing the area of a triangle using Heron's formula:

$$Area = sqrt(s(s - x)(s - y)(s - z)) \tag{330.8}$$

where: x, y, z are the length of the sides, and $s = (x + y + z)/2$.

For narrow, pointed, triangles this formula can give incorrect results, even when every floating-point operation is correctly rounded. Table 330.2 gives an example where the values are rounded to five significant digits. The final result can either be 0.0 or 1.5813 (the correct area is 1.000025).

Table 330.2: Area of triangle, using Heron's formula, calculated using different rounding directions.

	Correct	Rounding Down	Rounding Up
x	100.01	100.01	100.01
y	99.995	99.995	99.995
z	0.025	0.025	0.025
$(x+(y+z))/2$	100.015	100.01	100.02
Area	1.000025	0.0000	1.5813

By recognizing that intermediate results have a finite accuracy, the preceding formula can be reorganized. First the relative values of the length of the sides is important. They need to be sorted so that $x \le y \le z$. The formula:

$$A = sqrt(\frac{(x+(y+z))(z-(x-y))(x+(y-z))}{4}) \tag{330.9}$$

then gives a good, numerically stable approximation to the area. Note that it is only guaranteed to work correctly if the parentheses are not removed (they tell the translator that operands cannot be reordered). On processors that do not support denormal numbers, flushing very small values to zero, this formula fails because a subtraction, $(p-q)$, can underflow. For a more detailed analysis of this problem, see Kahan.[703]

Rev 330.1

Developers who are not familiar with floating-point error analysis shall not be involved in designing or implementing algorithms that use floating-point types.

Usage

Many of the following identifiers were referenced from one program, `enquire.c`, whose job was to deduce the characteristics of a host's floating-point support.

Table 330.3: Number of identifiers defined as macros in **<float.h>** (see Table 770.3 for information on the number of identifiers appearing in the source) appearing in the visible form of the `.c` and `.h` files.

The following parameters are used to define the model for each floating-point type: 331

Commentary

These parameters are not C-language specific. They are the values needed to fully define, mathematically, a floating-point representation. The values in this model are used, by developers, to:

- ensure that implementations support the range of values likely to be needed by an application,
- perform error analysis, and
- calculate the bit pattern representation of hexadecimal floating constants.

floating constant syntax 842

Common Implementations

Most implementations divide the representation of a floating-point type into groups of contiguous sequences of bits, each representing a different component of the model presented here.

---

332 s sign (± 1)

Commentary

One of the few operations that can be performed on a floating-point value, without fear of loss of accuracy, is to change its sign. Information on the sign of the value is held separately from the significand, unlike two's complement notation where it changes the encoding of the value. A consequence of this representation is that it is possible to represent both +0.0 and -0.0 (this possibility also occurs for integers in sign and magnitude representation; and one's complement, but for a different reason). The copysign library function can be used to directly access the sign of a floating-point number.

Common Implementations

Some floating-point formats, e.g., VAX and the HP–was DEC– Alpha in VAX mode, do not support -0.0 (it is considered to be a NaN). While IBM S/360 supports -0.0, any use of it is treated as +0.0. Also -0.0 cannot be generated by normal floating-point operations. The representation of NaNs have a sign bit, but it is not always possible to change this sign bit.

Processors using two's complement floating-point formats have been built in the past. In this representation –MAX is not representable.

---

333 b base or radix of exponent representation (an integer > 1)

Commentary

The FLT_RADIX macro specifies the radix used by an implementation. 366 FLT_RADIX

---

334 e exponent (an integer between a minimum e_{min} and a maximum e_{max}) exponent

Commentary

The range of possible exponent values is governed by the radix and the number of bits used in its representation. Discussions on how many bits of accuracy to trade-off against exponent range have now resolved themselves, or at least the Standard's Committee has published generally agreed-on numbers. The *_MIN_EXP and *_MAX_EXP macros, along with FLT_RADIX define the possible range of values.

Common Implementations

Most implementations use a biased exponent representation (the TMS320C3x[1341] is one of the few that uses two's complement). Here a fixed constant is added to the exponent as it appears in its human-readable form, so the value actually held in the bit pattern representation is always positive (hence the term *biased exponent*; this notation is also known as *excess-N*). By using such a notation for the exponent, it is possible to perform relational comparisons on floating-point values by treating their bit pattern as an *integer* type. This considerably simplifies the hardware implementation of floating-point comparison operations.

Some of the bit patterns representing possible exponent values are also given special meaning by IEC 60559 (e.g., all bits 1 is used to indicate one of several possible states). The Unisys A Series[1389] represents the value of the exponent using 6 bits to represent the magnitude and 1 bit to represent the sign. The CDC 6600[211] and 7600 used an 11-bit one's complement representation for the exponent.

Usage

The range of exponent values that can occur within programs may depend on the application domain. For instance, astronomy programs may contain ranges of very large values and subatomic particle programs contain ranges of very small values. A study of software for automotive control systems[267] showed (see Table 334.1) a relatively small range of exponents, close to zero.

Table 334.1: Dynamic distribution of decimal exponents, as a percentage, for operands of various floating point operations. Adapted from Connors, Yamada, and Hwu[267] (thanks to Connors for supplying the raw data).

Exponent	Compare	Add	Multiply	Divide	Exponent	Compare	Add	Multiply	Divide
0	15.60	11.4	6.7	3.0					
-1	2.5	2.5	1.9	0.0	1	10.80	9.3	1.6	1.0
-2	0.7	1.2	0.6	1.0	2	5.20	2.6	1.3	3.0
-3	0.1	0.0	0.7	0.0	3	8.50	4.3	0.7	0.0
-4	0.0	0.1	0.2	1.0	4	0.50	0.0	0.5	0.0
-5	0.0	0.0	0.5	0.0					
-6	0.0	0.6	1.4	0.0					

precision
floating-point

p precision (the number of base-b digits in the significand) 335

Commentary

The larger the value of p, the greater the precision that can be represented. This value is ultimately responsible for the values of the `*_DIG macros`.

*_DIG 369
macros

The points in the real continuum that can be represented by a floating-point value are not as self-evident as they are for the integer values. Because of the presence of an exponent and a normalized significand, the

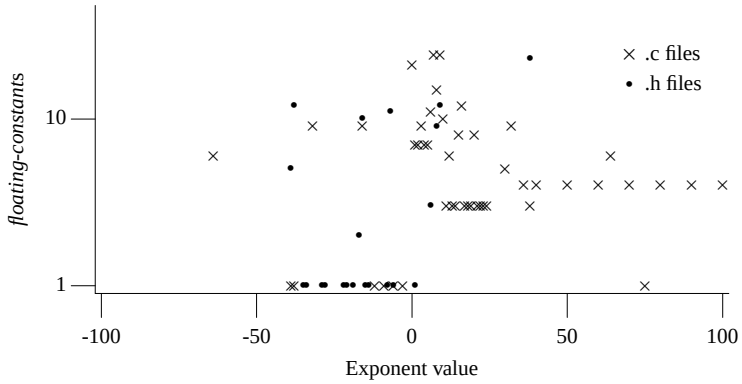

Figure 334.1: Number of *floating-constant*s (that included an *exponent-part*) having a given exponent value. Based on the visible form of the `.c` and `.h` files.

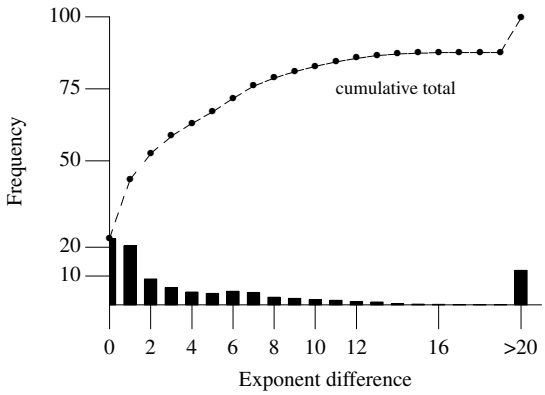

Figure 334.2: Difference in the value of the exponents (in powers of 2) of the two operands of floating-point addition and subtraction operations, obtained by executing the SPECfp92 benchmarks. Adapted from Oberman.[1024]

distance between representable values increases as the numbers get bigger. For a radix of 2, for instance, the number of representable values between each power of two is the same. This means there are as many representable floating-point values between 2 and 4 as there are between 1,048,576 and 2,097,152.

C++

The term *significand* is not used in the C++ Standard.

Common Implementations

The fact that there is a sign bit gives away the representation of the significand in IEC 60559. It is held in sign and magnitude format. This representation was chosen primarily on the grounds of ease of implementation in hardware.

The IEC 60559 representation also uses an additional hidden bit. The bits of the significand are shifted such that the most significant bit that is set, always occurs immediately to the left of the bits actually stored (the value of the exponent is updated to ensure that the actual value being represented remains unchanged), a process called *normalization*. Because this bit is always known to be set, there is no need to store it. Thus there is always one more effective bit of accuracy than is stored in the significand. Implementations that do not use a radix of 2 cannot make use of this hidden-bit technique to obtain more accuracy. For instance, with a radix of 16, bits in the significand need to be shifted by 4 for every incremental change in value of the exponent. The IEC 60559 technique of using a hidden bit can incur a significant performance penalty for software emulations of floating-point operations. Using a radix other than 2 reduces the performance overhead associated with normalizing the significand.[267]

On the WE DSP32[64] the least-significant bit of the significand representation can optionally be used as a parity (odd) bit. Floating-point operations treat this parity bit as part of the value representation. This introduces an error or 1 ULP in 50% of cases.

WE DSP32
346 ULP

The Motorola DSP563CCC[967] uses a 24-bit two's complement representation for the significand (no hidden bit). The CDC 6600[211] and 7600 used a 49-bit one's complement representation for the significand. The radix point was at the least significant end.

Research on hardware support for reusing the results of previously executed sequences of instructions usually requires that values input to an instruction sequence match those of previous evaluations, before the previous computed result can be reused. A study by Álvarev, Corbal, Salamí, and Valero,[21] using multimedia applications (e.g., JPEG encoding), investigated what they called *tolerant reuse*. By ignoring some of the least significant bits (up to four) of floating-point values, they were able to significantly increase the number of previously computed results that could be reused (because the input values matched at lower precisions). The number of instructions executed by programs was reduced by between 25% to 40%.

940 value profiling

A study by Tong, Rutenbar, and Nagle[1356] analyzed the performance of four floating-point intensive applications. They found that it was possible to significantly reduce the number of bits in the significand representation (a speech-recognition program to 5 bits; a fingerprint classification program to 11 bits; an image-processing benchmark to 9 bits; a neural network trainer to 5 bits), without unduly affecting final program accuracy. Customizing the design of floating-point units (i.e., the number of bit in the exponent and significand) to match the accuracy/performance/cost requirements of specific applications has also been proposed.[468]

Coding Guidelines

The term commonly used by developers is *mantissa*, not *significand*. There is probably little to be gained by attempting to change developers' common terminology.

---

336 f_k nonnegative integers less than b (the significand digits)

Commentary

If the radix is 2 (as specified by IEC 60559), possible values for this quantity are 0 and 1.

Common Implementations

Most implementations now follow IEC 60559. The IBM 360 originally used a radix of 16; possible values of f range from 0 to 15 for this implementation. Its successor, the IBM 390, also includes support for the IEC 60559 Standard.[1207]

---

floating-point model

A *floating-point number* (*x*) is defined by the following model: 337

$$x = sb^e \sum_{k=1}^{p} f_k b^{-k}, \quad e_{min} \le e \le e_{max}$$

Commentary

This defines the term *floating-point number*. This model applies to a broad range of floating-point implementations. It differs from the model for signed magnitude integer types in that it contains an exponent part (which enables the decimal point to *float*) and offers support for a radix other than two.

The presence of a decimal point is not unique to floating-point numbers. Both fixed-point and logarithmic representations provide support for a decimal point. In the fixed-point representation the position of the decimal point in the number is fixed (i.e., only two digits after the decimal point are supported). Support for fixed-point types in C is one of the constructs specified in the embedded C TR. In a logarithmic number system a numeric value is represented by its logarithm. This means that operations, such as multiply and divide, are very fast; however, addition and subtraction are much slower. Recent research,[254] using base 2 logarithms, has shown a factor of two speed improvement (over comparable floating-point implementations) when the ratio of floating-point add to multiple operations was 40% to 60%. A processor using this logarithmic number system has also been built.[255]

Embed-ded C TR 18

C90

A normalized floating-point number x ($f_1 > 0$ if $x \neq 0$) is defined by the following model:

$$x = s \times b^e \times \sum_{k=1}^{p} f_k \times b^{-k}, \quad e_{min} \le e \le e_{max}$$

The C90 Standard did not explicitly deal with subnormal or unnormalized floating-point numbers.

C++

The C++ document does not contain any description of a floating-point model. But, Clause 18.2.2 explicitly refers the reader to ISO C90 subclause 5.2.4.2.2

Coding Guidelines

This model specifies the maximum range of values and precision of a floating-point type. These, and other quantities, are exposed to the developer via macros defined in the header **<float.h>**. The relevant guidelines are covered where these identifiers are discussed.

---

floating types can represent

In addition to normalized floating-point numbers ($f_1 > 0$ if $x \neq 0$), floating types may be able to contain other kinds of floating-point numbers, such as subnormal floating-point numbers ($x \neq 0$, $e = e_{min}$, $f_1 = 0$) and unnormalized floating-point numbers ($x \neq 0$, $e > e_{min}$, $f_1 = 0$), and values that are not floating-point numbers, such as infinities and NaNs. 338

Commentary

This terminology and choice of values of x, f_1, and e originates with IEC 60559 (or to be exact IEEE-754 and IEEE-854 standards that eventually became the ISO/IEC Standard). The ability to support subnormal floating-point numbers, unnormalized floating-point numbers, and NaNs is not unique to ISO 60599, although they may be referred to by other names. A terminological note: The 854 Standard uses the term *subnormal* to refer to entities that the 754 Standard calls *denormals* (the term *denormal* and *denormalized* is not only seen in older books and papers but is still in use).

In a normalized floating-point number the value is always held in a form such that the significand has no leading zeros (i.e., the first digit is always one). The exponent is adjusted appropriately. The minimum values for floating-point quantities given elsewhere are required to be normalized numbers.

330 floating types characteristics
subnormal numbers

Subnormal numbers provide support for gradual underflow to zero. The difference in value between the smallest representable normalized number closest to zero and zero is much larger than the difference between the last two smallest adjacent representable normalized numbers. Rounding to zero is thus seen as a big jump. Subnormal numbers populate this chasm with values that provide a more gradual transition to zero. Their representation is such that most significant bits of the significand can be zero, hence the name *subnormal*. As the value moves toward zero, more and more of the significant bits of the significand become zero. There is obviously a decrease in precision for subnormal numbers, the exponent already having its minimum value and there being fewer representable bits available in the significand.

For implementations that support subnormals, the test `x != y` implies that `(x-y) != 0` (which need not be true if subnormals are not supported and enables code such as `if (x != y) z=1/(x-y)` to be written).

Floating-point infinities are used to handle overflows in arithmetic operations. The presence of a sign bit means that implementations often include representations for positive and negative infinity. The infinity values (positive and negative) are not a finite floating-point value. An infinity returned as the result of a subexpression does not necessarily percolate through the remainder of the evaluation of an expression. For instance, a nonzero value divided by infinity returns a zero value.

The `fpclassify` macro returns information on the classification of a floating-point value.

C90

The C90 Standard does not mention these kinds of floating-point numbers. However, the execution environments for C90 programs are likely to be the same as C99 in terms of their support for IEC 60559.

C++

The C++ Standard does not go into this level of detail.

Other Languages

The class `java.lang.Float` contains the members:

```
1  public static final float NEGATIVE_INFINITY = -1.0f/0.0f;
2  public static final float POSITIVE_INFINITY = 1.0f/0.0f;
3  public static final float NaN = 0.0f/0.0f;
```

The class `java.lang.Double` contains the same definitions, but using literals having type **`double`**.

Common Implementations

Handling subnormals in hardware would introduce a lot of complexity and because they are expected to occur very infrequently[700] operations on them are often handled in software (which the hardware traps to when such a value is encountered). In applications where subnormals are quiet common the overhead of software implementation can have a huge impact on performance.[815]

The first digit of a normalized floating-point number is always 1. The IEC 60559 Standard makes use of this property by not holding the 1 in the stored value. An IEC 60559 single-precision, 23-bit significand actually represents 24 bits, because there is an implicit leading digit with value 1. How is zero represented? A significand with all bits zero does not represent a value of zero because of the implicit, leading 1. To represent a value of zero, one of the values of the exponent is required (all bits zero in both the significand and the biased exponent is used).

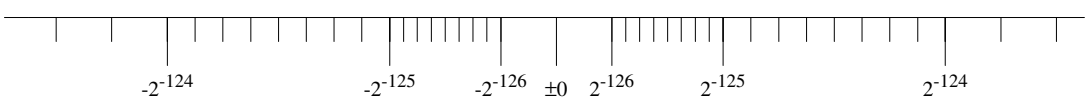

Figure 338.1: Range of normalized numbers about zero, including subnormal numbers.

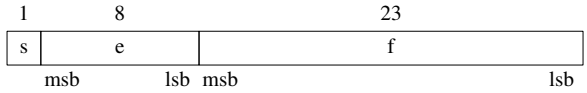

Figure 338.2: Single-precision IEC 60559 format.

guard digit

One of the consequences of having an implicit leading digit is that the significand needs to right-shifted by one digit (and the leading 1 used to fill the vacated bit) before any operations can be performed on it. This shift operation would remove one (binary) digit of accuracy unless the least significant digit was saved. The IEC 60559 Standard specifies that implementations use a so-called *guard digit* to hold this shifted value, preventing accuracy from being lost. Before returning the result of an arithmetic operation, the significand is left-shifted. This guard digit is described here because there are some implementations that do not support it (Cray is well-known for having some processors that don't).

Other information that needs to be maintained by a conforming IEC 60559 implementation, during arithmetic operations on floating-point types, include a *rounding digit* and a *sticky bit*. Carter[206] discusses some of the consequences of implementations that support a subset of this information.

Table 338.1: Format Parameters of IEC 60559 representation. All widths measured in bits. Intel's *extended-precision* format is a conforming IEC 60559 format derived from that standards *extended double-precision* format.

Parameter	Single	Single Extended	Double	Double Extended	Intel x86 Extended
Precision, p, (apparent mantissa width)	24	32	53	64	64
Actual mantissa width	23	31	52	63	64
Mantissa's MS-Bit	hidden bit	unspecified	hidden bit	unspecified	explicit bit
Decimal digits of precision, $p/\log_2(10)$	7.22	9.63	15.95	19.26	19.26
E_{max}	+127	+1023	+1023	+16383	+16383
E_{min}	-126	-1022	-1022	-16382	-16382
Exponent bias	+127	unspecified	+1023	unspecified	+16383
Exponent width	8	11	11	15	15
Sign width	1	1	1	1	1
Format width (9) + (8) + (4)	32	43	64	79	80
Maximum value, $2^{E_{max}+1}$	3.4028E+38	1.7976E+308	1.7976E+308	1.1897E+4932	1.1897E+4932
Minimum value, $2^{E_{min}}$	1.1754E-38	2.2250E-308	2.2250E-308	3.3621E-4932	3.3621E-4932
Denormalized minimum value, $2^{E_{min}-(4)}$	1.4012E-45	1.0361E-317	4.9406E-324	3.6451E-4951	1.8225E-4951

Unnormalized numbers can only occur in the extended formats. No extended formats, known to your author, uses unnormals. While the Intel 80387 (and later) double-extended format allows for unnormals, they are treated as signaling NaNs. The early Intel 80287 (produced before the IEEE-754 standard was finalized) used unnormals. The IBM S/360 supports them, but does not produce them as the result of any normalized floating-point operation. Use of an unnormalized representation can be used to provide an indication of the degree of precision available in a value[62] and reduce the time taken to perform floating-point operations. Unnormalized numbers are usually created by poor quality implementations.

Table 338.2: List of some results of operations on infinities and NaNs. Also see: "Expression transformations" in annex F.8.2 of the C Standard.

$Operation \Longrightarrow Result$	$Operation \Longrightarrow Result$
$x/(+\infty) \Longrightarrow +0$	$x/(+0) \Longrightarrow +\infty$
$x/(-\infty) \Longrightarrow -0$	$x/(-0) \Longrightarrow -\infty$
$(+\infty) + x \Longrightarrow +\infty$	$x + NaN \Longrightarrow NaN$
$(+\infty) \times x \Longrightarrow +\infty$	$\infty \times 0 \Longrightarrow NaN$
$(+\infty)/x \Longrightarrow +\infty$	$0/0 \Longrightarrow NaN$
$(+\infty) - (+\infty) \Longrightarrow NaN$	$NaN - NaN \Longrightarrow NaN$

Some processors do not support subnormal numbers in hardware. A solution sometimes adopted is for an occurrence of such a value to cause a trap to a software routine that handles it. On such processors operations on subnormals can execute significantly more slowly than on normalized values.[316]

- The Cray T90 and IBM S/360 do not handle subnormal numbers in hardware or software. Such a value input to a floating-point functional unit is forced to zero. Underflow results from arithmetic operations are forced to zero. Such an implementation choice is sometimes made to favor performance over accuracy.

- The AMD 3DNow! extensions[350] to the Intel x86 instruction set include support for an IEC 60559 single-precision, floating-point format that does not include NaNs, infinities, or subnormal numbers.

- The Intel SSE extensions[627] to the Intel x86 instruction set include a status bit that, when set, causes subnormal numbers to be treated as zero. Setting this status bit speeds up operations and can be used by those applications where the loss of accuracy is not significant.

- The Motorola DSP563CCC[967] does not support NaNs or infinities. Floating-point arithmetic operations do not overflow to infinity; they saturate at the maximum representable value.

- The HP Precision Architecture[571] supports a quad format (113-bit precision with a 15-bit exponent).

Example

```
1  #include <float.h>
2  #include <stdio.h>
3
4  double x, y;
5
6  int main(void)
7  {
8  double inverse;
9
10 if ((DBL_MIN / 2.0) > 0.0)
11    printf("This implementation supports extended precision or subnormal numbers\n");
12 if ((double)(DBL_MIN / 2.0) > 0.0)
13    printf("This implementation supports subnormal numbers\n");
14
15 if (x != y) /* Only works if subnormals are supported. */
16    inverse = 1.0 / (x - y);
17 }
```

Table 338.3: Example of gradual underflow. * Whenever division returns an inexact tiny value, the exception bit for underflow is set to indicate that a low-order bit has been lost.

NaN

A *NaN* is an encoding signifying Not-a-Number.

Commentary

The encoding for NaNs specified in IEC 60559 requires them to have the maximum exponent value (just like infinity) and a nonzero significand. There is no specification for how different kinds of NaN might be represented. In IEC 60559 the expression `0.0/0.0` returns a NaN value.

A NaN always compares unequal to any other value, even the identical NaN. Such a comparison can also lead to an exception being raised.

Rationale

However, C support for signaling NaNs, or for auxiliary information that could be encoded in NaNs, is problematic. Trap handling varies widely among implementations. Implementation mechanisms may trigger signaling NaNs, or fail to, in mysterious ways. The IEC 60559 floating-point standard recommends that NaNs propagate; but it does not require this and not all implementations do. And the floating-point standard fails to specify the contents of NaNs through format conversion. Making signaling NaNs predictable imposes optimization restrictions that anticipated benefits don't justify. For these reasons this standard does not define the behavior of signaling NaNs nor specify the interpretation of NaN significands.

Rationale

IEC 60559 (International version of IEEE-754) requires two kinds of NaNs: Quiet NaNs and Signaling NaNs. Standard C only adopted Quiet NaNs. It did not adopt Signaling NaNs because it was believed that they are of too limited utility for the amount of work required.

C90

This concept was not described in the C90 Standard.

C++

Although this concept was not described in C90, C++ does include the concept of NaN.

18.2.1.2p34 Template class numeric_limits

```
static const bool has_quiet_NaN;
```

True if the type has a representation for a quiet (non-signaling) "Not a Number."[193)]

18.2.2.1p37

```
static const bool has_signaling_NaN;
```

True if the type has a representation for a signaling "Not a Number."[194)]

Other Languages

As standards for existing languages are revised, they are usually updated to support the operations and properties described in IEC 60559.

Common Implementations

Support for NaNs has been available on a variety of hardware platforms and therefore C90 implementations since the late 1980s. Some implementations encode additional diagnostic information in the don't care bits of a NaN representation (e.g., the operation on the Apple PowerPC which created the NaN provides the offset of instruction that created it).

Coding Guidelines

Additional information encoded in a NaN value by an implementation may be of use in providing diagnostic information. The availability of such information and its encoding is not specified by the standard and such usage is making use of an extension.

Example

```
1  double d_max(double val1, double val2)
2  {
3  /*
4   * IEC 60559 requires an exception to be raised if
5   * either of the following operands is a NaN.
6   */
7  if (val1 < val2) /* Result is 0 (false) if either operand is a NaN. */
8     return val2;
9  else
10    return val1;
11 }
```

---

340 A *quiet NaN* propagates through almost every arithmetic operation without raising a floating-point exception;

NaN raising an exception

Commentary

Once a calculation yields a result of quiet NaN all other arithmetic operations having that value as an operand also return a result of quiet NaN. The advantage of the quiet NaN value is that it can be tested for explicitly at known points in a program chosen by the developer. There disadvantage is that the developer has to insert the checks explicitly. A quiet NaN can still cause an exception to be raised. If it is the operand of a relational or equality operator, IEC 60559 requires that an invalid floating-point exception be raised.

C90

The concept of NaN was not discussed in the C90 Standard.

C++

18.2.1.2p34

```
static const bool has_quiet_NaN;
```

True if the type has a representation for a quiet (non-signaling) "Not a Number."[193)]

Common Implementations

Most, if not all, implementations represent quiet NaN by setting the most significant bit of a value's significand.

Coding Guidelines

Checking the result of all floating-point operations against NaN enables problems to be caught very quickly, while a lot of context information is available. However, such pervasive checking could complicate the source significantly, may require context information to be passed back through calling functions, and may impact performance.

It is often more practical to view the implementation of some algorithm, involving floating-point values, as an atomic entity from the point of view of NaN handling. In this scenario the implementation of the algorithm does no checking against NaN. However, it is the responsibility of the user of that function, or inlined source code, to check that the input values are valid and to check that the output values are valid. This approach has the advantage of simplicity and efficiency, but the potential disadvantage of loss of context information on exactly where any NaNs were generated.

Designers of third-party libraries need to consider how information is passed back to the caller. A function may be capable of handling the complete range of possible floating-point values, plus the infinities. But NaN is likely to be an invalid input value. Provided that such an input value does not take part in any comparison operations, it may be possible to allow this value to percolate through to the result. If the input value does appear as the operand of a comparison operator, the possibility of a signal being raised means that either the floating-point comparison macros need to be used or an explicit check for NaN needs to be made.

Example

```
1  #include <math.h>
2
3  enum FLT_CMP {cmp_less, cmp_greater, cmp_equal, cmp_nan};
4
5  enum FLT_CMP cmp_float(float val1, float val2)
6  {
7  if (isnan(val1) || isnan(val2))
8     return cmp_nan;
9
10 if (val1 < val2)
11    return cmp_less;
12 if (val1 > val2)
13    return cmp_greater;
14
15 return cmp_equal;
16 }
```

---

a *signaling NaN* generally raises a floating-point exception when occurring as an arithmetic operand.[17)] 341

Commentary

A signaling NaN raises an exception at the point it is created. A signaling NaN cannot be generated from any arithmetic operation. Signaling NaNs can only be generated by extensions outside those specified in C99, and then only by the `scanf` and `strtod` functions. A signaling NaN cannot be generated from an initialization of an object with static storage duration (see annex F.7.5). Assignment of a signaling NaN may, or may not, raise an exception. It depends on how the implementation copies the value and the checks made by the host processor when objects are moved.

There is no requirement that any of the floating-point exceptions cause a signal to be raised. It is permissible for an implementation's behavior, when a signaling NaN is triggered, to crash the program (with

no method being provided to prevent this from occurring). However, if floating-point exceptions are turned into signals, the behavior should be equivalent to `raise(SIGFPE)`.

Signaling NaNs have the advantage of removing the need for the developer to insert explicit checks in the source code. Their disadvantage is that they can be difficult to recover from gracefully. The code that generated the exception may be unknown to the function handling the exception, and returning to continue execution within the previous program flow of control can be almost impossible. The state of the abstract machine is largely undefined after the signal is raised and the standard specifies that the behavior is undefined.

The `fegetexceptflag` function returns information that may enable a program to distinguish between an exception raised by a signaling NaN and an exception raised by other floating-point operations.

C++

```
static const bool has_signaling_NaN;
```

18.2.1.2p37

True if the type has a representation for a signaling "Not a Number."[194]

Common Implementations

Most, if not all, implementations represent signaling NaN by a zero in the most significant bit of a value's significand. Some processors (e.g., the Motorola 68000 family[968]) have configuration flags that control whether the signaling NaNs raise an exception.

Coding Guidelines

If a choice is available, is it better to use quiet NaNs or signaling NaNs? They each have their advantages and disadvantages. The exclusive use of signaling NaNs guarantees that, if one is an operand of an operator that treats it as a floating number (except assignment), a signal will be raised. Using the different kinds of NaNs requires use of different control flow structuring of a program. The type of application and how it handles data will also be important factors in selecting which kind of NaN is best suited. The choice, if one is available, of the type of NaN to use is a design issue that is outside the scope of these coding guidelines. Hauser discusses these issues in some detail.[553]

Example

```
#include <setjmp.h>
#include <signal.h>
#include <stdio.h>

static jmp_buf start_again;

void handle_sig_NaN(int sig_info)
{
longjmp(start_again, 2);
}

void calculate_something(void)
{ /* ... */ }

int main(void)
{
if (setjmp(start_again))
   printf("Let's start again\n");
signal(SIGFPE, handle_sig_NaN);

calculate_something();
}
```

signed of non-numeric values

An implementation may give zero and non-numeric values (such as infinities and NaNs) a sign or may leave them unsigned. 342

Commentary

This sentence was added by the response to DR #218, which also added the following wording to the Rationale.

Rationale

The committee has been made aware of at least one implementation (VAX and Alpha in VAX mode) whose floating-point format does not support signed zeros. The hardware representation that one thinks would represent `-0.0` is in fact treated as a non-numeric value similar to a NaN. Therefore, `copysign(+0.0,-1.0)` returns `+0.0`, not the expected `-0.0`, on this implementation. Some places that mention (or might have) signed zero results and the sign might be different than you expect:

The complex functions, in particular with branch cuts;

```
ceil()
conj()
copysign()
fmod()
modf()
fprintf()
fwprintf()
nearbyint()
nextafter()
nexttoward()
remainder()
remquo()
rint()
round()
signbit()
strtod()
trunc()
wcstod()
```

Underflow: In particular: `ldexp()`, `scalbn()`, `scalbln()`.

Wherever such values are unsigned, any requirement in this International Standard to retrieve the sign shall produce an unspecified sign, and any requirement to set the sign shall be ignored. 343

Commentary

This sentence was added by the response to DR #218.

footnote 15

Commentary

types 472

Clause 6.2.5 deals with types.

footnote 16

16) The floating-point model is intended to clarify the description of each floating-point characteristic and does not require the floating-point arithmetic of the implementation to be identical. 345

Commentary

Most translators take what they are given in terms of processor hardware support, as the starting point for implementing floating-point arithmetic. This wording is intended to justify just such a decision.

C++

The C++ Standard does not explicitly describe a floating-point model. However, it does include the template class `numeric_limits`. This provides a mechanism for accessing the values of many, but not all, of the characteristics used by the C model to describe its floating-point model.

Common Implementations

Most modern floating-point hardware is based on the IEEE-754 (now IEC 60559) standard. Some supercomputer designers made the design decision of improved performance over accuracy (which was degraded) for some arithmetic operations. Users of such machines tend to be supported by knowledgeable developers who take care to ensure that the final, applications answers are within acceptable tolerances. Users in a mass market have no such backup service and the IEEE floating-point standards have therefore aimed at providing reliable accuracy.

For economic reasons many DSPs implement fixed-point arithmetic rather than a floating-point. In some cases, because of the application-specific nature of the problems they are used in, the parameters (such as implied decimal point) of the fixed-point model do not need to be flexible; different processors can use different parameters. The C99 Standard does not support fixed-point data types, although they are described in a Technical Report.[657]

One solution to implementing floating-point types on processors that support fixed-point types is to convert the source containing floating-point data operations to make calls to a fixed-point library. A tool that automatically performs such a conversion is described by Kum, Kang, and Sung.[785] It works by first monitoring the range of values taken on by a floating-point object. This information is then used to perform the appropriate scaling of values in the transformed source. An analysis of the numerical errors introduced by such a conversion is given in.[1]

The Motorola 68000 processor[968] supports a packed decimal real format. All digits are represented in base 10 and are held one per byte. The 24-byte types consists of a 3-digit exponent, a 17-digit significand, two don't care bytes, a byte holding the two separate sign bits (one for the exponent, the other for the mantissa), and an extra exponent (for overflows that can occur when converting from the extended-precision real format to the packed decimal real format). The Motorola 68000 processor extended precision floating-point type contains 16 don't care bits in its object representation.

Coding Guidelines

The availability of IEC 60559 Standard compatible floating-point support is sufficiently widespread that concern for implementations that don't support it is not considered to be sufficient to warrant a guideline recommendation. Of greater concern is the widespread incorrect belief, among developers, that conformance to IEC 60559 guarantees the same results. This issue is discussed elsewhere. 29 IEC 60559

Testing scripts that operate by differencing the output from a program with its expected output, often show differences between processors when floating-point values are compared. The extent to which these differences are significant can only be decided by developers. A percentage change in a value is often a more important consideration that its absolute change. For small values close to zero it might also be necessary to take into account likely error bounds, which can lead to small values exhibiting a large percentage change that is not significant because the absolute difference is still within the bounds of error.

---

346 The accuracy of the floating-point operations (`+`, `-`, `*`, `/`) and of the library functions in `<math.h>` and `<complex.h>` that return floating-point results is implementation-defined , as is the accuracy of the conversion between floating-point internal representations and string representations performed by the library routine in `<stdio.h>`, `<stdlib.h>` and `<wchar.h>`. floating-point operations accuracy

Commentary

Accuracy has two edges— poor accuracy and excessive accuracy. The standard permits (but does not require) an implementation to return as little as one digit of accuracy, after the decimal point, for the result of arithmetic operations. In practice poor levels of accuracy are unlikely to be tolerated by developers. From

the practical point of view, it is possible to achieve accuracies of 1 ULP. A more insidious problem, in some cases, can be caused by additional accuracy; for instance, on a host that performs floating-point operations in some extended precision:

```
1  #include <stdio.h>
2
3  extern double a, b;
4
5  void f(void)
6  {
7  double x;
8
9  x = a + b;
10 if (x != a + b)
11    printf("x != a + b\n");
12 }
```

any extended precision bits will be lost in the first calculation of a+b when it is assigned to x. The result of the second calculation of a+b may be held in a working register at the extended precision and potentially contain additional value bits not held in x, the result of the equality test then being false.

Accuracy does not just relate to individual operations. The operator sequence of multiply followed by addition is sufficiently common that some vendors have created a fused multiply/add instruction. Such fused instructions not only execute more quickly than the sum of two instruction timings, but often deliver results containing greater accuracy (than would have been obtained by executing separate instructions performing the same mathematical operations).

How is the accuracy of a floating-point operation measured? There are two definitions in common use—relative error and units in the last place (ULP).

1. Relative error is the difference between the two values divided by the actual value; for instance, if the actual result of a calculation should be 3.14159, but the result obtained was 3.14×10^0, the relative error is $0.00159/3.14159 \Rightarrow 0.0005$.

ULP

2. If the floating-point number z is approximated by $d.d.d\ldots d\times b^e$ (where b is the base and p the number of digits in the significand), the ULP error is $\mid d.d.d\ldots d-(z/b^e)\mid b^{p-1}$. When a floating-point value is in error by n ULP the number of contaminated (possibly incorrect) digits in that value is $\log_b n$. For IEC arithmetic b is 2 and each contaminated digit corresponds to a bit in the representation of the value. See Muller[979] for a comprehensive discussion. The error in ULPs depends on the radix and the precision used in the representation of a floating-point number, but not the exponent. For instance, if the radix is 10 and there are three digits of precision, the difference between 0.314e+1 and 0.31416e+1 is 0.16 ULPs, the same as the difference between 0.314e+10 and 0.31416e+10. When the two numbers being compared span a power of the radix, the two possible error calculations differ by a factor of the radix. For instance, consider the two values 9.99e2 and 1.01e3, with a radix of 10 and three digits of precision. These two values are adjacent to the value 1.00e3, a power of the radix. If 9.99e2 is the correct value and 1.01e3 is the computed value, the error is 11 ULPs. But, if 1.01e3 is the correct value and 0.999e3 is the computed value, then the error is 1.1 ULPs.

A floating-point operation usually delivers more bits of accuracy than are held in the representation. The least significant digit is the result of rounding those other digits. A possible error of 0.5 ULP is inherent in any floating-point operation. If a variety of calculations all have the same relative error, their error expressed in ULP can vary (*wobble* is the proper technical term) by a factor of b. Similarly, if a set of calculations all have the same ULP, their relative error can vary by a factor of b.

Several programs have been written to test the accuracy of a processor's floating-point operations.[1204] Various mathematical identities can be used, making it possible for these programs to be written in a high-level language (many are written in C) and be processor-independent. For a description of the latest and most

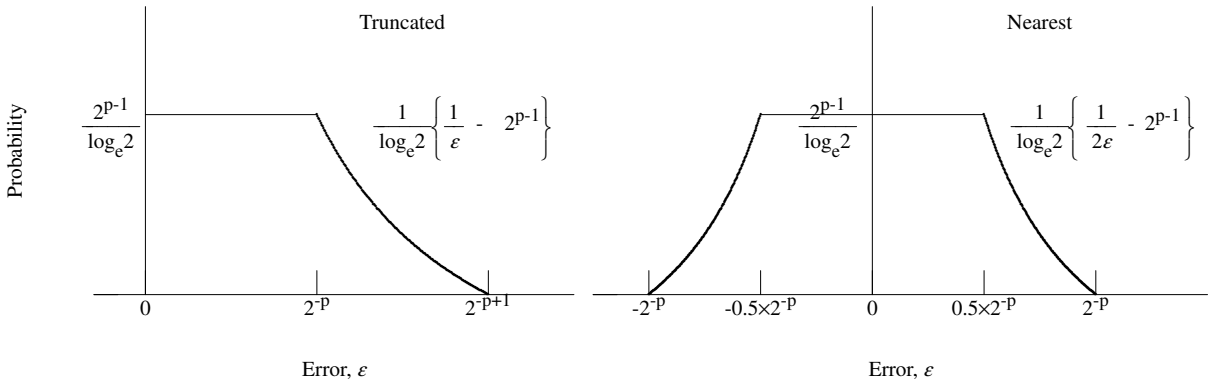

Figure 346.1: Probability of a floating-point operation having a given error (ϵ) for two kinds of rounding modes (truncated and to-nearest); p is the number of digits in the significand. Adapted from Tsao.[778]

thorough testing tool, as of 2001, see Verdonk, Cuyt, and Verschaeren.[1418] For a detailed, mathematical discussion of floating-point accuracy, see Priest.[1123]

The basic formula for error analysis of an operation, assuming $fl(a\ op\ b)$ does not overflow or underflow, is: error analysis

$$fl(a\ op\ b) = (1+\epsilon)\times(a\ op\ b) \tag{346.1}$$

where: $(a\ op\ b)$ is the exact result of the operation, where op is one of $+$, $-$, $*$ and $/$; $fl(a\ op\ b)$ is the floating-point result; $|\ \epsilon\ | \leq macheps$.

To incorporate underflow (but not overflow), we can write:

$$fl(a\ op\ b) = (1+\epsilon) * (a\ op\ b) + \eta \tag{346.2}$$

where:

$$|\ \eta\ | \leq macheps * underflow\ threshold \tag{346.3}$$

On machines that do not implement gradual underflow (including some IEEE machines, which have an option to perform flush-to-zero arithmetic instead), the corresponding error formula is:

$$|\ \eta\ | \leq underflow\ threshold \tag{346.4}$$

(i.e., the error is $1/macheps$ times larger).

Tsao[778] performed an analysis of the distribution of round-off errors, based on Benford's law,[574] to estimate the probability of ϵ having particular values.

Because of the practical difficulty involved in defining a uniform metric that all vendors would be willing to follow (just computing the accuracy reliably could be a significant), and because the importance of floating point accuracy differs greatly among users, the standard allows a great deal of latitude in how an implementation documents the accuracy of the real and complex floating point operations and functions. Rationale

. . .

If an implementation documents worst-case error, there is no requirement that it be the minimum worst-case error. That is, if a vendor believes that the worst-case error for a function is around 5 ULPs, they could document it as 7 ULPs to be safe.

The Committee could not agree on upper limits on accuracy that all conforming implementations must meet, for example, "addition is no worse than 2 ULPs for all implementations.". This is a quality-of-implementation issue.

Implementations that conform to IEC 60559 have one half ULP accuracy in round-to-nearest mode, and one ULP accuracy in the other three rounding modes, for the basic arithmetic operations and square root. For other floating point arithmetics, it is a rare implementation that has worse than one ULP accuracy for the basic arithmetic operations.

. . .

The C99 Committee discussed the idea of allowing the programmer to find out the accuracy of floating point operations and math functions during compilation (say, via macros) or during execution (with a function call), but neither got enough support to warrant the change to the Standard. The use of macros would require over one hundred symbols to name every math function, for example, `ULP_SINF`, `ULP_SIN`, and `ULP_SINL` just for the real-valued sin function. One possible function implementation might be a function that takes the name of the operation or math function as a string, `ulp_err("sin")` for example, that would return a double such as 3.5 to indicate the worst case error, with `-1.0` indicating unknown error. But such a simple scheme would likely be of very limited use given that so many functions have accuracies that differ significantly across their domains. Constrained to worst-case error across the entire domain, most implementations would wind up reporting either unknown error or else a uselessly large error for a very large percentage of functions. This would be useless because most programs that care about accuracy are written in the first place to try to compensate for accuracy problems that typically arise when pushing domain boundaries; and implementing something more useful like the worst case error for a user-specified partition of the domain would be excessively difficult.

DECIMAL_DIG macro

Some of the issues of how representation used can impact accuracy is discussed elsewhere. The issue of the accuracy of decimal string to/from *binary* (non-decimal) floating-point conversions was raised by DR #211. The resolution of this DR resulted in the change of wording highlighted in the preceding C99 sentence.

C90

In response to DR #063 the Committee stated (while the Committee did revisit this issue during the C99 revision of the C Standard, there was no change of requirements):

DR #063

Probably the most useful response would be to amend the C Standard by adding two requirements on implementations:

Require that an implementation document the maximum errors it permits in arithmetic operations and in evaluating math functions. These should be expressed in terms of "units in the least-significant position" (ULP) or "lost bits of precision."

Establish an upper bound for these errors that all implementations must adhere to. The state of the art, as the Committee understands it, is:

correctly rounded results for arithmetic operations (no loss of precision)

1 ULP for functions such as sqrt, sin, and cos (loss of 1 bit of precision)

4–6 ULP (loss of 2–3 bits of precision) for other math functions.

Since not all commercially viable machines and implementations meet these exacting requirements, the C Standard should be somewhat more liberal.

The Committee would, however, suggest a requirement no more liberal than a loss of 3 bits of precision, out of kindness to users. An implementation with worse performance can always conform by providing a more

conservative version of **<float.h>**, *even if that is not a desirable approach in the general case. The Committee should revisit this issue during the revision of the C Standard.*

C++

The C++ Standard says nothing on this issue.

Common Implementations

The accuracy of floating-point operations is usually at the mercy of the host floating-point processor hardware. Many implementations try to achieve an accuracy of 1 ULP in their floating-point operations and **<math.h>** 346 ULP library functions.

Use of the logarithmic number system, to represent real numbers, enables multiplication and division to be performed with no rounding error.[254]

There is an Open Source implementation of the IEEE-754 standard available in software.[552] This provides floating-point operations to a known, high level of accuracy, but somewhat slowly.

In IEC 60559 arithmetic the floating-point result $fl(a\ op\ b)$ of the exact operation $(a\ op\ b)$ is the nearest floating-point number to $(a\ op\ b)$, breaking ties by rounding to the floating-point number whose least significant bit is zero (an *even* number). Taking underflow into account requires an additional term to be added to the right side of the basic equation given earlier. For processors that make use of gradual underflow the value is bounded: $\mid \epsilon \mid \leq macheps \times underflow\_threshold$. On machines that do not implement gradual underflow (including some IEC 60559 base processors, which have an option to perform flush-to-zero arithmetic instead), the corresponding error formula is:

$$\mid \epsilon \mid \leq underflow\ threshold \tag{346.5}$$

Cray had a line of processors (the C90 and Cray 2) on which speed of execution was given priority over accuracy. For this processor the error analysis formula for addition and subtraction was:

$$fl(a \pm b) = ((1 + \epsilon_1) * a) \pm ((1 + \epsilon_2) * b) \tag{346.6}$$

Subtracting two values that are very close to each other can lead to a much larger than normal, in IEC 60559, error. On some Cray processors divide was emulated by multiplying by a reciprocal, leading to $x/x \neq 1.0$ in some cases.

The AMD 3DNow! extensions[350] to the Intel x86 processor include a reciprocal instruction that delivers a result accurate to 14 bits (instead of the normal 23 bits). Developers can choose, with suitable translator support, to accept this level of accuracy or to have two additional instructions generated which return a result more slowly, but is accurate to 1 ULP.

The accuracy of the trigonometric functions $\sin$, $\cos$, and $\tan$ depends on how well their argument is reduced, modulo $\pi/2$, and by the approximations used on the small domain near zero. Some implementations do a very poor job of argument reduction, so values near a multiple of $\pi/2$ often have few, if any, bits correct.[1009]

The Intel x86 processor family contains an instruction for computing the sine (and cosine and tangent) of its operand. This instruction requires the absolute value of its operand, in radians, to be less than 2^{63}. Values outside this range are returned as the result of the instruction and a processor flag, C2, is set. Such a result is a surprise in the sense that `sin` (and sine and tangent) is expected to return a value between -1 and 1.

Another accuracy problem with the Intel x86 instruction for computing the sine (and cosine) is accuracy near π ($\pi/2$ for cosine). When using 64-bit mode the 53-bit significand result may only be accurate in the first 15 bits and the 80-bit mode the 64-bit significand result may only be accurate in the first 5 bits (the

problem is caused by insufficient accuracy, 68 bits, in the approximation of π used; 126 bits are actually needed, and used by AMD in their x86 processors).

Given the difficulty in performing mathematical error analysis on algorithms, let alone coded implementations running on imperfect hardware, one solution is to have the translator generate machine code to estimate round-off errors during program execution. One such translator, Fortran-based, has been developed.[130]

double rounding

Processors that perform extended-based arithmetic operations do not always produce more accurate results. There is a source of error known as *double rounding* that occurs when the rounding mode is round-to-nearest. In the default precision mode, an extended-based system will initially round the result of an arithmetic operation to extended double-precision. If that result needs to be stored in double-precision, it has to be rounded again. The combination of these two rounding operations can yield a value that is different from what would have been obtained by rounding the result of the arithmetic operation directly to double-precision. This can happen when the result as rounded, to extended double-precision, is a *halfway case* (i.e., it lies exactly halfway between two double-precision numbers) so the second rounding is determined by the round-ties-to-even rule. If this second rounding rounds in the same direction as the first, the net rounding error will exceed half a unit in the last place. It can be shown[422] that the sum, difference, product, or quotient of two p-bit numbers, or the square root of a p-bit number, rounded first to q bits and then to p bits gives the same value as rounding the result of the operation just once to p bits provided $q \geq 2p + 2$.

Double-rounding can also prevent execution-time measurement of rounding errors in calculations. The formula:

```
1  t = s + y;
2  e = (s - t) + y;
```

recovers the roundoff error in computing `t`, provided double-rounding does not occur.

Coding Guidelines

There are three sources of inaccuracies in the output from a program that uses floating-point data types. Those caused by the implementation, those intrinsic to the algorithm used, and those caused by how the developer coded the algorithm. For instance, assume that `raise_to_power(valu, power)` is a function that returns `valu` raised to `power` (e.g., `raise_to_power(3.0, 2)` returns 9.0). If we want to raise a value to a negative power, the obvious solution is to use `raise_to_power(1.0/valu, power)`. However, there in a rounding error introduced by the calculation `1.0/valu` that will be compounded each time it is used inside the library function. The expression `1.0/raise_to_power(valu, power)` avoids this compounding of the rounding error; it has a single rounding error introduced by the final divide.

Minimizing the rounding error in floating-point calculations can require some theoretical knowledge. For instance, the simple loop for summing the elements of an array:

```
1  double sum_array(int num_elems, double a[num_elems])
2  {
3  double result = 0.0;
4
5  for (int a_index=0; a_index < num_elems; a_index++)
6     result += a[a_index];
7
8  return result;
9  }
```

can have the rounding error in the final result significantly reduced by replacing the body of the function by the Kahan summation formula:[500]

```
1  double sum_array(int num_elems, double a[num_elems])
2  {
3  double result = a[0],
4         C = 0.0,
```

```
        T, Y;

for (int a_index=1; a_index < num_elems; a_index++)
   {
   Y = a[a_index] - C;
   T = result + Y;
   C = (T - result) - Y;
   result = T;
   }

return result;
}
```

which takes account of the rounding properties of floating-point operations to deliver a final result that contains significantly less rounding error than the simple iterative addition. The correct operation of this summation formula also requires the translator to be aware that algebraic identities that might apply to integer objects, allowing most of the body of the loop to be optimized away, do not apply to floating-point objects.

Usage

In theory it is possible to measure the accuracy required/expected by an application. However, it is not possible to do this automatically — it requires detailed manual analysis. Consequently, there are no usage figures for this sentence (because no such analyses have been carried out by your author for any of the programs in the measurement set).

---

347 The implementation may state that the accuracy is unknown.

Commentary

It is not always possible for an implementation to give a simple formula for the accuracy of its floating-point arithmetic operations, or the accuracy of the **<math.h>** functions. A variety of different implementation techniques may be applied to each floating-point operator[1024, 1035] and to the **<math.h>** functions. The accuracy in individual cases may be known. But a complete specification for all cases may be sufficiently complex that a vendor chooses not to specify any details.

C++

The C++ Standard does not explicitly give this permission.

Other Languages

Most languages don't get involved in this level of detail. However, Ada specifies a sophisticated model of accuracy requirements on floating point operations.

Common Implementations

No vendors known to your author state that the accuracy is unknown.

Coding Guidelines

How such a statement in an implementation's documentation should be addressed is a management issue and is outside the scope of these guidelines.

---

348 All integer values in the **<float.h>** header, except **FLT_ROUNDS**, shall be constant expressions suitable for use in **#if** preprocessing directives;

float.h suitable for #if

Commentary

This is a requirement on the implementation. It is more restrictive than simply requiring an integer constant expression. The cast and **sizeof** operators cannot appear in **#if** preprocessing directives, although they can appear within a constant expression.

FLT_ROUNDS may be an expression whose value varies at execution time, through use of the `fesetround` library function.

C90

Of the values in the **<float.h>** *header, FLT_RADIX shall be a constant expression suitable for use in* **#if** *preprocessing directives;*

C99 requires a larger number of values to be constant expressions suitable for use in a **#if** preprocessing directive and in static and aggregate initializers.

C++

The requirement in C++ only applies if the header **<cfloat>** is used (17.4.1.2p3). While this requirement does not apply to the contents of the header **<float.h>**, it is very likely that implementations will meet it and no difference is flagged here. The namespace issues associated with using **<cfloat>** do not apply to names defined as macros in C (17.4.1.2p4)

17.4.4.2p2 *All object-like macros defined by the Standard C library and described in this clause as expanding to integral constant expressions are also suitable for use in* **#if** *preprocessing directives, unless explicitly stated otherwise.*

The C++ wording does not specify the C99 Standard and some implementations may only support the requirements specified in C90.

Common Implementations

This statement was true of some C90 implementations. But, there were many implementations that defined the *_MAX macros in terms of external variables, so the *_MAX macros were not usable in static or aggregate initializers. Exact figures are hard to come by, but perhaps 50% of C90 implementations did not use constant expressions.[1379]

Coding Guidelines

It will take time for implementations to migrate to C99. The extent to which a program relies on a C99 translator being available is outside the scope of these coding guidelines.

Example

```
1  #include <float.h>
2
3  #if FLT_RADIX == 10 /* A suitable constant in C90 and C99. */
4  #endif
5
6  #if FLT_DIG == 5 /* Not required to be conforming in C90. */
7  #error This is not a C99 conforming implementation
8  #endif
```

---

all floating values shall be constant expressions. 349

Commentary

This is a requirement on the implementation. It ensures that floating values can be used as initializers for objects defined with static storage duration.

address constant 1341

C90

all other values need not be constant expressions.

This specification has become more restrictive, from the implementations point of view, in C99.

C++

It is possible that some implementations will only meet the requirements contained in the C90 Standard.

Common Implementations

This C99 requirement was met by many C90 implementations.

Coding Guidelines

It will take time for implementations to migrate to C99. The extent to which a program relies on a C99 translator being available is outside the scope of these coding guidelines.

---

350 All except **DECIMAL_DIG**, **FLT_EVAL_METHOD**, **FLT_RADIX**, and **FLT_ROUNDS** have separate names for all three floating-point types.

Commentary

DECIMAL_DIG applies to " . . . the widest supported floating type . . . ". One of the floating types has to be selected; there cannot be three widest types. It is the type **long double**, even if an implementation supports a floating type with more precision as an extension (the standard requires it to be one of the types it specifies, and is silent on the issue of additional floating-point types provided by the implementation, as an extension).

The fact that the three FLT_* macros have a single value for all three floating-point types implies a requirement that the floating-point evaluation method, radix, and rounding behavior be the same for these floating-point types, which is also required in IEC 60559.

C90

Support for DECIMAL_DIG and FLT_EVAL_METHOD is new in C99. The FLT_EVAL_METHOD macro appears to add functionality that could cause a change of behavior in existing programs. However, in practice it provides access to information on an implementation's behavior that was not previously available at the source code level. Implementations are not likely to change their behavior because of this macro, other than to support it.

C++

It is possible that some implementations will only meet the requirements contained in the C90 Standard.

Common Implementations

For those processors containing more than one floating-point unit (e.g., Intel Pentium with SSE extensions,[626] AMD Athlon with 3Dnow!,[350] and PowerPC with AltiVec support[971]) implementations may chose to evaluate some expressions in different units. Such implementations may then support more than one name/value for some of these macros; for instance, the evaluation method each representing the characteristics of a different floating-point unit.

1147 multiply always truncate

---

351 The floating-point model representation is provided for all values except **FLT_EVAL_METHOD** and **FLT_ROUNDS**.

Commentary

That is, the characteristics of the model used to define floating types does not include FLT_EVAL_METHOD or FLT_ROUNDS as one of its parameters. The standard lists the possible values for these macros and their meaning separately. The actual values used are implementation-defined. These two macros correspond to two classes of implementation-defined behavior described by the IEC 60559 Standard.

330 floating types characteristics
354 FLT_EVAL_ME
352 FLT_ROUNDS

The IEC 60559 Standard also allows implementations latitude in how some constructs are performed. These macros give software developers explicit control over some aspects of the evaluation of arithmetic operations.

C90

Support for FLT_EVAL_METHOD is new in C99.

C++

It is possible that some implementations will only meet the requirements contained in the C90 Standard.

Coding Guidelines

Educating developers about the availability of these options and there implications is outside the scope of these coding guidelines. A statement of the form "It is possible to obtain different results, using the same expression, operand values and compiler, between different IEC 60559 implementations or even the same implementation operating in a different mode." might be used as an introductory overview of floating point.

FLT_ROUNDS The rounding mode for floating-point addition is characterized by the implementation-defined value of **FLT_ROUNDS**:[18)] 352

-1 indeterminable
0 toward zero
1 to nearest
2 toward positive infinity
3 toward negative infinity

All other values for **FLT_ROUNDS** characterize implementation-defined rounding behavior.

Commentary

One form of rounding that would be classified as indeterminable is known as ROM-rounding.[781] Here a small number of the least significant bits of the value are used as an index into a table (usually held in ROM on the hardware floating-point unit). The output from this table lookup is appended to the other digits to give the rounded result. In the boundary case where there would normally be a ripple add up through to the next significant bit the result is the same as a round toward zero (thus simplifying the hardware and possible improving performance at the cost of an inconsistent rounding operation for a small percentage of values).

Rounding to zero, also known as *chopping*, occurs when floating-point values are converted to integers. Of the methods listed, it generates the largest rounding error in a series of calculations.

Rounding to nearest has minimum rounding error, of the known methods, in a series of calculations. The C Standard does not specify the result in the case where there are two nearest representable values. The IEC 60559 behavior is to round to the even value (i.e., the value with the least significant bit set to zero).

Rounding to positive and negative infinity is used to implement interval arithmetic. In this arithmetic, values are not discrete points; they are represented as a range, with a minimum and maximum limit. Adding two such intervals, for instance, generates another interval whose lower and upper bounds delimit the possible range of values represented by the addition. Calculating the lower bound requires rounding to negative infinity, the upper bound requires rounding to positive infinity.

FLT_ROUNDS is not required to be an lvalue. It could be an internal function that is called. It is generally assumed, but not required, that the rounding mode used for other floating-point operators is the same as that for addition.

The FENV_ACCESS pragma may need to be used in source that uses the FLT_ROUNDS macro. The value of a particular occurrence of the FLT_ROUNDS macro is only valid at the point at which it occurs. The value of this macro could be different on the next statement (or even within the same expression if it contains multiple calls to the `fesetround` library function).

C++

It is possible that some implementations will only meet the requirements contained in the C90 Standard.

The C++ header **<limits>** also contains the enumerated type:

18.2.1.3

```
namespace std {
  enum float_round_style {
    round_indeterminable       = -1,
    round_toward_zero          = 0,
    round_to_nearest           = 1,
```

```
        round_toward_infinity      = 2,
        round_toward_neg_infinity  = 3
      };
    }
```

which is referenced by the following member, which exists for every specialization of an arithmetic type (in theory this allows every floating-point type to support a different rounding mode):

18.2.1.2p62

Meaningful for all floating point types.

```
static const float_round_style round_style;
```

The rounding style for the type.[206)]

Other Languages

Most other language specifications say nothing on this subject. Java specifies round-to-nearest for floating-point arithmetic.

Common Implementations

On most implementations the rounding mode does not just affect addition. It is applied equally to all operations. It can also control how overflow is handled. Some applications may choose a round-to-zero rounding behavior because overflow then returns a saturated result, not infinity. Most implementations follow the IEC 60559 recommendation and use *to nearest* as the default rounding mode.

698 floating value converted not representable

Almost all processors (the INMOS T800[622] does not) allow the rounding mode of floating-point operations to be changed during program execution (often using two bits in one of the processor control registers). The HP–was DEC– Alpha processor[1247] includes both instructions that take the rounding mode from a setable control register and instructions that encode the floating-point rounding mode within their bit-pattern (a translator can generate either form of instruction). The translator for the Motorola DSP563CCC[967] only supports *round-to-nearest*.

Some of the older Cray processors make use of implementation-defined rounding modes for some operators, resulting in greater than 1 ULP errors.

The HP–was DEC– VAX processor[284] has two rounding modes. Round-to-nearest, with the tie break being to round to the larger of the absolute values (i.e., away from zero, as does the HP 2000 series). The other is called *chopped* (i.e., round toward zero). The HP–was DEC– Alpha processor[1247] contains instructions that emulate this behavior for compatibility with existing code.

Some processors have two sets of floating-point instructions. For instance AMD Athlon processors containing the 3DNow! extensions[350] have instructions that perform operations on IEC 60559 compatible single and double floating-point values. The extensions operate on a single-precision type only and do not support full IEC 60559 functionality (only one rounding mode— underflow saturates to the minimum normalized value or negative infinity; overflow saturates to the maximum normalized value or positive infinity; no support for infinities or NaN as operands). The advantage of using these floating-point instructions is that they operate on two sets of operands at the same time (each operand is two 32-bit floating-point values packed into 64 bits), offering twice the number-crunching rate for the right kind of algorithms.

1147 multiply always truncate

Coding Guidelines

Applications that need to change the rounding mode are rare. For instance, a set of library functions implementing interval arithmetic[229,716] needs to switch between rounding to positive and negative infinity. The C Standard lists the programming conventions that its model of the floating-point environment is based on (in the library section). These conventions can be used by implementation's to limit the number of possible different permutations of floating-point status they need to correctly handle.

Example

Table 352.1: Effect of rounding mode (FLT_ROUNDS taking on values 0, 1, 2, or 3) on the result of a single precision value (given in the left column).

	0	1	2	3
1.00000007	1.0	1.00000012	1.00000012	1.0
1.00000003	1.0	1.0	1.00000012	1.0
-1.00000003	-1.0	-1.0	-1.0	-1.00000012
-1.00000007	-1.0	-1.00000012	-1.0	-1.00000012

floating operands evaluation format

~~The~~ Except for assignment and cast (which remove all extra range and precision), the values of operations with floating operands and values subject to the usual arithmetic conversions and of floating constants are evaluated to a format whose range and precision may be greater than required by the type. 353

Commentary

Operands of both the arithmetic, comparison, and relational operators are subject to the usual arithmetic conversions. Operations that do not cause their operands to be the subject of the usually arithmetic conversions are assignment (both through the assignment operator and the passing of a value as an argument) and casts.

A floating-point expression has both a semantic type (as defined by the usual arithmetic conversion rules) and an evaluation format (as defined by the FLT_EVAL_METHOD). The need for an evaluation format arises because of historical practice and because of how floating-point arithmetic is implemented on some processors. Including floating constants in this list means that, for instance, `0.1f` will be represented using **float** only if FLT_EVAL_METHOD is 0; one guaranteed way of obtaining a **float** representation of this value is:

FLT_EVAL_METHOD [354]

```
1   static const float tenth_f = 0.1f;
```

However, this is not a floating constant (in C, it is in C++).

The wording was changed by the response to DR #290.

C90

6.2.1.5 *The values of floating operands and of the results of floating expressions may be represented in greater precision and range than that required by the type;*

This wording allows wider representations to be used for floating-point operands and expressions. It could also be interpreted (somewhat liberally) to support the idea that C90 permitted floating constants to be represented in wider formats where the usual arithmetic conversions applied.

Having the representation of floating constants change depending on how an implementation chooses to specify FLT_EVAL_METHOD is new in C99.

C++

Like C90, the FLT_EVAL_METHOD macro is not available in C++.

Other Languages

Java requires that floating-point arithmetic behave as if every floating-point operator rounded its floating-point result to the result precision.

Most other language specifications do not get involved in this level of detail.

Common Implementations

Early implementations of C evaluated all floating-point expressions in double-precision. This practice has continued in some implementations because developers have become used to the extra precision in calculations (also some existing code relies on it).

floating-point architectures

Processor designers have taken a number of different approaches to the architecture of hardware floating-point units.

- *Extended based.* Here all floating-point operands are evaluated in an extended format. For instance, the Intel x86 operates on an 80-bit extended floating-point format. Other processors whose arithmetic engine operates on an extended format include the Motorola 6888x and Intel 960.
- *Double based.* Here floating-point operands are evaluated in the double format. Processors whose arithmetic engine operates on double format includes IBM RS/6000 and Cray (which has no IEC 60559 single format at all).
- *Single/double based.* Here the processor instructions operate on floating-point values according to their type. Operations on the single format are often faster than those on double. Processors whose arithmetic engine operates like this include MIPS, SUN SPARC, and HP PA-RISC.
- *Single/double/extended based.* Here the processor provides instructions that can operate on three different floating-point types. Processors whose arithmetic engine operates like this include the IBM/370.

Coding Guidelines

The existence of evaluation formats are a cause for concern (i.e., they are a potential cost). Porting a program, which uses floating-point types, to an implementation that is identical except for a difference in `FLT_EVAL_METHOD` can result in considerably different output.

64 correctly rounded result

Many floating-point expressions are exact, or correctly rounded, when evaluated using twice the number of digits of precision as the data. For instance:

```
1  float cross_product(float w, float x, float y, float z)
2  {
3  return w * x - y * z;
4  }
```

yields a correctly rounded result if the expression is evaluated to the range and precision of type **`double`** (and the type **`double`** has at least twice the precision of the type **`float`**). By a happy coincidence, the developer may have obtained the most accurate result. Writing code that has less dependence of happy coincidences requires more effort:

```
1  float cross_product(float w, float x, float y, float z)
2  {
3  return ((double)w) * x - ((double)y) * z;
4  }
```

These coding guidelines are not intended as an introductory course on the theory and practicalities of coding floating-point expressions. But, it is hoped that readers will be sufficiently worried by the issues pointed out to either not use floating-point types in their programs or to become properly trained in the subject.

Example

```
#include <tgmath.h>

static float glob;

float f(void)
{
/*
 * If FLT_EVAL_METHOD is zero, we want to invoke the float version of
 * the following function to avoid the double rounding that would occur
 * if the double sqrt function were invoked.
 */
return hypot(+glob, 0.0);
}
```

FLT_EVAL_METHOD

The use of evaluation formats is characterized by the implementation-defined value of **FLT_EVAL_METHOD**:[19)] 354

Commentary

This specification is based on existing practice and provides a mechanism to make evaluation format information available to developers (many C90 implementations were already using the concept of an evaluation format, even though that standard did not explicitly mention it)— existing practice is affected by processor characteristics. Some processors do not provide hardware support to perform some floating-point operations in specific formats. This means that either an available format is used, or additional instruction is executed to convert the result value (slowing the performance of the application).

Demmel and Hida 1163

The actual types denoted by the typedef names `float_t` and `double_t` are dependent on the value of the `FLT_EVAL_METHOD` macro. Demmel and Hida give an error analysis for summing a series when the intermediate results are held to greater precision than the values in the series.

C90

Support for the `FLT_EVAL_METHOD` macro is new in C99. Its significant attendant baggage was also present in C90 implementations, but was explicitly not highlighted in that standard.

C++

Support for the `FLT_EVAL_METHOD` macro is new in C99 and it is not available in C++. However, it is likely that the implementation of floating point in C++ will be the same as in C.

Other Languages

Most language implementations use the support provided by their hosts' floating-point unit, if available. They may also be influenced by the representation of floating types used by other language implementations (e.g., C). Even those languages that only contain a single floating-point type are not immune to evaluation format issues, they simply have fewer permutations to consider. Fortran has quite a complex floating-point expression evaluation specification. This also includes a concept called *widest-need*.

Common Implementations

Implementations often follow the default behavior of the hardware floating point unit, if one is available. In some cases the time taken to perform a floating-point operation does not depend on the evaluation format.[627,968] In these cases the widest format is often the default. When floating-point operations have to be emulated in software, performance does depend on evaluation format and implementations often choose the narrowest format.

The Intel IA64[631] provides a mechanism for software emulation, as does the HP–was DEC– Alpha.[1247]

Coding Guidelines

Calculations involving floating-point values often involve large arrays of these values. Before the late 1990s, the availability of storage to hold these large arrays was often an important issue. Many applications used arrays of floats, rather than arrays of doubles, to save storage space. These days the availability of storage is rarely an important issue in selecting the base type of an array.

The choice of floating-point type controls the precision to which results are rounded when they are assigned to an object. Depending on the value of FLT_EVAL_METHOD, this choice may also have some influence on the precision to which operations, on floating-point operands, are performed.

Example

```
#include <float.h>

#if FLT_EVAL_METHOD < 1
#error Program won't give the correct answers using this implementation
#endif
```

355-1 indeterminable;

Commentary

Some processors support more than one evaluation format and provide a mechanism for encoding the choice within the instruction encoding (rather than in a separate configuration register), and some support both mechanisms.[1247] A program executing on such a processor, may have been built from two translation units—one that was translated using one evaluation format and one using a different evaluation format.

Common Implementations

An example of a processor where a translator might want to support a FLT_EVAL_METHOD macro value of less than zero is the Acorn ARM processor. The ARM machine code generated for the following expression statement:

```
float a;
double b, c;
a = b + c;
```

might be (if the FLT_EVAL_METHOD macro had a value of 0 or 1):

```
adfd    f0, f0, f1   # f0 = f0 + f1, rounded to double
mvfs    f0, f0       # f0 = f0, rounded to single
```

however, the following would be a more efficient sequence:

```
adfs    f0, f0, f1   # f0 = f0 + f1, rounded to single
```

but the addition operation is performed to less precision than is available in the operands. An implementation can only generate this instruction sequence if the FLT_EVAL_METHOD macro has a value less than zero.

Coding Guidelines

At first sight, having to use an implementation that specified a value of -1 for FLT_EVAL_METHOD would appear to be very bad news. It means that developers cannot depend on any particular evaluation format being used consistently when a program is translated. In this case, the responsible developer is forced to ensure that explicit casts are used before and after every arithmetic operation. Casting an operand before an operation guarantees a minimum level of precision. Casting the result of an operation ensures that any extra

precision is not passed on to the next evaluation. The end result is a program that gives much more consistent results when ported.

The extent to which an indeterminable value will affect the irresponsible developer cannot be estimated (i.e., will the differences in behavior be significant; will an indeterminate value for FLT_EVAL_METHOD have made any difference compared to some other value?) For source written by that developer, perhaps not. But the developer may have copied some code from an expert who assumed a particular evaluation method. There is little these coding guidelines can do to address the issue of the irresponsible developer. Given that implementations using an indeterminate value appears to be rare a guideline recommendations is not considered worthwhile.

---

0 evaluate all operations and constants just to the range and precision of the type; 356

Commentary

usual arithmetic conversions 706

In many contexts, operands will have been subject to the usual arithmetic conversions, so objects having type **float** will have been converted to type **double**. The difference between this and an evaluation format value of 1 is that constants may be represented to greater precision. In:

```
1  float f1, f2;
2  if (f1 < f2)
```

as-if rule 122

an implementation may choose to perform the relational test without performing the usual arithmetic conversions by invoking the as-if rule. No recourse to the value of FLT_EVAL_METHOD is needed. But in:

```
1  float f1;
2  if (f1 < 0.1f)
```

the value of FLT_EVAL_METHOD needs to be taken into account because of a possible impact on the representation used for `0.1f`.

Other Languages

This might be thought to be the default specification for many languages that do not aim to get as close to the hardware as C does. However, few languages define the behavior of operations on floating-point values with the precision needed to make this the only implementation option. Performance of the translated program is an issue for all languages and many follow, like C, the default behavior of the underlying hardware (even Fortran).

Common Implementations

This form of evaluation is most often used by implementations that perform floating-point operations in software; it being generally felt that the execution-time penalty of using greater precision is not compensated for by improvements in the accuracy of results. (If a developer wants the accuracy of **double**, let them insert explicit casts).

This evaluation format is not always used on hosts whose floating-point hardware performs operations in **float** and **double** types. The desire for compatibility with behavior seen on other processors may have a higher priority. Some translators provide an option to select possible evaluation modes.

Coding Guidelines

This evaluation format is probably what the naive developer thinks occurs in all implementations. Developers who have been using C for many years may be expecting the behavior specified by an evaluation format value of 1. As such, this evaluation format contains the fewest surprises for a developer expecting the generated machine code to mimic the type of operations in the source code. An implementation is doing exactly what it is asked to do.

---

footnote 17

17) IEC 60559:1989 specifies quiet and signaling NaNs. 357

Commentary

The IEEE 754R committee is tentatively planning to remove the requirement of support for signaling NaNs from the floating-point standard and to not recommend such support. The collected experience of the 754R committee is that use of signaling NaNs has been vanishingly small and in most of those cases alternate methods would suffice. The minimal utility does not justify the considerable cost required of system and tool implementors to support signaling NaNs in a coherent manner nor the cost to users in dealing with overburdened tools and overly complicated specification.

Liaison report to WG14, Sep 2002

---

358 For implementations that do not support IEC 60559:1989, the terms quiet NaN and signaling NaN are intended to apply to encodings with similar behavior.

Commentary

The standard does not require that such encoding be provided, only that, if there are encodings with similar behavior, the terms quiet NaN and signaling NaN can be applied to them.

C90

The concept of NaN is new, in terms of being explicitly discussed, in C99.

C++

```
static const bool has_quiet_NaN;
```

18.2.1.2p34

True if the type has a representation for a quiet (non-signaling) "Not a Number."[193)]

Meaningful for all floating point types.

Shall be true for all specializations in which `is_iec559 != false`.

```
static const bool has_signaling_NaN;
```

18.2.1.2p37

True if the type has a representation for a signaling "Not a Number."194)

Meaningful for all floating point types.

Shall be true for all specializations in which is_iec559 != false.

```
static const bool is_iec559;
```

18.2.1.2p52

True if and only if the type adheres to IEC 559 standard.[201)]

The C++ Standard requires NaNs to be supported if IEC 60559 is supported, but says nothing about the situation where that standard is not supported by an implementation.

Other Languages

Few languages get involved in this level of detail.

Common Implementations

HP–was DEC– VAX has a bit representation for reserved, Cray a bit representation for indefinite. They behave like NaNs.

Coding Guidelines

If developers only make use of the functionality specified by the standard, this representation detail is unlikely to be of significance to them.

---

footnote 18

18) Evaluation of **FLT_ROUNDS** correctly reflects any execution-time change of rounding mode through the function **fesetround** in **<fenv.h>**. 359

Commentary

float.h 348 suitable for #if

This footnote clarifies the intended behavior for the FLT_ROUNDS (an earlier requirement also points out that this macro need not be a constant expression), at least for values between 0 and 3. It is possible for FLT_ROUNDS to have a value of -1 (or perhaps a value indicating an implementation-defined rounding behavior) and be unaffected by changes in rounding mode through calls to the function fesetround. The evaluation of FLT_ROUNDS also needs to correctly reflect any translation-time change of rounding mode through, for instance, use of a **#pragma** directive.

FLT_ROUNDS 352

Like errno FLT_ROUNDS provides a method of accessing information in the execution environment.

C90

Support for the header **<fenv.h>** is new in C99. The C90 Standard did not provide a mechanism for changing the rounding direction.

C++

Support for the header **<fenv.h>** and the fesetround function is new in C99 and is not specified in the C++ Standard.

---

footnote 19

19) The evaluation method determines evaluation formats of expressions involving all floating types, not just real types. 360

Commentary

complex types 500

Floating types are made up of the real and complex types

C90

Support for complex types is new in C99.

C++

The complex types are a template class in C++. The definitions of the instantiation of these classes do not specify that the evaluation format shall be the same as for the real types. But then, the C++ Standard does not specify the evaluation format for the real types.

Other Languages

The complex types in Fortran and Ada follow the same evaluation rules as the real types in those languages.

For example, if **FLT_EVAL_METHOD** is 1, then the product of two **float _Complex** operands is represented in the **double _Complex** format, and its parts are evaluated to **double**. 361

Commentary

This restatement of the specification makes doubly sure that there is no possible ambiguity of the intent.

C++

The C++ Standard does not specify a FLT_EVAL_METHOD mechanism.

---

1 evaluate operations and constants of type **float** and **double** to the range and precision of the **double** type, evaluate **long double** operations and constants to the range and precision of the **long double** type; 362

Commentary

Historically, this is the behavior many experienced C developers have come to expect.

Common Implementations

This is how translators are affected (i.e., existing source expects this behavior and a vendor wants their product to handle existing source) by the original K&R behavior.

Coding Guidelines

Although this behavior is implicitly assumed in much existing source, inexperienced developers may not be aware of it. As such it is an educational rather than a coding guidelines issue.

---

363 2 evaluate all operations and constants to the range and precision of the **long double** type.

Commentary

This choice reflects the fact that some hardware floating-point units (e.g., the Intel x86) support a single evaluation format for all floating-point operations. Continually having to convert the intermediate results, during the evaluation of an expression, to another format imposes an execution-time overhead that translator vendors may feel their customers will not tolerate.

Common Implementations

The Intel x86[627] performs floating-point operations in an 80-bit extended representation (later versions of this processor contained additional instructions that operated on a 32-bit representation only). Some translators, for this processor, use a **long double** type that has 96 bits in its object representation and 80 bits in its value representation.

574 object representation
595 value representation

---

364 All other negative values for **FLT_EVAL_METHOD** characterize implementation-defined behavior.

Commentary

The standard does not say anything about other possible positive values, not even reserving them for future revisions.

Common Implementations

One form of evaluation format seen in some implementations is widest-need.[52] This format was also described in the Floating-point C Extensions technical report[1019] produced by the NCEG (Numerical C Extensions Group) subcommittee of X3J11. Widest-need examines a full expression for the widest real type in that expression. All of the floating-point operations in that expression are then evaluated to that widest type.

0 X3J11

Coding Guidelines

The issues behind a widest-need evaluation strategy are the same as those for integer types. A change of type of one operand can affect the final result of an expression. Recommending the use of a single floating type is not such an obvious solution (as it is for integer types). Producing a correctly rounded result requires the use of two different floating types. This is a complex issue and your author knows of no simple guideline recommendation that might be applicable.

64 correctly rounded result

Example

```
1  extern float f1, f2;
2  extern double d1, d2;
3  extern long double ld1, ld2;
4
5  void f(void)
6  {
7  f1 = f1 * f2; /* Widest type is float. */
8  /*
9   * Widest type is double.
10  * If FLT_EVAL_METHOD is 0 f1 * f2 would be evaluated in float.
11  */
```

```
12  f1 = d1 + f1 * f2;
13  }
```

The values given in the following list shall be replaced by constant expressions with implementation-defined values that are greater or equal in magnitude (absolute value) to those shown, with the same sign: 365

Commentary

The values listed below are all integers. The descriptions imply an integer type, but this is not explicitly specified (other requirements apply to integer values). One likely use of the values listed here are as the size in an array definition.

float.h 348 suitable for #if

C90

In C90 the only expression that was required to be a constant expression was FLT_RADIX. It was explicitly stated that the others need not be constant expressions; however, in most implementations, the values were constant expressions.

C++

18.2.1p3 *For all members declared* `static const` *in the* `numeric_limits` *template, specializations shall define these values in such a way that they are usable as integral constant expressions.*

Other Languages

Java specifies the exact floating-point format to use, so many of the following values are already implicitly defined in that language. It also defines the classes `java.lang.Float` and `java.lang.Double` which contain a minimal set of related information.

Coding Guidelines

Like other identifiers, which are constant expressions, defined by the C Standard, they represent a symbolic property. As discussed elsewhere, making use of the property rather than a particular arithmetic value has many advantages.

symbolic name 822

FLT_RADIX — radix of exponent representation, b 366

FLT_RADIX **2**

Commentary

A poorly worded way of saying the radix of the significand. The value of this macro is an input parameter to many formulas used in the calculation of rounding errors. The constants used in some numerical algorithms may depend on the value of FLT_RADIX. For instance, minimizing the error in the calculation of sine requires using different constant values for different radixs.

The radix used by humans is 10. A fraction that has a finite representation in one radix may have an infinitely repeating representation in another radix. This only occurs when there is some prime number, p, that divides one radix but not the other. There is no prime divisor of 2, 8, or 16 that does not also divide 10. Therefore, it is always possible to exactly represent binary, octal, or hexadecimal fractions exactly as base 10 fractions. The prime number 5 divides 10, but not 2, 8, or 16. Therefore, there are decimal fractions that have no exact representation in binary, octal, or hexadecimal. For instance, 0.1_{10} has an infinitely recurring representation in base 2 (i.e., $1.10011001100110011\ldots_2 \times 2^{-4}$).

When FLT_RADIX has a value other than 2, the precision wobbles. For instance, with a FLT_RADIX of 16 for the type **float**, there are 4×6 or 24 bits of significand, but only 21 bits of precision that can be counted

on. The shifting of the bits in the significand, to ensure correct alignment, occurs in groups of 4, meaning that 3 bits can be 0. A large radix has the advantages of a large range (of representable values) and high speed (of execution). The price paid for this advantage may be less accuracy and larger errors in the results of arithmetic operations. A radix of 2 provides the best accuracy (it minimizes the root mean square round-off error[158]).

The base of the exponent affects the significand if it has a value other than 2. In these cases the significand will contain leading zeros for some floating-point values. A discussion of the trade-off involved in choosing the base and the exponent range is given by Richman.[1165]

C++

```
static const int radix;
```

18.2.1.2p16

For floating types, specifies the base or radix of the exponent representation (often 2).[185)]

Other Languages

A numeric inquiry function, RADIX, which returns the radix of a real or integer argument was added to Fortran 90. Few other languages get involved in exposing such details to developers.

Common Implementations

Because of the widespread use of IEC 60559 by processor vendors, the most commonly encountered value is 2. Values of 8 and 16 are still sometimes encountered, but such usage is becoming rarer as the machines supporting them are scrapped (or move to support IEC 60559, like the IBM 390, and existing software is migrated); although software emulation of floating-point operators sometimes uses a non-2 value.[267]

The Unisys A Series[1389] uses a FLT_RADIX of 8. The Motorola 68000 processor[968] supports a packed decimal real format that has a FLT_RADIX of 10. This processor also supports IEC 60559 format floating-point types. The original IBM 390 floating-point format uses a FLT_RADIX of 16. Later versions of this processor also support the IEC 60559 format.[1207] The Data General Nova[319] also uses a FLT_RADIX of 16. The Los Alamos MANIAC II used a radix of 256, only one was every built, using valves, in 1955. The Moscow State University SETUN experimental computer[1442] used a radix of 3.

The advantage of a larger radix is that it increases the probability[1323] that the exponents of two floating-point values, of a binary operator, will be the same, reducing the need to align the value significands. A larger radix is also likely to require less work to normalise result of an operation.

The advantage of a smaller radix is that it has a smaller maximum and average representation error[249] (for the same total number of bits in the floating-point representation).

A radix of 2 introduces a significant performance penalty for software implementations of floating-point operations and a radix of 8 has been found[267] to be a better choice.

Hardware support for a radix of 10 has started to take off in environments where accurate calculations involving values represented in *human form* is important[298] (Cowlishaw[297] provides a specification of IEC 60559 conforming decimal arithmetic). There is a strong possibility that use of radix 10 will eventually become the norm, as the economic (e.g., impact on chip fabrication costs) and technical (e.g., runtime efficiency) costs become less important than the benefits, to end-users, of decimal arithmetic.

Example

Malcolm[889] provides Fortran source that computes the radix used by the processor on which the code executes.

```
#include <float.h>

#if FLT_RADIX != 16
#error Go away!  This program only translates on old cranky hosts.
#endif
```

*_MANT_DIG macros — number of base-FLT_RADIX digits in the floating-point significand, p 367

FLT_MANT_DIG
DBL_MANT_DIG
LDBL_MANT_DIG

Commentary

Assumed to be an integer (which it is for almost all implementations).

Rationale The term FLT_MANT_DIG stands for "float mantissa digits." The Standard now uses the more precise term *significand* rather than *mantissa*.

Other Languages

Few languages get involved in exposing such details to the developer. A numeric inquiry function, DIGITS, which returns the number of base b digits in the significand of the argument, was added in Fortran 90.

Common Implementations

The IEC 60559 Standard defines single-precision as 24 bits (base-2 digits) and double-precision as 53 bits. It also defines a single extended as having 32 or more bits and a double extended as having 64 or more bits. In the actual bit representation (for single and double) there is always 1 less bit. This is because normalized numbers contain an implied 1 in the most significant bit and subnormals an implied 0 in that position.

subnormal numbers 338

In many freestanding environments the host processor does not support floating-point operations in hardware; they are emulated via library calls. To reduce the significant execution-time overhead of performing floating-point operations in software, a 16-bit significand is sometimes used (the exponent and sign occupy 8 bits, giving a total of 24 bits).

Some processors (e.g., the ADSP–2106x[29] and Intel XScale microarchitecture[629]) support single extended by adding an extra byte to the type representation, giving a 40-bit significand. Some processors also support a floating-point format, in hardware, that cannot represent the full range of values supported by IEC 60559. For instance, the ADSP–2106x[29] has what it calls a *short word* floating-point format— occupying 16 bits with a 4-bit exponent, sign bit and an 11-bit significand.

Example

Malcolm[889] provides Fortran source that computes the number of mantissa digits used by the processor on which the code executes.

```
1  #include <float.h>
2
3  #if (DBL_MANT_DIG != 53) || (FLT_MANT_DIG != 24)
4  #error Please rewrite the hex floating-point literals
5  #endif
```

DECIMAL_DIG macro — number of decimal digits, n, such that any floating-point number in the widest supported floating type with p_{max} radix b digits can be rounded to a floating-point number with n decimal digits and back again without change to the value, 368

$$\begin{cases} p_{max} \log_{10} b & \text{if } b \text{ is a power of 10} \\ \lceil 1 + p_{max} \log_{10} b \rceil & \text{otherwise} \end{cases}$$

DECIMAL_DIG 10

Commentary

The conversion process here is base-FLT_RADIX⇒base-10⇒base-FLT_RADIX (the opposite conversion ordering is discussed in the following C sentence). The binary fraction 0.00011001100110011001100110011 is exactly equal to the decimal fraction 0.09999999962747097015380859375, which might suggest that a DECIMAL_DIG value of 10 is not large enough. However, the second part of the above requirement is that the number be converted back without change, not that the exact decimal representation be used. If FLT_RADIX is less than 10, then for the same number of digits there will be more than one decimal representation for each binary number. The number N of radix-B digits required to represent an n-digit FLT_RADIX floating-point number is given by the condition (after substituting C Standard values):[904]

$$10^{N-1} > FLT\_RADIX^{LDBL\_MANT\_DIG} \tag{368.1}$$

Minimizing for N, we get:

$$N = 2 + \frac{LDBL\_MANT\_DIG}{\log_{FLT\_RADIX} 10} \tag{368.2}$$

When FLT_RADIX is 2, this simplifies to:

$$N = 2 + \frac{LDBL\_MANT\_DIG}{3.321928095} \tag{368.3}$$

By using fewer decimal digits, we are accepting that the decimal value may not be the one closest to the binary value. It is simply a member of the set of decimal values having the same binary value that is representable in DECIMAL_DIG digits. For instance, the decimal fraction 0.1 is closer to the preceding binary fraction than any other nearby binary fractions.[1287]

379 DECIMAL_DIG conversion recommended practice

When b is not a power of 10, this value will be larger than the equivalent *_DIG macro. But not all of the possible combinations of DECIMAL_DIG decimal digits can be generated by a conversion. The number of representable values between each power of the radix is fixed. However, each successive power of 10 supports a greater number of representable values (see Figure 368.1). Eventually the number of representable decimal values, in a range, is greater than the number of representable p radix values. The value of DECIMAL_DIG denotes the power of 10 just before this occurs.

335 precision floating-point

C90

Support for the DECIMAL_DIG macro is new in C99.

C++

Support for the DECIMAL_DIG macro is new in C99 and specified in the C++ Standard.

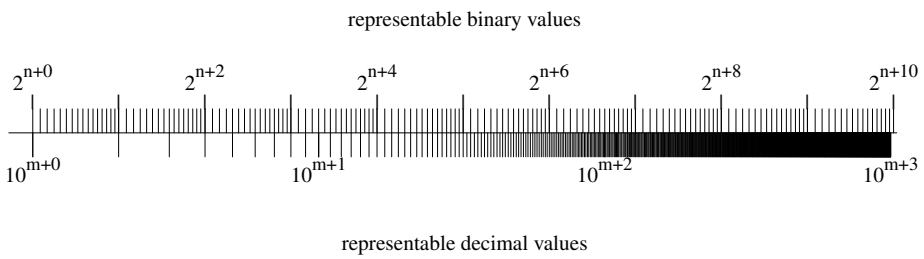

Figure 368.1: Representable powers of 10 and powers of 2 on the real line.

Other Languages

Few other languages get involved in exposing such details to the developer.

Common Implementations

A value of 17 would be required to support IEC 60559 double precision. A value of 9 is sufficient to support IEC 60559 single precision.

long double Apple

The format used by Apple on the PowerPC[52] to represent the **long double** type is the concatenation of two **double** types. Apple recommends that the difference in exponents, between the two doubles, be 54. However, it is not possible to guarantee this will always be the case, giving the representation an indefinite precision. The number of decimal digits needed to ensure that a cycle of conversions delivers the original value is proportional to the difference between the exponents in the two doubles. When the least significant double has a value of zero, the difference can be very large.

The following example is based on the one given in the Apple Macintosh PowerPC numerics documentation.[52] If an object with type **double**, having the value `1.2`, is assigned to an object having **long double** type, the least significant bits of the significand are given the zero value. In hexadecimal (and decimal to 34 digits of accuracy):

```
0x3FF33333 33333333 00000000 00000000
  1.19999999999999995559107901493738
```

The decimal form is the closest 34-digit approximation of the long double number (represented using double-double). It is also the closest 34-decimal digit approximation to an infinitely precise binary value whose exponent is 0 and whose fractional part is represented by 13 sequences of `0011` followed by 52 binary zeros, followed by some nonzero bits. Converting this decimal representation back to a binary representation, the Apple PowerPC Numerics library returns the closest double-double approximation of the infinitely precise value, using all of the bits of precision available to it. It will use all 53 bits in the head and 53 bits in the tail to store nonzero values and adjust the exponent of the tail accordingly. The result is:

```
0x3FF33333 33333333 xxxyzzzz zzzzzzzz
```

where xxx represents the sign and exponent of the tail, and `yzzz...` represents the start of a nonzero value. Because the tail is always nonzero, this value is guaranteed to be not equal to the original value.

Implementations add additional bits to the exponent and significand to support a greater range of values and precision, and most keep the bits representing the various components contiguous. The Unisys A Series[1389] represents the type **double** using the same representation as type **float** in the first word, and by having additional exponent and significand bits in a second word. The external effect is the same. But it is an example of how developer assumptions about representation, in this case bits being contiguous, can be proved wrong.

Coding Guidelines

One use of this macro is in calculating the amount of storage needed to hold the character representation, in decimal, of a floating-point value. The definition of the macro excludes any characters (digits or otherwise) that may be used to represent the exponent in any printed representation.

The only portable method of transferring data having a floating-point type is to use a character-based representation (e.g., a list of decimal floating-point numbers in character form). For a given implementation, this macro gives the minimum number of digits that must be written if that value is to be read back in without change of value.

```
printf("%#.*g", DECIMAL_DIG, float_valu);
```

Space can be saved by writing out fewer than `DECIMAL_DIG` digits, provided the floating-point value contains less precision than the widest supported floating type. Trailing zeros may or may not be important; the issues involved are discussed elsewhere.

Converting a floating-point number to a decimal value containing more than DECIMAL_DIG digits may, or may not, be meaningful. The implementation of the printf function may, or may not, choose to convert to the decimal value closest to the internally represented floating-point value, while other implementations simply produce garbage digits.[1287]

Example

```
#include <float.h>

/*
 * Array big enough to hold any decimal representation (at least for one
 * implementation).  Extra characters needed for sign, decimal point,
 * and exponent (which could be six, E-1234, or perhaps even more).
 */
#if LDBL_MAX_10_EXP < 10000

char float_digits[DECIMAL_DIG + 1 + 1 + 6 + 1];

#else
#error Looks like we need to handle this case
#endif
```

---

369 — number of decimal digits, q, such that any floating-point number with q decimal digits can be rounded into a floating-point number with p radix b digits and back again without change to the q decimal digits, * _DIG macros

$$\begin{cases} p_{max} \log_{10} b & \text{if } b \text{ is a power of 10} \\ \lfloor (p-1) \log_{10} b \rfloor & \text{otherwise} \end{cases}$$

FLT_DIG	**6**
DBL_DIG	**10**
LDBL_DIG	**10**

Commentary

The conversion process here is base-10⇒base-FLT_RADIX⇒base-10 (the opposite ordering is described elsewhere). These macros represent the maximum number of decimal digits, such that each possible digit sequence (value) maps to a different (it need not be exact) radix b representation (value). If more than one decimal digit sequence maps to the same radix b representation, it is possible for a different decimal sequence (value) to be generated when the radix b form is converted back to its decimal representation.

368 DECIMAL_DIG macro

C++

18.2.1.2p9

```
static const int digits10;
```

Number of base 10 digits that can be represented without change.

Footnote 184

Equivalent to FLT_DIG, DBL_DIG, LDBL_DIG.

18.2.2p4

Header **<cfloat>** *(Table 17): . . . The contents are the same as the Standard C library header* **<float.h>**.

Other Languages

The Fortran 90 `PRECISION` inquiry function is defined as `INT((p-1) * LOG10(b)) + k`, where `k` is 1 is `b` is an integer power of 10 and 0 otherwise.

Example

```
1  #include <limits.h>
2  #include <stdio.h>
3
4  float real_float;
5
6  int main(void)
7  {
8  for (int findex = INT_MAX; findex > INT_MAX-20; findex--)
9     {
10    real_float=(float)findex; /* Just in case we have a 'clever' optimizer. */
11    printf("I=%d, F1=%f, F2=%f\n", findex, (float)findex, real_float);
12    }
13 }
```

---

*_MIN_EXP — minimum negative integer such that **FLT_RADIX** raised to one less than that power is a normalized floating-point number, e_{min} 370

FLT_MIN_EXP
DBL_MIN_EXP
LDBL_MIN_EXP

Commentary

*_MIN macros 378 These values are essentially the minimum value of the exponent used in the internal floating-point representation. The `*_MIN` macros provide constant values for the respective minimum normalized floating-point value. No minimum values are given in the standard. The possible values can be calculated from the following:

$$FLT\_MIN\_EXP = \frac{FLT\_MIN\_10\_EXP}{\log(FLT\_RADIX)} \pm 1 \tag{370.1}$$

C++

18.2.1.2p23

```
static const int min_exponent;
```

Minimum negative integer such that `radix` *raised to that power is in the range of normalised floating point numbers.*[189)]

Footnote 189 *Equivalent to FLT_MIN_EXP, DBL_MIN_EXP, LDBL_MIN_EXP.*

18.2.2p4

Header **<cfloat>** *(Table 17): . . . The contents are the same as the Standard C library header* **<float.h>**.

Other Languages

Fortran 90 contains the inquiry function MINEXPONENT which performs a similar function.

Common Implementations

In IEC 60559 the value for single-precision is -125 and for double-precision -1021. The two missing values (available in the biased notation used to represent the exponent) are used to represent 0.0, subnormals, infinities, and NaNs.

338 floating types can represent

Coding Guidelines

The usage of these macros in existing code is so rare that reliable information on incorrect usage is not available, making it impossible to provide any guideline recommendations. (The rare usage could also imply that a guideline recommendation would not be worthwhile).

---

371 — minimum negative integer such that 10 raised to that power is in the range of normalized floating-point numbers, $\lceil \log_{10} b^{e_{min}-1} \rceil$ *_MIN_10_EXP

FLT_MIN_10_EXP	**-37**
DBL_MIN_10_EXP	**-37**
LDBL_MIN_10_EXP	**-37**

Commentary

Making this information available as an integer constant allows it to be accessed in a **#if** preprocessing directive.

These are the exponent values for normalized numbers. If subnormal numbers are supported, the smallest representable value is likely to have an exponent whose value is FLT_DIG, DBL_DIG, and LDBL_DIG less than (toward negative infinity) these values, respectively.

338 subnormal numbers

The Committee is being very conservative in specifying the minimum values for the exponents of the types **double** and **long double**. An implementation is permitted to define the same range of exponents for all floating-point types. There may be normalized numbers whose respective exponent value is smaller than the values given for these macros; for instance, the exponents appearing in the *_MIN macros. The power of 10 exponent values given for these *_MIN_10_EXP macros can be applied to any normalized significand.

C++

```
static const int min_exponent10;
```

18.2.1.2p25

Minimum negative integer such that 10 raised to that power is in the range of normalised floating point numbers.[190)]

Equivalent to FLT_MIN_10_EXP, DBL_MIN_10_EXP, LDBL_MIN_10_EXP. Footnote 190

Header **<cfloat>** *(Table 17): . . . The contents are the same as the Standard C library header* **<float.h>**. 18.2.2p4

Common Implementations

The value of DBL_MIN_10_EXP is usually the same as FLT_MIN_10_EXP or LDBL_MIN_10_EXP. In the latter case a value of -307 is often seen.

*_MAX_EXP — maximum integer such that **FLT_RADIX** raised to one less than that power is a representable finite floating-point number, e_{max} 372

FLT_MAX_EXP
DBL_MAX_EXP
LDBL_MAX_EXP

Commentary

*_MIN_EXP 370 FLT_RADIX to the power *_MAX_EXP is the smallest large number that cannot be represented (because of limited exponent range).

C++

18.2.1.2p27

```
static const int max_exponent;
```

Maximum positive integer such that `radix` *raised to the power one less than that integer is a representable finite floating point number.*[191)]

Footnote 191 *Equivalent to FLT_MAX_EXP, DBL_MAX_EXP, LDBL_MAX_EXP.*

18.2.2p4 *Header* **<cfloat>** *(Table 17): . . . The contents are the same as the Standard C library header* **<float.h>**.

Other Languages

Fortran 90 contains the inquiry function MAXEXPONENT which performs a similar function.

Common Implementations

In IEC 60559 the value for single-precision is 128 and for double-precision 1024.

*_MAX_10_EXP — maximum integer such that 10 raised to that power is in the range of representable finite floating-point numbers, $\lfloor \log_{10}((1 - b^{-p})b^{e_{max}}) \rfloor$ 373

FLT_MAX_10_EXP	**+37**
DBL_MAX_10_EXP	**+37**
LDBL_MAX_10_EXP	**+37**

Commentary

*_MIN_10_EXP 371 As in choosing the *_MIN_10_EXP values, the Committee is being conservative.

C++

18.2.1.2p29

```
static const int max_exponent10;
```

Maximum positive integer such that 10 raised to that power is in the range of normalised floating point numbers.

Footnote 192

Equivalent to FLT_MAX_10_EXP, DBL_MAX_10_EXP, LDBL_MAX_10_EXP.

Header **<cfloat>** *(Table 17): . . . The contents are the same as the Standard C library header* **<float.h>**. 18.2.2

Common Implementations

The value of DBL_MAX_10_EXP is usually the same as FLT_MAX_10_EXP or LDBL_MAX_10_EXP. In the latter case a value of 307 is often seen.

---

374 The values given in the following list shall be replaced by constant expressions with implementation-defined values that are greater than or equal to those shown: floating values listed

Commentary

This is a requirement on the implementation. The requirement that they be constant expressions ensures that they can be used to initialize an object having static storage duration.

The values listed represent a floating-point number. Their equivalents in the integer domain are required to have appropriate promoted types. There is no such requirement specified for these floating-point values. 822 symbolic name 303 integer types sizes

C90

C90 did not contain the requirement that the values be constant expressions.

C++

This requirement is not specified in the C++ Standard, which refers to the C90 Standard by reference.

---

375 — maximum representable finite floating-point number, $(1 - b^{-p})b^{e_{max}}$

FLT_MAX	**1E+37**
DBL_MAX	**1E+37**
LDBL_MAX	**1E+37**

Commentary

There is no requirement that the type of the value of these macros match the real type whose maximum they denote. Although some implementations include a representation for infinity, the definition of these macros require the value to be finite. These values correspond to a FLT_RADIX value of 10 and the exponent values given by the *_MAX_10_EXP macros. 373 *_MAX_10_EXP

The HUGE_VAL macro value may compare larger than any of these values.

C++

```
static T max() throw();
```

Maximum finite value.[182] 18.2.1.2p4

Equivalent to CHAR_MAX, SHRT_MAX, FLT_MAX, DBL_MAX, etc. Footnote 182

18.2.2p4

Header **<cfloat>** *(Table 17): . . . The contents are the same as the Standard C library header* **<float.h>**.

Other Languages

The class `java.lang.Float` contains the member:

```
1  public static final float MAX_VALUE = 3.4028235e+38f
```

The class `java.lang.Double` contains the member:

```
1  public static final double MAX_VALUE = 1.7976931348623157e+308
```

Fortran 90 contains the inquiry function `HUGE` which performs a similar function.

Common Implementations

Many implementations use a suffix to give the value a type corresponding to what the macro represents. The IEC 60559 values of these macros are:

```
single float FLT_MAX        3.40282347e+38
double float DBL_MAX        1.7976931348623157e+308
```

EXAMPLE 380 minimum floating-point representation

EXAMPLE 381 IEC 60559 floating-point

Coding Guidelines

How many calculations ever produce a value that is anywhere near `FLT_MAX`? The known Universe is thought to be 3×10^{29}mm in diameter, 5×10^{19} milliseconds old, and contain 10^{79} atoms, while the Earth is known to have a mass of 6×10^{24}Kg.

Floating-point values whose magnitude approaches `DBL_MAX`, or even `FLT_MAX` are only likely to occur as the intermediate results of calculating a final value. Very small numbers are easily created from values that do not quite cancel. Dividing by a very small value can lead to a very large value. Very large values are thus more often a symptom of a problem, rounding errors or poor handling of values that almost cancel, than of an application meaningful value.

Some processors saturate to the maximum representable value on overflow, while others return an infinity. Testing whether an operation will overflow is one use for these identifiers. However, in C99, tests such as (`x > LDBL_MAX`) can now be replaced by the `isinf` macro.

Example

```
1  #include <float.h>
2
3  #define FALSE 0
4  #define TRUE 1
5
6  extern float f_glob;
7
8  _Bool f(float p1, float p2)
9  {
10 if (f_glob > (FLT_MAX / p1))
11    return FALSE;
12
13 f_glob *= p1;
14
15 if (f_glob > (FLT_MAX - p2))
16    return FALSE;
17
18 f_glob += p2;
19
20 return TRUE;
21 }
```

376 The values given in the following list shall be replaced by constant expressions with implementation-defined (positive) values that are less than or equal to those shown:

Commentary

The previous discussion is applicable here.

374 floating values listed

377 — the difference between 1 and the least value greater than 1 that is representable in the given floating point type, b^{1-p} *_EPSILON

FLT_EPSILON	**1E-5**
DBL_EPSILON	**1E-9**
LDBL_EPSILON	**1E-9**

Commentary

The Committee is being very conservative in specifying these values. Although IEC 60559 arithmetic is in common use, there are several major floating-point implementations of it that do not support an extended precision. The Committee could not confidently expect implementations to support the type **long double** containing greater accuracy than the type **double**.

29 IEC 60559

Like the *_DIG macros more significand digits are required for the types **double** and **long double**.

369 *_DIG macros

C++

18.2.1.2p20

```
static T epsilon() throw();
```

Machine epsilon: the difference between 1 and the least value greater than 1 that is representable.[187)]

Footnote 187

Equivalent to FLT_EPSILON, DBL_EPSILON, LDBL_EPSILON.

18.2.2p4

Header **<cfloat>** *(Table 17): . . . The contents are the same as the Standard C library header* **<float.h>**.

Other Languages

Fortran 90 contains the inquiry function EPSILON, which performs a similar function.

Common Implementations

Some implementations (e.g., Apple) use a contiguous pair of objects having type **double** to represent an object having type **long double**. Such a representation creates a second meaning for LDBL_EPSILON. This is because, in such a representation, the least value greater than 1.0 is 1.0+LDBL_MIN, a difference of LDBL_MIN (which is not the same as $b^{(1-p)}$)— the correct definition of *_EPSILON. Their IEC 60559 values are:

368 long double Apple

```
FLT_EPSILON     1.19209290e-7 /* 0x1p-23 */
DBL_EPSILON     2.2204460492503131e-16 /* 0x1p-52 */
```

Coding Guidelines

It is a common mistake for these values to be naively used in equality comparisons:

```
#define EQUAL_DBL(x, y) ((((x)-DBL_EPSILON) < (y)) && \
                             (((x)+DBL_EPSILON) > (y)))
```

This test will only work as expected when x is close to 1.0. The difference value not only needs to scale with x, (x + x*DBL_EPSILON), but the value DBL_EPSILON is probably too small (equality within 1 ULP is a very tight bound):

ULP 346

```
#define EQUAL_DBL(x, y) ((((x)*(1.0-MY_EPSILON)) < (y)) && \
                             (((x)*(1.0+MY_EPSILON)) > (y)))
```

Even this test fails to work as expected if x and y are subnormal values. For instance, if x is the smallest subnormal and y is just 1 ULP bigger, y is twice x.

Another, less computationally intensive, method is to subtract the values and check whether the result is within some scaled approximation of zero.

```
#include <math.h>

_Bool equalish(double f_1, double f_2)
{
int exponent;
frexp(((fabs(f_1) > fabs(f_2)) ? f_1 : f_2), &exponent);
return (fabs(f_1-f_2) < ldexp(MY_EPSILON, exponent));
}
```

---

*_MIN macros

— minimum normalized positive floating-point number, $b^{e_{min}-1}$

378

FLT_MIN	**1E-37**
DBL_MIN	**1E-37**
LDBL_MIN	**1E-37**

Commentary

These values correspond to a FLT_RADIX value of 10 and the exponent values given by the *_MIN_10_EXP macros. There is no requirement that the type of these macros match the real type whose minimum they denote. Implementations that support subnormal numbers will be able to represent smaller quantities than these.

*_MIN_10_EXP 371
subnormal numbers 338

C++

18.2.1.2p1

> *static T min() throw();*
>
> *Maximum finite value.*[181)]

Footnote 181

> *Equivalent to CHAR_MIN, SHRT_MIN, FLT_MIN, DBL_MIN, etc.*

18.2.2p4

Header **<cfloat>** *(Table 17): . . . The contents are the same as the Standard C library header* **<float.h>**.

Other Languages

The class `java.lang.Float` contains the member:

```
1  public static final float MIN_VALUE = 1.4e-45f;
```

The class `java.lang.Double` contains the member:

```
1  public static final double MIN_VALUE = 5e-324;
```

which are the smallest subnormal, rather than normal, values.

Fortran 90 contains the inquiry function `TINY` which performs a similar function.

Common Implementations

Their IEC 60559 values are:

```
FLT_MIN          1.17549435e-38f
DBL_MIN          2.2250738585072014e-308
```

Implementations without hardware support for floating point sometimes chose the minimum required limits because of the execution-time overhead in supporting additional bits in the floating-point representation.

Coding Guidelines

How many calculations ever produce a value that is anywhere near as small as `FLT_MIN`? The hydrogen atom weighs 10^{-26}Kg and has an approximate radius of $5{\times}10^{-11}$ meters, well within limits. But current theories on the origin of the Universe start at approximately 10^{-36} seconds, a very small number. However, writers of third-party libraries might not know whether their users are simulating the Big Bang, or weighing groceries. They need to ensure that all cases are handled.

Given everyday physical measurements, which don't have very small values, where can very small numbers originate? Subtracting two floating-point quantities that differ by 1 ULP, for instance, produces a value that is approximately 10^{-5} smaller. Such a difference can result from random fluctuations in the values input to a program, or because of rounding errors in calculations. Producing a value that is close to `FLT_MIN` invariably requires either a very complex calculation, or an iterative algorithm using values from previous iterations. Intermediate results that are expected to produce a value of zero may in fact deliver a very small value. Subsequent tests against zero fail and the very small value is passed through into further calculations. One solution to this problem is to have a relatively wide test of zeroness. In many physical systems a value that is a factor of 10^{-6} smaller than the smallest measurable quantity would be considered to be zero.

Rev 378.1 Floating-point comparisons against zero shall take into account the physical properties or engineering tolerances of the system being controlled or simulated.

There might be some uncertainty in the interpretation of the test `(abs(x) < FLT_MIN);` is it an approximate test against zero, or a test for a subnormal value? The C Standard now includes the `fpclassify` macro for obtaining the classification of its argument, including subnormal.

Example

```
1  #include <math.h>
2
3  #define MIN_TOLERANCE (1e-9)
4
5  _Bool inline effectively_zero(float valu)
6  {
7  return (abs(valu) < MIN_TOLERANCE);
8  }
```

Recommended practice

DECIMAL_DIG conversion recommended practice

Conversion from (at least) **double** to decimal with **DECIMAL_DIG** digits and back should be the identity function. 379

Commentary

Why is this a recommended practice? Unfortunately many existing implementations of `printf` and `scanf` do a poor job of base conversions, and they are not the identity functions.

To claim conformance to both C99 and IEC 60559 (Annex F in force), the requirements of F.5 Binary-decimal conversion must be met. Just making use of IEC 60559 floating-point hardware is not sufficient. The I/O library can still be implemented incorrectly and the conversions be wrong.

Rationale When the radix b is not a power of 10, it can be difficult to find a case where a decimal number with $p \times \log_{10} b$ digits fails. Consider a four-bit mantissa system (that is, base $b = 2$ and precision $p = 4$) used to represent one-digit decimal numbers. While four bits are enough to represent one-digit numbers, they are not enough to support the conversions of decimal to binary and back to decimal in all cases (but they are enough for most cases). Consider a power of 2 that is just under 9.5e21, for example, 2^{73} = 9.44e21. For this number, the three consecutive one-digit numbers near that special value and their round-to-nearest representations are:

```
  9e21    1e22    2e22
0xFp69  0x8p70  0x8p71
```

No problems so far; but when these representations are converted back to decimal, the values as three-digit numbers and the rounded one-digit numbers are:

```
8.85e21  9.44e21  1.89e22
   9e21     9e21     2e22
```

and we end up with two values the same. For this reason, four-bit mantissas are not enough to start with any one-digit decimal number, convert it to a binary floating-point representation, and then convert back to the same one-digit decimal number in all cases; and so p radix b digits are (just barely) not enough to allow any decimal numbers with $p \times \log_{10} b$ digits to do the round-trip conversion. p radix b digits are enough, however, for $(p-1) \times \log_{10} b$ digits in all cases.

The issues involved in performing correctly rounded decimal-to-binary and binary-to-decimal conversions are discussed mathematically by Gay.[475]

C90

The *Recommended practice* clauses are new in the C99 Standard.

C++

There is no such macro, or requirement specified in the C++ Standard.

Other Languages

The specification of the Java base conversions is poor.

Common Implementations

Experience with testing various translators shows that the majority don't, at the time of this publication, implement this Recommended Practice. The extent to which vendors will improve their implementations is unknown.

There is a publicly available set of tests for testing binary to decimal conversions.[1380]

Coding Guidelines

A Recommended Practice shall not be relied on to be followed by an implementation.

---

380 EXAMPLE 1 The following describes an artificial floating-point representation that meets the minimum requirements of this International Standard, and the appropriate values in a **<float.h>** header for type **float**:

EXAMPLE minimum floating-point representation

$$x = s16^e \sum_{k=1}^{6} f_k 16^{-k}, \quad -31 \le e \le +32$$

```
FLT_RADIX                       16
FLT_MANT_DIG                     6
FLT_EPSILON         9.53674316E-07F
FLT_DIG                          6
FLT_MIN_EXP                    -31
FLT_MIN             2.93873588E-39F
FLT_MIN_10_EXP                 -38
FLT_MAX_EXP                    +32
FLT_MAX             3.40282347E+38F
FLT_MAX_10_EXP                 +38
```

Commentary

Note that this example has a FLT_RADIX of 16, not 2.

---

381 EXAMPLE 2 The following describes floating-point representations that also meet the requirements for single-precision and double-precision normalized numbers in IEC 60559,[20] and the appropriate values in a **<float.h>** header for types **float** and **double**:

EXAMPLE IEC 60559 floating-point

$$x_f = s2^e \sum_{k=1}^{24} f_k 2^{-k}, \quad -125 \le e \le +128$$

$$x_d = s2^e \sum_{k=1}^{53} f_k 2^{-k}, \quad -1021 \le e \le +1024$$

```
FLT_RADIX                       2

DBL_MAX_10_EXP                +308
```

If a type wider than **double** were supported, then **DECIMAL_DIG** would be greater than 17. For example, if the widest type were to use the minimal-width IEC 60559 double-extended format (64 bits of precision), then **DECIMAL_DIG** would be 21.

Commentary

The values given here are important in that they are the most likely values to be provided by a conforming implementation using IEC 60559, which is what the majority of modern implementations use. These values correspond to the IEC 60559 single- and double-precision formats. This standard also defines extended single and extended double formats, which contain more bits in the significand and greater range in the exponent.

Note that this example gives the decimal and hexadecimal floating-constant representation for some of the macro definitions. A real header will only contain one of these definitions.

C90

The C90 wording referred to the ANSI/IEEE-754–1985 standard.

---

footnote 20

20) The floating-point model in that standard sums powers of b from zero, so the values of the exponent limits are one less than shown here. 382

Commentary

Fortran counts from 1, not 0 and the much of the contents of **<float.h>**, in C90, came from Fortran.

Forward references: conditional inclusion (6.10.1), complex arithmetic **<complex.h>** (7.3), extended multibyte and wide character utilities **<wchar.h>** (7.24), floating-point environment **<fenv.h>** (7.6), general utilities **<stdlib.h>** (7.20), input/output **<stdio.h>** (7.19), mathematics **<math.h>** (7.12). 383

6. Language

6.1 Notation

In the syntax notation used in this clause, syntactic categories (nonterminals) are indicated by *italic type*, and literal words and character set members (terminals) by **bold type**. 384

Commentary

A *terminal* is a token that can appear in the source code. A *nonterminal* is the name of a syntax rule used to group together zero or more terminals and other nonterminals. The nonterminals can be viewed as a tree. The root is the nonterminal *translation-unit*. The terminals are the leaves of this tree.

Syntax analysis is the processing of a sequence of terminals (as written in the source) via various nonterminals until the nonterminal *translation-unit* is reached. Failure to reach this final nonterminal, or encountering an unexpected sequence of tokens, is a violation of syntax.

The syntax notation used in the C Standard is not overly formal; it is often supported by text in the semantics clause. The C syntax can be written in LALR(1) form. (Although some reorganization of the productions listed in the standard is needed), assuming the **typedef** issue is fudged (the only way to know whether an identifier is a typedef name or not is to look it up in a symbol table, which introduces a context dependency; the alternative of syntactically treating a typedef name as an identifier requires more than one token lookahead.) This also happens to be the class of grammars that can be processed by `yacc` and many other parser generators.

```
A(B) /* Declare B to have type A, or call function A with argument B? */
```

The syntax specified in the C Standard effectively describes four different grammars:

1. A grammar whose start symbol is *preprocessing-token*; the input stream processed by this grammar contains the source characters output by translation phase 2.
2. A grammar whose start symbol is *preprocessing-file*; the input stream processed by this grammar contains the *preprocessing-token*s output by translation phase 3.
3. A grammar whose start symbol is *token*; the input to this grammar is a single *preprocessing-token*. The syntax of the characters forming the *preprocessing-token* need to form a valid parse of the *token* syntax.
4. A grammar whose start symbol is *translation-unit*; the input stream processed by this grammar contains the *token*s output by translation phase 6.

770 preprocessing token syntax
118 translation phase 2
1854 preprocessor directives syntax
124 translation phase 3
770 token syntax
1810 translation unit syntax
135 translation phase 6

The *preprocessor-token* and *token* syntax is sometimes known as the *lexical grammar* of C.

There are many factors that affect the decision of whether to specify language constructs using syntax or English prose in a Constraints clause. The C Standard took the approach of having a relatively simple, general syntax specification and using wording in constraints clauses to handle the special cases. There are techniques available (e.g., two-level grammars) for specifying the requirements (including the type rules) through syntax. This approach was famously taken, because of its impenetrability, in the specification of Algol 68[1407]

The first published standard for syntax notation was BS 6154:1981, *Method of Defining— Syntactic metalanguage*. Although a British rather than an International standard this document was widely circulated. It was also used as the base document for ISO/IEC 14977,[648] which specified an extended BNF. Most compiler books limit there discussion to LR and LL related methods. For a good introduction to a variety of parsing methods see Grune and Jacobs,[525] which is now freely available online.

C++

> *In the syntax notation used in this International Standard, syntactic categories are indicated by italic type, and literal words and characters in* `constant width` *type.* 1.6p1

The C++ grammar contains significantly more syntactic ambiguities than C. Some implementations have used mainly syntactic approaches to resolving these,[1467] while others make use of semantic information to guide the parse.[485] For instance, knowing what an identifier has been declared as, simplifies the parsing of the following:

```
template_name     < a , b > - 5  // equivalent to (template_name < a , b >) - 5)
non_template_name < a , b > - 5  // equivalent to (non_template_name < a) , (b > - 5)
```

Other Languages

Most computer languages definitions use some form of semiformal notation to define their syntax. The availability of parser generators is an incentive to try to ensure that the syntax is, or can be, rewritten in LALR(1) form.

Some languages are line-based, for instance Fortran (prior to Fortran 90). Each statement or declaration has its syntax and sequences of them can be used to build functions; there is no nesting of constructs over multiple statements.

The method used to analyze the syntax of a language can be influenced by several factors. Many Pascal translators used a handwritten recursive descent parser; the original, widely available, implementation of the language uses just this technique. Many Fortran translators use ad hoc techniques to process each statement or declaration as it is encountered, the full power of a parser generator not being necessary (also, it is easier to perform error recovery in an ad hoc approach).

Common Implementations

Most implementations use an automated tool-based approach to analyzing some aspects of the C syntax. Although tools do exist for automating the lexical grammar (e.g., `lex`) a handwritten lexer offers greater flexibility for handling erroneous input. The tool almost universally used to handle the language syntax is `yacc`, or one of its derivatives. The preprocessor syntax is usually handled in a handwritten ad hoc manner, although a few implementations use an automated tool approach.

Tools that do not require the input to be consolidated into tokens, but parsed at the character sequence level, are available.[1424]

Coding Guidelines

It is unlikely that a coding guideline recommendation would specify language syntax unless an extension was being discussed. Coding guideline documents that place restrictions on the syntax that can be used are rare.

A colon (*:*) following a nonterminal introduces its definition. 385

Commentary

This is a simple notation. Some syntax notations have been known to be almost as complex as the languages they describe.

C++

The C++ Standard does not go into this level of detail (although it does use this notation).

Other Languages

The notation *::=* is used in some language definitions and more formal specifications. The notation = is specified by the ISO Standard for extended BNF.[648]

Alternative definitions are listed on separate lines, except when prefaced by the words "one of". 386

Commentary

The Syntax clauses in the standard are written in an informal notation. As typified by this simple, nonformal rule.

Other Languages

The character | often used to indicate alternative definitions. This character is used by ISO/IEC 14977.

An optional symbol is indicated by the subscript "opt", so that 387

{ $expression_{opt}$ **}**

indicates an optional expression enclosed in braces.

Commentary

This is a more informal notation. In this example *expression* is optional; the braces are not optional.

Other Languages

Some languages use a more formal syntax notation where an empty alternative indicates that it is possible for a nonterminal to match against nothing (i.e., the symbol is optional).

When syntactic categories are referred to in the main text, they are not italicized and words are separated by spaces instead of hyphens. 388

Commentary

There are some places in the main text where words are separated by hyphens instead of spaces.

C90

This convention was not explicitly specified in the C90 Standard.

C++

The C++ Standard does not explicitly specify the conventions used. However, based on the examples given in clause 1.6 and usage within the standard, the conventions used appear to be the reverse of those used in C (i.e., syntactic categories are italicized and words are separated by hyphens).

Coding Guidelines

Companies may have typographical conventions for their documents which differ from those used by ISO. The issue of which typographical conventions to use in a company's coding guideline document is outside the scope of these coding guidelines.

---

389 A summary of the language syntax is given in annex A.

C90

The summary appeared in Annex B of the C90 Standard, and this fact was not pointed out in the normative text.

6.2 Concepts

Commentary

The concepts introduced here are identifiers (and their associated attributes), objects, and types.

6.2.1 Scopes of identifiers

---

390 An identifier can denote an object;

scope of identifiers

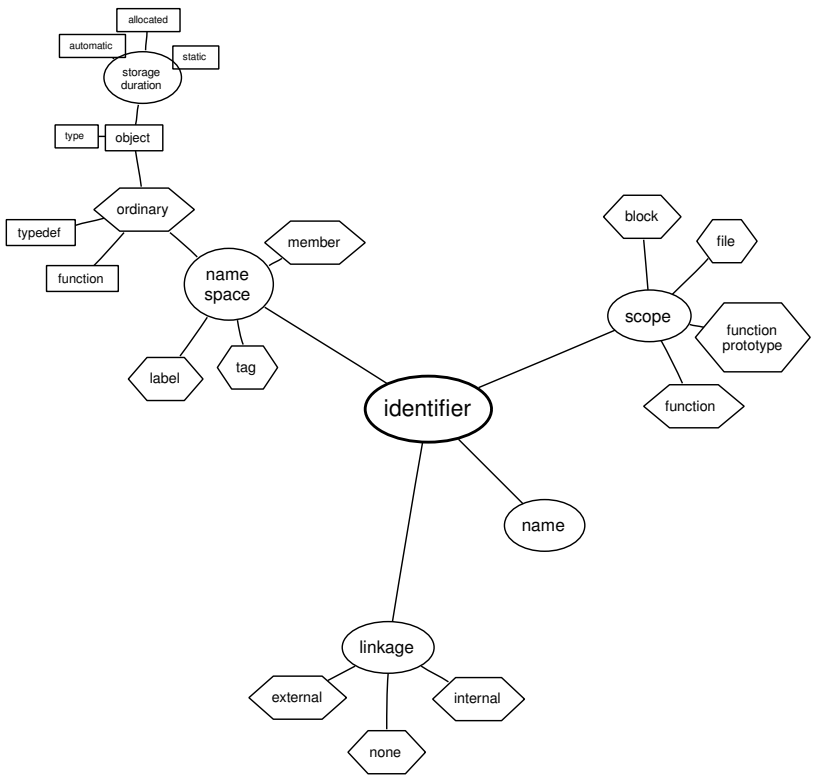

Figure 389.1: Attributes a C language identifier can have.

Commentary

This association is created by an explicit declaration.

Some objects do not have names— they are anonymous. An anonymous object can be created by a call to a memory-allocation function; an unnamed bit-field can be denoted by the identifier defined to have its containing union type.

Other Languages

Many languages use the term *variable* to denote what the C Standard calls an *object*. All languages provide a mechanism for declaring identifiers to denote objects (or variables).

Coding Guidelines

The use to which an identifier is put has been known to influence the choice of its name. This issue is fully discussed elsewhere.

naming conventions 792

---

a function; 391

Commentary

It is not possible to define an anonymous function within a strictly conforming program. Machine code can be copied into an object and executed on some implementations. Such copying and execution does not create something that is normally thought of as a function.

Coding Guidelines

Various coding guideline documents have recommended that names based on various parts of speech be used in the creating of identifier names denoting function. These recommendations are invariably biased towards the parts of speech found in English. (Not speaking any other human language, your author has not read documents written in other languages but suspects they are also biased toward their respective languages.) The general issue of identifier names is discussed elsewhere.

identifier introduction 792

---

a tag or a member of a structure, union, or enumeration; 392

Commentary

It is possible to create anonymous structure and union types, and anonymous members within these types. It is not possible to create an anonymous member of an enumeration. Even if there are gaps in the values assigned to each enumeration constant, there are no implicit named members.

C++

The C++ Standard does not define the term *tag*. It uses the terms *enum-name* (7.2p1) for enumeration definitions and *class-name* (9p1) for classes.

Common Implementations

Some translators support anonymous structure and union members within a structure definition; there was even a C9X revision proposal, WG14/N498 (submitted by one Ken Thompson):

```
1  struct S {
2            int mem1;
3            union {
4                   long umem1;
5                   float umem2;
6                  }; /* No member name. */
7           } s_o;
8
9  void f(void)
10 {
11 s_o.umem1=99; /* Translator deduces 'expected' member. */
12 }
```

There are several implementations that support this form of declaration. It is also supported in C++.

393 a typedef name;

Commentary

Character sequences such as **char**, **short** and **int** are types, not typedef names. They are also language keywords— a different lexical category from identifiers.

Common Implementations

Typedef names are specified as being identifiers, not keywords. However, most implementations treat them as a different syntactic terminal from identifiers. Translators usually performs a symbol table lookup just before translation phase 7, to see if an identifier is currently defined as a typedef name. This differentiation is made to simplify the parsing of C source and not visible to the user of a translator.

136 translation phase 7

Coding Guidelines

The issue of naming conventions typedef names is discussed elsewhere.

792 typedef naming conventions

394 a label name;

label name

Commentary

A label name occurs in a different syntactic context to other kinds of identifiers, which is how a translator deduces it is a label.

440 label name space
1722 labeled statements syntax

Other Languages

Fortran and Pascal require that label names consist of digits only.

Coding Guidelines

The issue of naming conventions for label names is discussed elsewhere.

792 label naming conventions

395 a macro name;

Commentary

An identifier can only exist as a macro name during translation phases 3 and 4.

1974 macro definition lasts until
124 translation phase 3
129 translation phase 4

Coding Guidelines

The issue of typedef names is discussed elsewhere.

792 macro naming conventions

396 or a macro parameter.

identifier macro parameter

Commentary

An identifier can only exist as a macro parameter during translation phases 3 and 4.

Function parameters are objects, not a special kind of identifier.

124 translation phase 3
129 translation phase 4

C++

The C++ Standard does not list macro parameters as one of the entities that can be denoted by an identifier.

71 parameter

Coding Guidelines

The issue of typedef names is discussed elsewhere.

792 typedef naming conventions

397 The same identifier can denote different entities at different points in the program.

identifier denote different entities

Commentary

The word *entities* is just a way of naming the different kinds of things that an identifier can refer to in C. The concept of scope allows the same identifier to be defined in a different scope, in the same name space, to refer to another entity. The concept of name space allows the same identifier to be defined in a different name space, in the same scope, to refer to another entity.

400 scope
438 name space

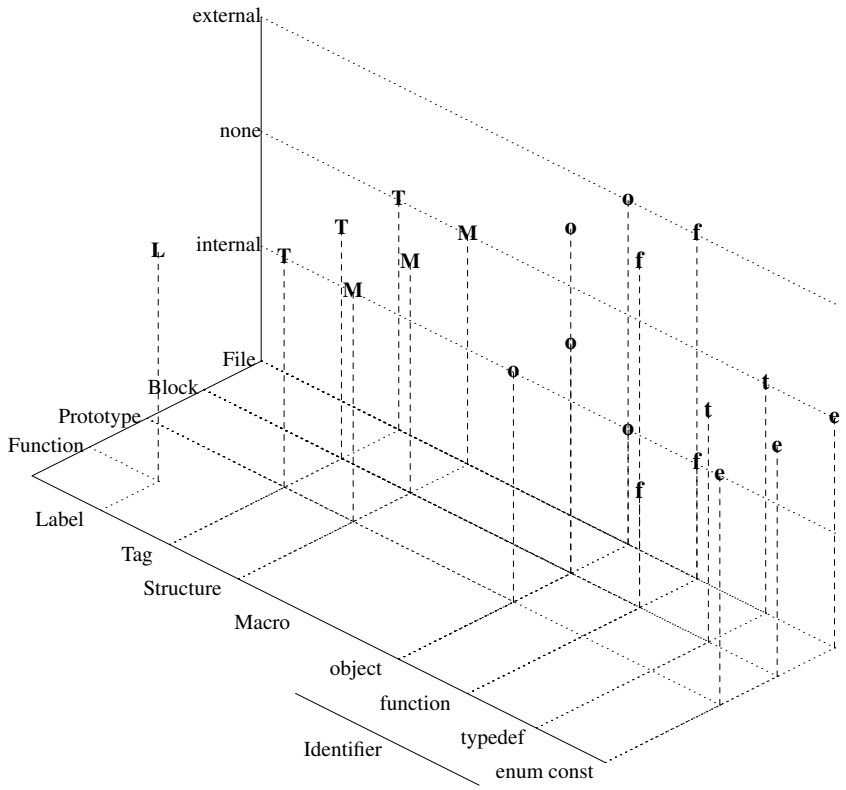

Figure 397.1: All combinations of linkage, scope, and name space that all possible kinds of identifiers, supported by C, can have. **M** refers to the members of a structure or union type. There is a separate name space for macro names and they have *no linkage*, but their scope has no formally specified name.

C++

The C++ Standard does not explicitly state this possibility, although it does include wording (e.g., 3.3p4) that implies it is possible.

Other Languages

Languages that support some kind of scoping rules usually allow the same identifier to denote different entities at different points in a program.

Cobol has a single scope and requires that identifiers be defined in a declaration section. This severely limits the extent to which the same identifier can be used to denote different entities. However, members of the structure data type can use the same names in different types. Some dialects of Basic have a single scope.

Coding Guidelines

Some of the costs and benefits of using the same identifier to denote different entities include:

- costs: an increase in the number of developer miscomprehensions when reading the source. For instance, the same identifier defined as a file scope, static linkage, object in one source file and a file scope, extern linkage, object in another source file could mislead the unwary developer, who was not aware of the two uses of the same name, into making incorrect assumptions about an assignment to one of the objects. The confusability of one identifier with another identifier is one of the major issues of identifier naming and is discussed elsewhere,

identifier 792 confusability

- benefits: an increase in reader recall performance through consistent use of identifier names to denote the same set of semantic attributes. For instance, having the same identifier denoting a member in

identifier 792 semantic associations

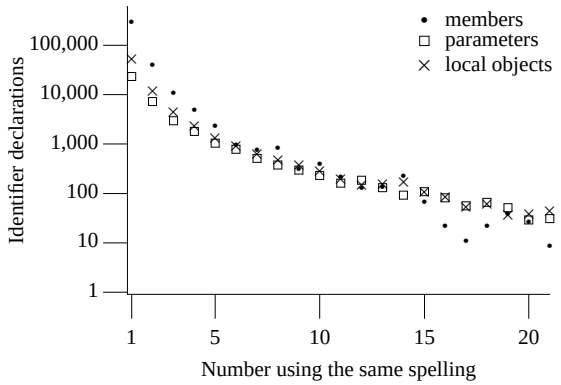

Figure 397.2: Number of declarations of an identifier with the same spelling in the same translation unit. Based on the translated form of this book's benchmark programs. Note that members of the same type are likely to be counted more than once (i.e., they are counted in every translation unit that declares them), while parameters and objects declared within function definitions are likely to be only counted once.

different structures can indicate that they all have the same usage (e.g., `x_cord` to hold the position on the x axis in a graph drawing program).

792 member naming conventions

The issues involved in making cost/benefit trade-offs related to identifier spelling and the role played by an identifier and are discussed elsewhere.

792 identifier syntax
1352 object role

Example

```
#define SAME(SAME) SAME /* Macro and macro parameter name spaces. */
/*
 * Additional lack of clarity could be obtained by replacing
 * any of the following identifiers, say id, by SAME(id).
 */

typedef struct SAME {          /* Tag name space. */
                    int SAME;  /* Unique name space of this structure definition. */
                    } SAME;    /* Ordinary identifier name space. */

SAME *(f(SAME SAME))(struct SAME SAME) /* Different scopes. */
{
SAME(SAME);                    /* A use (of the macro). */
if (SAME.SAME == sizeof(SAME)) /* More uses. */
   goto SAME;                  /* Label name space. */
else
   {                           /* A new scope. */
   enum SAME {
               SAME            /* Different name space. */
             } loc = SAME;     /* A use. */
   }

SAME:;                         /* Label name space. */
}
```

398 A member of an enumeration is called an *enumeration constant*.

enumeration constant

Commentary

This defines the term *enumeration constant*.

C++

There is no such explicit definition in the C++ Standard (7.2p1 comes close), although the term *enumeration constant* is used.

Other Languages

The term *enumeration constant* is generic to most languages that contain enumerated types.

Coding Guidelines

It is important to use this terminology. Sometimes the terms *enumeration identifier* or *enumeration value* are used by developers. It is easy to confuse these terms with other kinds of identifiers, or values.

Macro names and macro parameters are not considered further here, because prior to the semantic phase of program translation any occurrences of macro names in the source file are replaced by the preprocessing token sequences that constitute their macro definitions. 399

Commentary

macro definition lasts until 1974
macro definition 1975
no significance after preprocessing directives deleted 132
translation phase 7 136

Macro names are different from all other names in that they exist in a single scope that has no nesting. Macro definitions cease to exist after translation phase 4, as do preprocessing directives. The so-called *semantic phase* is translation phase 7.

Common Implementations

A few translators tag tokens with the macros they were expanded from, if any, as an aid to providing more informative diagnostic messages.

Coding Guidelines

Some of these coding guidelines apply to the source code that is visible to the developer. In such cases macro names, if they appear in the visible source, need to be considered in their unexpanded form.

preprocessor directives syntax 1854
#undef 1976

The concept of scope implies a coding structure that does not really exist during preprocessing (use of conditional inclusion does not create a new scope). The preprocessor views its input as an unstructured (apart from preprocessing directives) sequence of preprocessing tokens, some of which have special meaning. While it is possible to use **`#define`**/**`#undef`** pairs to simulate a scope, this usage is not common in practice.

---

visible identifier scope

For each different entity that an identifier designates, the identifier is *visible* (i.e., can be used) only within a region of program text called its *scope*. 400

Commentary

This defines the terms *visible* and *scope*. Visibility here means visible using the mechanisms defined in the standard for looking up identifiers (that have been previously declared). The concept of scope, in C, is based on the textual context in which an identifier occurs in translation phase 7— so-called *lexical scoping* (sometimes called *static scoping*, as opposed to *dynamic scoping*, which is based on when an object is created during program execution). The scope of a named object is closely associated with its lifetime in many cases.

translation phase 7 136
lifetime of object 451

C++

3.3p1 *In general, each particular name is valid only within some possibly discontiguous portion of program text called its scope.*

3.3p4 *Local extern declarations (3.5) may introduce a name into the declarative region where the declaration appears and also introduce a (possibly not visible) name into an enclosing namespace; these restrictions apply to both regions.*

If a name is in scope and is not hidden it is said to be visible. 3.3.7p5

Other Languages

The concept of scope exists in most programming languages. In Cobol, and some dialects of Basic, all variables have the same scope. Languages which make use of dynamic scoping include APL, Perl, Snobol 4, and Lisp (later versions of Lisp use static scoping; support for static scoping was introduced in version 5 of Perl). While being very flexible, dynamic scoping is not very runtime efficient because the actual object referenced has to be found during program execution; not being known at translation time, it is not possible to fix its address prior to program execution.

```
1  #include <stdlib.h>
2
3  int total = 0;
4
5  void f_1(void)
6  {
7  /*
8   * With dynamic scoping the current function call chain is important.
9   * If f_1 is called via f_2 then the local definition of total in f_2
10  * would be assigned to.  If f_1 was called directly from main, the
11  * file scope declaration of total would be assigned to.
12  */
13 total=1;
14 }
15
16 void f_2(void)
17 {
18 int total;
19
20 f_1();
21 }
22
23 int main(void)
24 {
25 if (rand() > 20)
26    f_1();
27 else
28    f_2();
29
30 return total;
31 }
```

In some languages the scope of an identifier may not be the same region of program text as the one it is visible in. For instance Pascal specifies that the scope of an identifier starts at the beginning of the block that contains its declaration, but it is only visible from the point at which it is declared.

```
1  int sum;
2
3  void pascal_scope_rules(void)
4  {
5  /*
6   * In Pascal the scope of the local declarations start here.  The scope of the
7   * nested declaration of sum starts here and hides the file scope declaration.
8   * But the nested declaration of sum does not become visible until after its'
9   * declaration.
10  */
11 int add_up = sum; /* In Pascal there is no identifier called sum visible here. */
```

```
12  int sum = 3;
13  }
```

Common Implementations

Implementations used to make use of the fact that identifiers were only visible (and therefore needed to be in their symbol table) within a scope to reduce their internal storage requirements; freeing up the storage used for an identifier's symbol table entry when the processing of the scope that contained its declaration was complete. Many modern implementations are not driven by tight storage restrictions and may keep the information for reasons of optimization or improved diagnostic messages.

Some implementations *exported* external declarations that occurred in block scope to file scope. For instance:

```
1   void f1(void)
2   {
3   /*
4    * Some translators make the following external linkage
5    * declaration visible at file scope...
6    */
7   extern int glob;
8   }
9
10  void f2(void)
11  {
12  /*
13   * ... which means that the following reference to glob refers
14   * to the one declared in function f1.
15   */
16  glob++;
17  }
18
19  void f3(void)
20  {
21  /*
22   * Linkage ensures that the following declaration always
23   * refers to the same glob object declared in function f1.
24   */
25  extern int glob;
26
27  glob++;
28  }
```

Coding Guidelines

Objects and functions are different from other entities in that it is possible to refer to them, via pointers, when the identifiers that designate them are not visible. While such anonymous accesses (objects referenced in this way are said to be *aliased*) can be very useful, but they can also increase the effort needed, by developers, to comprehend code. The issue of object aliases is discussed elsewhere.

alias analysis 1491
object 971 aliased

---

same identifier

Different entities designated by the same identifier either have different scopes, or are in different name spaces. 401

Commentary

The C Standard's meaning of same identifier is that the significant characters used to spell the identifier are identical. Differences in non-significant characters are not considered. Attempting to declare an identifier in the same scope and name space as another identifier with the same spelling is always a constraint violation.

C90

In all but one case, duplicate label names having the same identifier designate different entities in the same scope, or in the same name space, was a constraint violation in C90. Having the same identifier denote two different labels in the same function caused undefined behavior. The wording in C99 changed to make this case a constraint violation.

1725 label name unique

C++

The C++ Standard does not explicitly make this observation, although it does include wording (e.g., 3.6.1p3) that implies it is possible.

Coding Guidelines

The concept of name space is not widely appreciated by C developers. Given the guideline recommendation that identifier names be unique, independently of what name space they are in, there does not appear to be any reason for wanting to educate developers further on the concept of name space.

792.3 identifier reusing names

---

402 There are four kinds of scopes: function, file, block, and function prototype.

scope kinds of

Commentary

File scope is also commonly called *global scope*, not a term defined by the standard. Objects declared at file scope are sometimes called *global objects*, or simply *globals*.

Block scope is also commonly called *local scope*, not a term defined by the standard. Objects declared in block scope are sometimes called *local objects*, or simply *locals*. A block scope that is nested within another block scope is often called a *nested scope*.

The careful reader will have noticed a subtle difference between the previous two paragraphs. Objects were declared "at" file scope, while they were declared "in" block scope. Your author cannot find any good reason to break with this common developer usage and leaves it to English majors to rant against the irregular usage.

Identifiers defined as macro definitions are also said to have a scope.

1974 macro definition lasts until

C++

The C++ Standard does not list the possible scopes in a single sentence. There are subclauses of 3.3 that discuss the five kinds of C++ scope: function, namespace, local, function prototype, and class. A C declaration at file scope is said to have *namespace scope* or *global scope* in C++. A C declaration with block scope is said to have *local scope* in C++. Class scope is what appears inside the curly braces in a structure/union declaration (or other types of declaration in C++).

Given the following declaration, at file scope:

```
1  struct S {
2            int m; /* has file scope */
3                   // has class scope
4            } v;   /* has file scope */
5                   // has namespace scope
```

Other Languages

File and block scope are concepts that occur in many other languages. Some languages only allow definitions within functions to occur in the outermost block (e.g., Pascal); this may nor may not be equated to function scope. Function prototype scope is unique to C (and C++).

Coding Guidelines

Many developers are aware of file and block scope, but not the other two kinds of scope. Is anything to be gained by educating developers about these other scopes? Probably not. There are few situations where they are significant. These coding guidelines concentrate on the two most common cases— file and block scope (one issue involving function prototype scope is discussed elsewhere).

404 scope function
409 scope function prototype
409 prototype providing identifiers

(A *function prototype* is a declaration of a function that declares the types of its parameters.) 403

Commentary

This defines the term *function prototype*; it appears in parentheses because it is not part of the main subject of discussion in this subclause. A function prototype can occur in both a function declaration and a function definition. Function prototype scope only applies to the parameters in a function prototype that is purely a declaration. The parameters in a function prototype that is also a definition have block scope.

scope 409
function prototype
block scope 408
terminates

scope
function

A label name is the only kind of identifier that has *function scope*. 404

Commentary

labeled 1722
statements
syntax
goto 1787
statement

Labels are part of a mechanism (the **goto** statement) that can be used to change the flow of program execution. The C language permits arbitrary jumps to the start of any statement within a function (that contains the jump). To support this functionality label name visibility needs to cut across block boundaries, being visible anywhere within the function that defines them.

Other Languages

Few other languages define a special scope for labels. Most simply state that the labels are visible within the function that defines them, although a few (e.g., Algol 68) give labels block scope (this prevents jumps into nested blocks).

Languages that supported nested function definitions and require labels to be defined along with objects, often allow labels defined in outer function definitions to be referenced from functions defined within them.

Common Implementations

gcc supports taking the address of a label. It can be assigned to an object having a pointer type and passed as an argument in a function call. The label identifier still has function scope, but anonymous references to it may exist in other function scopes during program execution.

Coding Guidelines

This scope, which is specific to labels, is not generally known about by developers. Although they are aware that labels are visible throughout a function, developers tend not to equate this to the concept of a separate kind of scope. There does not appear to be benefit educating developers about its existence.

label
declared implicitly

It can be used (in a **goto** statement) anywhere in the function in which it appears, and is declared implicitly by its syntactic appearance (followed by a **:** and a statement). 405

Commentary

The C Standard provides no other mechanism for defining labels. Labels are the only entities that may, of necessity, be used before they are defined (a forward jump).

goto 1787
statement

Other Languages

Some languages allow labels to be passed as arguments in calls to functions and even assigned to objects (whose contents can then be **goto**ed.)

Pascal uses the **label** keyword to define a list of labels. Once defined, these labels may subsequently label a statement or be referenced in a **goto** statement. Pascal does not support declarations in nested blocks; so labels, along with all locally declared objects and types, effectively have function scope.

Common Implementations

gcc allows a label to appear as the operand of the **&&** unary operator (an extension that returns the address of the label).

identifier
scope determined
by declaration
placement

Every other identifier has scope determined by the placement of its declaration (in a declarator or type specifier). 406

Commentary

Every other identifier must also appear in a declarator before it is referenced. The C90 support for implicit declarations of functions, if none was currently visible, has been removed in C99. The textual placement of a declarator is the only mechanism available in C for controlling the visibility of the identifiers declared.

Other Languages

Languages that support a more formal approach to separate compilation have mechanisms for importing previously declared identifiers into a scope. Both Java and C++ support the **`private`** and **`public`** keywords, these can appear on a declarator to control the visibility of any identifiers it declares. Ada has a sophisticated separate compilation mechanism. Many other languages use very similar scoping mechanisms to those defined by the C Standard.

1810 translation unit syntax

Coding Guidelines

Some coding guideline documents recommend that the scope of identifiers be minimized. However, such a recommendation is based on a misplaced rationale. It is not an identifier's scope that should be minimized, but its visibility. For instance, an identifier at file scope may, or may not, be visible outside of the translation unit that defines it. Some related issues are discussed elsewhere.

1348 identifier definition close to usage

---

407 If the declarator or type specifier that declares the identifier appears outside of any block or list of parameters, the identifier has *file scope*, which terminates at the end of the translation unit.

file scope

Commentary

Structure and union members and any other identifiers declared within them, at file scope, also have file scope.

The return type on a function definition is outside of the outermost block associated with that definition. However, the parameters are treated as being inside it. Thus, any identifiers declared in the return type have file scope, while any declared in the parameter list have block scope.

408 block scope terminates

File scope may terminate at the end of the translation unit, but an identifier may have a linkage which causes it to be associated with declarations outside of that translation unit.

112 translation units communication between

Where the scope of an identifier begins is defined elsewhere.

416 tag scope begins
417 enumeration constant scope begins
418 identifier scope begins

C++

A name declared outside all named or unnamed namespaces (7.3), blocks (6.3), function declarations (8.3.5), function definitions (8.4) and classes (9) has global namespace scope (also called global scope). The potential scope of such a name begins at its point of declaration (3.3.1) and ends at the end of the translation unit that is its declarative region.

3.3.5p3

Other Languages

Nearly every other computer language supports some form of file scope declaration. A few languages, usually used in formal verification, do not allow objects to have file scope (allowing such usage can make it significantly more difficult to prove properties about a program).

In some languages individual identifiers do not exist independently at file scope— they must be part of a larger whole. For instance, in Fortran file scope objects are declared within **`common`** blocks (there can be multiple named common blocks, but only one unnamed common block). An entire common block (with all the identifiers it contains) needs to be declared within a source file, it is not possible to declare one single identifier (unless it is the only one declared by the common block). Other kinds of identifier groupings include *package* (Ada and Java), *namespace* (C++), *module* (Modula-2, Pascal), *cluster* (Clu), and *unit* (Borland Delphi). The underlying concept is the same, identifiers are exported and imported as a set.

Coding Guidelines

Some coding guidelines documents recommend that the number of objects declared at file scope be minimized. However, there have been no studies showing that alternative design/coding techniques would have a more worthwhile cost/benefit associated with their use.

The reasons for the declaration of an identifier to appear at file can depend on the kind of identifier being declared. Identifiers declared at file scope often appear in an order that depends on what they denote (e.g., macro, typedef, object, function, etc.). The issues associated with this usage are discussed elsewhere. The rest of this coding guideline subsection discusses the declaration of types, functions, and objects at file scope. Identifiers declared as types must appear at file scope if

external declaration 1810 syntax

- objects declared to have these types appear at file scope,
- objects declared to have these types appear within more than one function definition (having multiple, textual, declarations of the same type in different block scopes is likely to increase the cost of maintenance and C does not support the passing of types as parameters),
- other types, at files scope, reference these types in their own declaration.

Identifiers declared as functions must appear at file scope in those cases where two or more functions have a mutual calling relationship. This issue is discussed elsewhere.

function call 1026 recursive

Any program using file scope objects can be written in a form that does not use file scope objects. This can be achieved either by putting all statements in the function `main`, or by passing, what were file scope, objects as parameters. Are these solutions more cost effective than what they replaced? The following is a brief discussion of some of the issues.

The following are some of the advantages of defining objects at file scope (rather than passing the values they contain via parameters) include:

- Efficiency of execution. Accessing objects at file scope does not incur any parameter passing overheads. The execution-time efficiency and storage issues are likely to be a consideration in a freestanding environment, and unlikely to be an issue in a hosted environment.
- Minimizes the cost of adding new function definitions to existing source code. If the information needed by the new function is not available in a visible object, it will have to be passed as an argument. The function calling the new function now has a requirement to access this information, to pass it as a parameter. This requirement goes back through all call chains that go through the newly created function. If the objects that need to be accessed have file scope, there will be no need to add any new arguments to function calls and parameters to existing function definitions. In some cases using parameters, instead of file scope objects, can dramatically increase the number of arguments that need to be passed to many functions; it depends on how information flows through a program. If the flow is hierarchical (i.e., functions are called in a tree-like structure), it is straight-forward to pass information via parameters. If the data flow is not hierarchical, but like an undirected graph: with both `x` and `y` calling `a`, it is necessary for `p` to act as key holder for any information they need to share with `a`. The degree to which information flow and control flow follow each other will determine the ease, or complexity, of using parameters to access information. The further up the call chain the shared calling function, the greater the number of parameters that need to be passed through.

limit 288 parameters in definition

The following are some of the disadvantages of defining objects at file scope:

- Storage is used for the duration of program execution.
- There is a single instance of object. Most functions are not recursive, so separate objects for nested invocations of a function are not usually necessary.

function call 1026 recursive

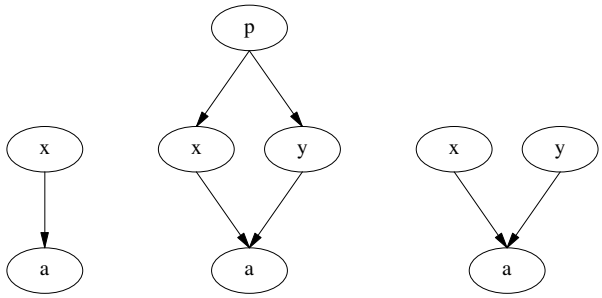

Figure 407.1: Some of the ways in which a function can be called— a single call from one other function; called from two or more functions, which in turn are all called by a single function; and called from two or more functions whose nearest shared calling function is not immediately above them.

- Reorganizing a program by moving function definitions into different translation units requires considering the objects they access. These may need to be given external linkage.
- Greater visibility of identifiers reduces the developer effort needed to access them, leading to a greater number of *temporary accesses* (the answer to the question, "how did all these unstructured accesses get into the source?" is, "one at a time").
- Information flow between functions is implicit. Developers need to make a greater investment in comprehending which calls cause which objects to be modified. Experience shows that developers tend to overestimate the reliability of their knowledge of which functions access which file scope identifiers.
- When reading the source of a translation unit, it is usually necessary to remember all of the file scope objects defined within it (locality of reference suggests that file scope identifiers referenced are more likely to be those defined in the current, rather than other, translation units). Reducing the number of file scope objects reduces the amount of information that needs to be in developers long-term memory.
- The only checks made on references to file scope objects is that they are visible and that the necessary type requirements are met. For issues, such as information flow, objects required to have certain values at certain points are not checked (such checking is in the realm of formal checking against specifications). Passing information via parameters does not guarantee that mistakes will not be made; but the need to provide arguments acts as a reminder of the information accessed by a function and the possible consequences of the call.

What is the algorithm for deciding whether to use parameters or file scope objects? The answer to this question involves many complex issues that are still poorly understood.

The argument that many programs exhibit faults because of the unconstrained use of objects at file scope, therefore use of parameters must be given preference, is too narrowly focused. Because it is the least costly solution, in terms of developer effort, file scope objects are more likely to be used than parameter passing. Given that many programs do not have long lifespans their maintenance costs are small, or non-existent. The many small savings accrued over incremental changes to many small programs over a relatively short lifespan may be greater than the total costs incurred from the few programs that are maintained over longer periods of time. If these savings are not greater than the costs, what is the size of the loss? Is it less than the value $saving - cost$ for the case in which developers have to invest additional effort in passing information via parameters? Without reliable evidence gathered from commercial development projects, these coding guidelines are silent on the topic of use file scope versus use of parameters.

Although they don't have file scope, the scope of macro names does terminate at the same point as identifiers that have file scope. Macro definitions are discussed elsewhere.

1974 macro definition lasts until
792 scope naming conventions

The issue of how an identifier's scope might interact with its spellings is discussed elsewhere.

Example

```
1  enum {E1, E2} /* File scope. */
2                f(enum {E3, E4} x) /* Block scope. */
3  { /* ... */ }
4
5  void g(c)
6  enum m {q, r} c; /* Block scope, in the list of parameter declarations. */
7  { /* ... */ }
```

---

block scope terminates

If the declarator or type specifier that declares the identifier appears inside a block or within the list of parameter declarations in a function definition, the identifier has *block scope*, which terminates at the end of the associated block. 408

Commentary

This defines the term *block scope* and specifies where it terminates. Where the scope of an identifier begins is defined elsewhere.

tag 416 scope begins
enumeration 417 constant scope begins
identifier 418 scope begins

Structure and union members, and other identifiers declared within them (but not those defined as macro names), in block scope, also have block scope.

The reference to parameter declarations does not distinguish between those declared via a function prototype, or an old style function declaration. They both have block scope, denoted by the outermost pair of braces.

It is possible for an object or function declared in block scope to refer to the same object or function at file scope, or even in a different translation unit, through a process called *linkage*.

linkage 420

C++

3.3.2p1 *A name declared in a block (6.3) is local to that block. Its potential scope begins at its point of declaration (3.3.1) and ends at the end of its declarative region.*

3.3.2p2 *The potential scope of a function parameter name in a function definition (8.4) begins at its point of declaration. . . . , else it ends at the outermost block of the function definition.*

Other Languages

A few languages, for instance Cobol, do not have any equivalent to block scope. In Java local variables declared in blocks follow rules similar to C. However, there are situations where the scope of a declaration can reach back to before its textual declaration.

Gosling[508] *The scope of a member declared in or inherited by a class type (8.2) or interface (9.2) is the entire declaration of the class or interface type.*

```
class Test {
   test() { k = 2; }
   int k;
   }
```

Common Implementations

Parameters in a function definition having block scope, rather than function prototype scope causes headache for translator implementors. The traditional single pass, on-the-fly translation process does not know that the parameters have block scope until an opening curly bracket, a semicolon, or a type (for old style function definitions) is seen during syntax analysis.

10 implementation single pass

Coding Guidelines

When should identifiers be defined with block scope?

Possible benefits of declaring functions in block scope is to remove the overhead associated with having to **#include** the appropriate header (in translation environments having limited storage capacity this can be a worthwhile saving), and to allow the source of a function definition to be easily copied to other source files (the cut-and-paste model of software development). Possible benefits of defining objects in block scope is that storage only needs to be allocated when the block containing it is executed, and objects within each block can be thought about independently (i.e., developers do not need to remember information about objects defined in other blocks).

Experience shows that when writing programs, developers often start out giving most objects block scope. It is only when information needs to be shared between different functions that the possible use of file scope, as opposed to parameters, needs to be considered. This issue is discussed in the previous C sentence.

407 file scope

It is rare for a declaration of an identifier denoting a typedef, tag, or enumeration constant to occur in block scope. Data structures important enough to warrant such a declaration are normally referenced by more than one function. Such usage could be an indicator that a function is overly long and needs to be broken up into smaller functions.

286 identifiers number in block scope

The same coding guideline issues might also apply to macro definitions. That is, macro names that are only used within a single function definition be defined at the start of that function (along with other definitions local to that function). However, macros do not have block scope and existing practice is for macro definitions to be located at the start of source files (and this is where developers learned to expect to find them). Calculating whether there is a worthwhile cost/benefit in using **#define**/**#undef** pairs to emulate a block scope is likely to be difficult and these coding guidelines are silent on the issue.

macro definition emulate block scope
1854 preprocessor directives syntax

Example

```
1  void DR_035(c)
2  enum m{q, r} /* m, q and r all have block scope, not file scope. */
3               c;
4  { /* ... */ }
5
6  void f(void)
7  {
8  /*
9   * The following function declaration declares a type in its
10  * return type.  This has block scope, effectively rendering
11  * calls to this function as undefined behavior.
12  */
13 extern struct {int i;} undefined_func(void);
14 }
```

---

409 If the declarator or type specifier that declares the identifier appears within the list of parameter declarations in a function prototype (not part of a function definition), the identifier has *function prototype scope*, which terminates at the end of the function declarator.

scope function prototype

Commentary

This type of scope was created by the C Committee for the C90 Standard (it was not in the original base document). This kind of scope is needed because the Committee decide to permit declarations of the form

1 base document

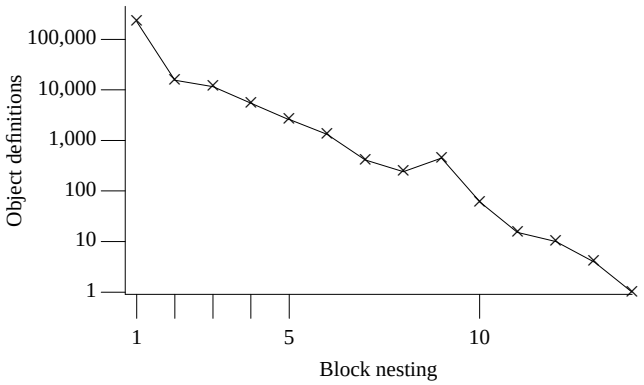

Figure 408.1: Number of object declarations appearing at various block nesting levels (level 1 is the outermost block). Based on the translated form of this book's benchmark programs.

prototype 409 providing identifiers

`extern void f(int x);`, where an identifier is specified for the parameter. Some developers believe that use of parameter names provides a benefit (this issue is discussed elsewhere).

A function declaration that defines a structure or union tag, or an anonymous structure or union type, in its function prototype scope renders the identifier it declares uncallable within the current translation unit (unless an explicit cast is applied to the function declarator at the point of call). This is because any calls to it cannot contain arguments whose types are compatible with the types of the parameters (which are declared using types that are only visible inside the function prototype scope). In the case of enumeration types declared in a function prototype scope, the identifier declared is callable (any arguments having an integer type will be converted to the enumerated types compatible integer type).

Other Languages

C (and C++) is unique in having this kind of scope. Other languages tend to simply state that the identifiers within the matching parentheses must be unique and do not allow new types to be defined between them, removing the need to create a scope to make use of the associated functionality to correctly process the parameter declarations.

Coding Guidelines

Tags, enumeration constants and parameter identifiers declared in function prototype scope are not visible outside of that scope and there are no mechanisms available for making them visible. Such usage serves no useful purpose since function prototype scope hides them completely. Anonymous structure and union types declared in function prototype scope do nothing but render the declared function unreferenceable.

prototype providing identifiers

The identifiers appearing in a prototype essentially fill the same role as comments, i.e., they may provide a reader of the source with useful information. The only reason that identifiers appear in such declarations may be because the author cut-and-pasted from the function definition. The presence of identifiers slightly increases the probability that a match against a defined macro will occur, but the consequences are either harmless or a syntax error. There does not appear to be a worthwhile cost/benefit in a guideline recommendation for or against this usage.

Example

```
1  /*
2   * Declaring a new type in a function prototype scope renders that
3   * function uncallable.  No other function can be compatible with it.
4   */
5  extern void uncallable(struct s_tag{int m1;} p);
6
7  extern void call_if_compatible_int(enum {E1, E2} p);
```

410 If an identifier designates two different entities in the same name space, the scopes might overlap.

scope overlapping

Commentary

Or they will be disjoint, or the translation unit contains a constraint violation.

Note that if a tag denoting an incomplete type is visible, then another declaration of that identifier in a different scope in the tag name space introduces a new type; it does not complete the previously visible incomplete type.

1459 tag declarations different scope

C90

This sentence does not appear in the C90 Standard, but the situation it describes could have occurred in C90.

C++

The scope of a declaration is the same as its potential scope unless the potential scope contains another declaration of the same name. 3.3p1

Other Languages

Languages that support at least two forms of scope (file and block) invariably allow identifiers declared in them to have overlapping scopes.

Coding Guidelines

Why would a developer want to use the same name to designate different entities in the same name space with overlapping scopes? Such usage can occur accidentally; for instance, when a block scope identifier has the same name as a file scope identifier that is beyond the developer's control (e.g., in a system header). Having the same identifier designate different entities, irrespective of name space and scope, is likely to be a potential cause of confusion to developers.

When two identifiers in the same name space have overlapping scopes, it is possible for a small change to the source to result in a completely unexpected change in behavior. For instance, if the identifier definition in the inner scope is deleted, all references that previously referred to that, inner scoped, identifier will now refer to the identifier in the outer scope. Deleting the definition of an identifier is usually intended to be accompanied by deletions of all references to it; the omission of a deletion usually generates a diagnostic when the source is translated (because of a type mismatch). However, if there is an alternative definition, with a compatible type, for an access to refer to, translators are unlikely to issue a diagnostic.

Dev 792.3 Identifiers denoting objects, functions, or types need only be compared against other identifiers having, or returning, a scalar type.

Example

```
1  extern int total_valu;
2  extern struct T {
3                   int m1;
4                  } data_fields;
5
6  void f(void)
7  {
8  float total_valu = 0.0;
9  int data_fields = 0;
10 }
11
```

```
12  void g(void)
13  {
14  int X;
15
16     {
17     int Y = X; /* Scope of second X not yet opened. */
18     int X;
19     }
20  }
```

Once an outer identifier has been hidden by the declaration in an inner scope, it is not possible to refer, by name, to the outer object.

---

scope inner
scope outer

If so, the scope of one entity (the *inner scope*) will be a strict subset of the scope of the other entity (the *outer scope*). 411

Commentary

This defines the terms *inner scope* and *outer scope*. The term *nested scope* is also commonly used to describe a scope that exists within another scope (often a block scope nested inside another block scope).

file scope accessing hidden names

This C statement only describes the behavior of identifiers. It is possible to refer to objects in disjoint scopes by using pointers to them. It is also possible, through use of linkage, for an identifier denoting an object at file scope to be visible within a nested block scope even though there is another declaration of the same identifier in an intervening scope.

```
1   extern int glob;
2
3   void f1(void)
4   {
5   int glob = 0;
6
7      {
8      extern int glob; /* Refers to same object as file scope glob. */
9
10     glob++;
11     }
12  /* Visible glob still has value 0 here. */
13  }
```

C++

The C observation can be inferred from the C++ wording.

3.3p1 *In that case, the potential scope of the declaration in the inner (contained) declarative region is excluded from the scope of the declaration in the outer (containing) declarative region.*

Other Languages

This terminology is common to most programming languages.

Within the inner scope, the identifier designates the entity declared in the inner scope; 412

Commentary

identifier 418 scope begins

The scopes of identifiers, in C, do not begin at the opening curly brace of a compound block (for block scope). It is possible for an identifier to denote different entities within the same compound block.

```
1   typedef int I;
2
3   void f(void)
```

```
4   {
5   I I; /* The inner scope begins at the second I. */
6   }
```

Coding Guidelines

Developers are unlikely to spend much time thinking about where the scope of an identifier starts. A cost effective simplification is to think of an identifier's scope being the complete block that contains its declaration. One of the rationales for the guideline recommendation dealing with reusing identifier names is to allow developers to continue to use this simplification.

792.3 identifier reusing names

---

413 the entity declared in the outer scope is *hidden* (and not visible) within the inner scope.

outer scope identifier hidden

Commentary

This defines the term *hidden*. The entity is hidden in the sense that the identifier is not visible. If the entity is an object, its storage location will still be accessible through any previous assignments of its address to an object of the appropriate pointer type. If such identifiers are file scope objects, they may also be accessible via, developer-written, functions that access them (possibly returning, or modifying, their value).

There is only one mechanism for directly accessing the outer identifier via its name, and that only applies to objects having file scope.

411 file scope accessing hidden names

C++

The C rules are a subset of those for C++ (3.3p1), which include other constructs. For instance, the scope resolution operator, `::`, allows a file scope identifier to be accessed, but it does not introduce that identifier into the current scope.

Other Languages

The hiding of identifiers by inner, nested declarations is common to all block-structured languages. Some languages, such as Lisp, base the terms *inner scope* and *outer scope* on a time-of-creation basis rather than lexically textual occurrence in the source code.

Coding Guidelines

The discussion of the impact of scope on identifier spellings is applicable here.

792 scope naming conventions

Example

It is still possible to access an outer scope identifier, denoting an object, via a pointer to it:

```
1   void f(void)
2   {
3   int i,
4       *pi = &i;
5
6       {
7       int i = 3;
8
9       i += *pi; /* Assign the value of the outer object i, to the inner object i. */
10      }
11  }
```

Usage

In the translated form of this book's benchmark programs there were 1,945 identifier definitions (out of 270,394 identifiers defined in block scope) where an identifier declared in an inner scope hid an identifier declared in an outer block scope.

---

414 Unless explicitly stated otherwise, where this International Standard uses the term "identifier" to refer to some entity (as opposed to the syntactic construct), it refers to the entity in the relevant name space whose declaration is visible at the point the identifier occurs.

Commentary

The C Standard is a definition of a computer language in a stylized form of English. It is not intended as a tutorial. As such, it is brief and to the point. This wording ensures that uses of the term *identifier* are not misconstrued. For instance, later wording in the standard should not treat the declaration of `glob` as being a prior declaration in the context of what is being discussed.

prior declaration not 429

```
1  struct glob {
2              int mem;
3              };
4
5  extern int glob;
```

C90

There is no such statement in the C90 Standard.

C++

There is no such statement in the C++ Standard (which does contain uses of *identifier* that refer to its syntactic form).

Coding Guidelines

Coding guidelines are likely to be read by inexperienced developers. Particular guidelines may be read in isolation, relative to other guidelines. Being brief is not always a positive attribute for them to have. A few additional words clarifying the status of the identifier referred to can help confirm the intent and reduce possible, unintended ambiguities.

---

scope same

Two identifiers have the *same scope* if and only if their scopes terminate at the same point. 415

Commentary

incomplete type completed by 550

This defines the term *same scope* (it is used in the description of incomplete types). The scope of every identifier, except labels, starts at a different point than the scope of any other identifier in the source file. Scopes end at well-defined boundaries; the closing **}** of a block, the closing **)** of a prototype, or on reaching the end of the source file, the end of an *iteration-statement*, loop body, the end of a *selection-statement*, or the end of a substatement associated with a selection statement.

block iteration statement 1768
block loop body 1769
block selection statement 1741
block selection sub-statement 1742

C90

Although the wording of this sentence is the same in C90 and C99, there are more blocks available to have their scopes terminated in C99. The issues caused by this difference are discussed in the relevant sentences for iteration-statement, loop body, a *selection-statement* a substatement associated with a selection statement.

block iteration statement 1768
block loop body 1769
block selection statement 1741
block selection sub-statement 1742

C++

The C++ Standard uses the term *same scope* (in the sense "in the same scope", but does not provide a definition for it. Possible interpretations include using the common English usage of the word *same* or interpreting the following wording

3.3p1 *In general, each particular name is valid only within some possibly discontiguous portion of program text called its scope. To determine the scope of a declaration, it is sometimes convenient to refer to the potential scope of a declaration. The scope of a declaration is the same as its potential scope unless the potential scope contains another declaration of the same name. In that case, the potential scope of the declaration in the inner (contained) declarative region is excluded from the scope of the declaration in the outer (containing) declarative region.*

to imply that the scope of the first declaration of `a` is not the same as the scope of `b` in the following:

```
{
int a;
int b;
   {
   int a;
   }
}
```

Other Languages

A few languages define the concept of same scope, often based on where identifiers are declared not where their scope ends.

Example

In the following example the identifiers `X` and `Y` have the same scope; the identifier `Z` is in a different scope.

```
void f(void)
{
int X;
int Y;

   {
   int X; /* A different object named X. */
   int Z;

   } /* Scope of X and Z ended at the } */
}    /* Scope of X and Y ended at the } */

void g(void)
{
for (int index = 0; index < 10; index++)
   {
   int index;
   /* Scope of second index ends here. */ }
/* Scope of first one ends here.    */ }
```

---

416 Structure, union, and enumeration tags have scope that begins just after the appearance of the tag in a type specifier that declares the tag.

tag scope begins

Commentary

The scope of some identifiers does not start until their declarator is complete. Applying such a rule to tags would prevent self-referencing structure and union types (i.e., from having members that pointed at the type currently being defined).

418 identifier scope begins

```
struct S1_TAG {
               struct S1_TAG *next;
               };
```

However, just because a tag is in scope and visible does not mean it can be referenced in all of the contexts that a tag can appear in. A tag name may be visible, but denoting what is known as an *incomplete type*.

550 incomplete type completed by

```
struct S2_TAG {
               char mem1[sizeof(struct S2_TAG)]; /* Constraint violation. */
               };

/*
 * Here E_TAG becomes visible once the opening { is reached.
 * However, the decision on the size of the integer type chosen may
```

```
 * require information on all of the enumeration constant values and
 * its type is incomplete until the closing }.
 */
enum E_TAG {E1 = sizeof(enum E_TAG)};
```

C++

The C++ Standard defines the term *point of declaration* (3.3.1p1). The C++ point of declaration of the identifier that C refers to as a tag is the same (3.3.1p5). The scope of this identifier starts at the same place in C and C++ (3.3.2p1, 3.3.5p3).

Coding Guidelines

incom-plete type completed by 550

The scope of a tag is important because of how it relates to completing a previous incomplete structure or union type declaration. This issue is discussed in more detail elsewhere.

---

enumera-tion constant scope begins

Each enumeration constant has scope that begins just after the appearance of its defining enumerator in an enumerator list. 417

Commentary

enumeration specifier syntax 1439

The definition of an enumerator constant can include a constant expression that specifies its value. The scope of the enumeration constant begins when the following comma or closing brace is encountered. This enables subsequent enumerators to refer to ones previously defined in the same enumerated type definition.

C++

3.3.1p3

The point of declaration for an enumerator is immediately after its `enumerator-definition`*. [Example:*

```
const int x = 12;

{ enum { x = x }; }
```

Here, the enumerator `x` *is initialized with the value of the constant* `x`*, namely 12.]*

In C, the first declaration of x is not a constant expression. Replacing it by a definition of an enumeration of the same name would have an equivalent, conforming effect in C.

Coding Guidelines

identifier reusing names 792.3

The example below illustrates an extreme case of the confusion that can result from reusing identifier names. The guideline recommendation dealing with reusing identifier names is applicable here.

Example

```
enum {E = 99};

void f(void)
{
enum { E = E + 1  /* Original E still in scope here. */
                , /* After comma, new E in scope here, with value 100. */
       F = E};    /* Value 100 assigned to F. */
}
```

---

identifier scope begins

Any other identifier has scope that begins just after the completion of its declarator. 418

Commentary

The other identifiers are objects, typedefs, and functions. For objects' definitions, the declarator does not include any initializer that may be present. A declarator may begin the scope of an identifier, but subsequent declarators in the same scope for the same identifier may also appear (and sometimes be necessary) in some cases.

1547 declarator syntax

550 incomplete type completed by

C++

The C++ Standard defines the potential scope of an identifier having either local (3.3.2p1) or global (3.3.5p3) scope to begin at its *point of declaration* (3.3.1p1). However, there is no such specification for identifiers having function prototype scope (which means that in the following declaration the second occurrence of `p1` might not be considered to be in scope).

```
1  void f(int p1, int p2[sizeof(p1)]);
```

No difference is flagged here because it is not thought likely that C++ implementation will behave different from C implementations in this case.

Other Languages

Some languages define the scope of an identifier to start at the beginning of the block containing its declaration. This design choice can make it difficult for a translator to operate in a single pass. An identifier from an outer scope may be referenced in the declaration of an object; a subsequent declaration in the same block of an identifier with the same name as the referenced outer scope one invalidates the reference to the previous object declaration and requiring the language translator to change the associated reference.

In some cases the scope of an identifier in Java can extend to before its point of declaration.

408 block scope terminates

Coding Guidelines

Cases such as the one given in the next example, where two entities share the same name and are visible in different portions of the same block are covered by the guideline recommendation dealing with reusing identifier names.

792.3 identifier reusing names

Example

```
1  void f(void)
2  {
3  enum {c, b, a};
4  typedef int I;
5
6     {
7     I I; /*
8           * The identifier object does not become visible until the ;
9           * is reached, by which time the typedefed I has done its job.
10          */
11
12    int a[a]; /*
13                * Declarator completed after the closing ], number of
14                * elements refers to the enumeration constant a.
15                */
16
17    struct T {struct T *m;} x = /* declarator complete here. */
18                                {&x};
19    }
20 }
```

419 **Forward references:** declarations (6.7), function calls (6.5.2.2), function definitions (6.9.1), identifiers (6.4.2), name spaces of identifiers (6.2.3), macro replacement (6.10.3), source file inclusion (6.10.2), statements (6.8).

6.2.2 Linkages of identifiers

linkage

An identifier declared in different scopes or in the same scope more than once can be made to refer to the same object or function by a process called *linkage*.[21)] 420

Commentary

This defines the term *linkage*. It was introduced into C90 by the Committee as a means of specifying a model of separate compilation for C programs.

It is intended that the different scopes mentioned apply to file scopes in both the same and different translation units (block scopes can also be involved in the case of tags). The need to handle multiple declarations, in the same and different translation units, of the same file scope objects was made necessary by the large body of existing source code that contained such declarations. Linkage is the mechanism that makes it possible to translate different parts of a program at different times, each referring to objects and functions defined elsewhere.

program 107
not translated at same time

Rationale

The definition model to be used for objects with external linkage was a major C89 standardization issue. The basic problem was to decide which declarations of an object define storage for the object, and which merely reference an existing object. A related problem was whether multiple definitions of storage are allowed, or only one is acceptable. Pre-C89 implementations exhibit at least four different models, listed here in order of increasing restrictiveness:

Common Every object declaration with external linkage, regardless of whether the keyword extern appears in the declaration, creates a definition of storage. When all of the modules are combined together, each definition with the same name is located at the same address in memory. (The name is derived from common storage in Fortran.) This model was the intent of the original designer of C, Dennis Ritchie.

Relaxed Ref/Def The appearance of the keyword extern in a declaration, regardless of whether it is used inside or outside of the scope of a function, indicates a pure reference (ref), which does not define storage. Somewhere in all of the translation units, at least one definition (def) of the object must exist. An external definition is indicated by an object declaration in file scope containing no storage class indication. A reference without a corresponding definition is an error. Some implementations also will not generate a reference for items which are declared with the extern keyword but are never used in the code. The UNIX operating system C compiler and linker implement this model, which is recognized as a common extension to the C language (see §K.5.11). UNIX C programs which take advantage of this model are standard conforming in their environment, but are not maximally portable (not strictly conforming).

Strict Ref/Def This is the same as the relaxed ref/def model, save that only one definition is allowed. Again, some implementations may decide not to put out references to items that are not used. This is the model specified in K&R .

Initialization This model requires an explicit initialization to define storage. All other declarations are references.

Table 420.1: Comparison of identifier linkage models

Model	File 1	File 2
common	`extern int I; int main() { I = 1; second(); }`	`extern int I; void second() { third( I ); }`
Relaxed Ref/Def	`int I; int main() { I = 1; second(); }`	`int I; void second() { third( I ); }`
Strict Ref/Def	`int I; int main() { I = 1; second(); }`	`extern int I; void second() { third( I ); }`
Initializer	`int I = 0; int main() { I = 1; second(); }`	`int I; void second() { third( I ); }`

C++

The C++ Standard also defines the term *linkage*. However, it is much less relaxed about multiple declarations of the same identifier (3.3p4).

A name is said to have linkage when it might denote the same object, reference, function, type, template, namespace or value as a name introduced by a declaration in another scope:

Other Languages

Few languages permit multiple declarations of the same identifier in the same scope. The mechanisms used by different languages to cause an identifier to refer to the same object, or function, in separately translated source files varies enormously. Some languages, such as Ada and Java, have a fully defined separate compilation mechanism. Fortran requires that shared objects be defined in an area known as a common block. (The semantics of this model was used by some early C translators.) Other languages do not specify a separate compilation mechanism and leave it up to the implementation to provide one.

1810 translation unit syntax

Fortran specifies the common block construct as the mechanism by which storage may be shared across translation units. Common blocks having the same name share the same storage. The declarations within a common block are effectively offsets into that storage. There is no requirement that identifiers within each common block have the same name as identifiers at the corresponding storage locations of matching common blocks.

```
1          SUBROUTINE A
2          COMMON /XXX/ IFRED
3          END
4
5          SUBROUTINE B
6          COMMON /XXX/ JIM
7    C     IFRED and JIM share the same storage
8          END
```

Common Implementations

Early implementations provided a variety of models for deducing which declarations referred to the same object, as described in the previous Rationale discussion.

Coding Guidelines

The term *linkage* is not generally used by developers. Terms such as *externally visible* (or just *external*) and *not externally visible* (or *not external*, *only visible within one translation unit*) are used by developers when discussing issues covered by the C term *linkage*. Is it worthwhile educating developers about linkage and how it applies to different entities? From the developers point of view, the most important property is whether an object can be referenced from more than one translation unit. The common usage terms *external* and *not external* effectively describe the two states that are of interest to developers. Unless a developer wants to become an expert on the C Standard, the cost/benefit of learning how to apply the technically correct terminology (*linkage*) is not worthwhile.

linkage educating developers

In many ways following the guideline recommendation dealing with having a single point of declaration for each identifier often removes the need for developers to think about linkage issues.

422.1 identifier declared in one file

---

421 There are three kinds of linkage: external, internal, and none.

linkage kinds of

Commentary

The linkage *none* is sometimes referred to (in this standard and by developers) as *no linkage*.

C++

The C++ Standard defines the three kinds of linkage: external, internal, and no linkage. However, it also defines the concept of *language linkage*:

All function types, function names, and variable names have a language linkage. [Note: Some of the properties associated with an entity with language linkage are specific to each implementation and are not described here.

7.5p1

For example, a particular language linkage may be associated with a particular form of representing names of objects and functions with external linkage, or with a particular calling convention, etc.] The default language linkage of all function types, function names, and variable names is C++ language linkage. Two function types with different language linkages are distinct types even if they are otherwise identical.

Other Languages

The term *linkage* is unique to C (and C++). The idea behind it— of making identifiers declared in one separately translated source file visible to other translated files— is defined in several different ways by other languages.

Coding Guidelines

The term *external* is well-known to developers; some are also aware of the term *internal*. However, the fact that they relate to a concept called *linkage*, and that there is a third *none*, is almost unknown. The term *visible* is also sometimes used with these terms (e.g., *externally visible*).

---

object external linkage denotes same function external linkage denotes same

In the set of translation units and libraries that constitutes an entire program, each declaration of a particular identifier with *external linkage* denotes the same object or function. 422

Commentary

same object 640 have compatible types

translation phase 139 8

The phrase *particular identifier* means identifiers spelled with the same character sequence (i.e., ignoring any nonsignificant characters). Other wording in the standard requires that the types of the identifiers be compatible (otherwise the behavior is undefined). The process of making sure that particular identifiers with external linkage refer to the same object, or function, occurs in translation phase 8.

C++

The situation in C++ is complicated by its explicit support for linkage to identifiers whose definition occurs in other languages and its support for overloaded functions (which is based on a function's signature (1.3.10) rather than its name). As the following references show, the C++ Standard does not appear to explicitly specify the same requirements as C.

3.2p3 *Every program shall contain exactly one definition of every non-inline function or object that is used in that program; no diagnostic required. The definition can appear explicitly in the program, it can be found in the standard or a user-defined library, or (when appropriate) it is implicitly defined (see 12.1, 12.4 and 12.8). An inline function shall be defined in every translation unit in which it is used.*

C++ 1350 one definition rule

Some of the consequences of the C++ *one definition rule* are discussed elsewhere.

3.5p2

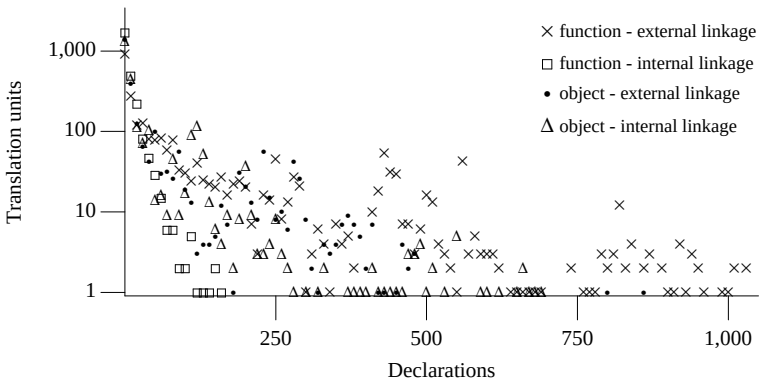

Figure 421.1: Number of translation units containing a given number of objects and functions declared with internal and external linkage (excluding declarations in system headers). Based on the translated form of this book's benchmark programs.

A name is said to have linkage when it might denote the same object, reference, function, type, template, namespace or value as a name introduced by a declaration in another scope:

— When a name has external linkage, the entity it denotes can be referred to by names from scopes of other translation units or from other scopes of the same translation unit.

At most one function with a particular name can have C language linkage. 7.5p6

Common Implementations

As a bare minimum, translators have to write information on the spelling of identifiers having external linkage to the object code file produced from each translation unit. Some translators contain options to write out information on other identifiers. This might be used, for instance, for symbolic debugging information.

Most linkers (the tool invariably used) simply match up identifiers (having external linkage) in different translated translation units with the same spelling (the spelling that was written to the object file by the previous phase, which will have removed nonsignificant characters). While type information is sometimes available (e.g., for symbolic debugging), most linkers ignore it. Very few do any cross translation unit type checking. The commonly seen behavior is to use the start address of the storage allocated (irrespective of whether an object or function is involved). 140 linkers

Issues, such as identifiers not having a definition in at least one of the translation units, or there being more than one definition of the same identifier, are discussed elsewhere. 1818 external linkage
exactly one external definition

Coding Guidelines

There is no requirement for a translator to generate a diagnostic message when a particular identifier is declared using incompatible types in different translation units. The standard defines no behavior for such usage and accessing such identifiers results in undefined behavior. A translator is not required to, and most don't, issue any diagnostic messages as a result of requirements in translation phase 8. 640 same object
have compatible types
139 translation phase
8

Because of the likely lack of tool support for detecting instances of incompatible declarations across translations units, these guidelines recommend the use of code-structuring techniques that make it impossible to declare the same identifier differently in different translation units. The lack of checking by translators, and other tools, then becomes a nonissue. The basic idea is to ensure that there is only ever one textual instance of the declaration of an identifier. This can never be different from itself, assuming any referenced macro names or typedefs are also the same. The issue then becomes how to organize the source to use this single textual declaration.

The simplest way of organizing source code to use single declarations is to place these declarations in header files. These header files can be included wherever their contents need to be referenced. A consequence of this guideline is that there are no visible external declarations in `.c` source files.

Cg 422.1

Only one of the source files translated to create a program image shall contain the textual declaration of a given identifier having file scope.

The C Standard requires all identifiers to be explicitly declared before they are referenced. However, this requirement is new in C99. The following guideline recommendation is intended to cover those cases where the translator used does not support the current standard, or where the translator is running in some C90 compatibility mode. 1000 operator ()

Cg 422.2

A source file that references an identifier with external linkage shall **`#include`** the header file that contains its textual declaration.

header name same as .c file
header name 918
external linkage 1818
exactly one external definition

A commonly used convention is for the `.h` file, containing the external declarations of identifiers defined in some `.c` file, to have the same header name as the `.c` file. The issue of ensuring that there is a unique definition for every referenced identifier is discussed elsewhere.

Example

The types of the object `array` in the following two files are incompatible.

file_1.c

```
1 extern int glob;
2 extern char array[10]; /* An array of 10 objects of type char. */
```

file_2.c

```
1 extern float glob;
2 extern char *array; /* A pointer to one or more objects of type char. */
```

Usage

A study of 29 Open Source programs by Srivastava, Hicks, Foster and Jenkins[1277] found 1,161 identifiers with external linkage, referenced in more than one translation unit, that were not declared in a header, and 809 instances where a header containing the declaration of a referenced identifier was not **#include**d (i.e., the source file contained a textual external declaration of the identifier).

---

identifier same if internal linkage

Within one translation unit, each declaration of an identifier with *internal linkage* denotes the same object or function. 423

Commentary

tentative definition 1849
same object 640
have compatible types

This describes the behavior for the situation, described elsewhere, where there is more than one declaration of the same identifier with internal linkage in a translation unit. Other wording in the standard requires that the types of the identifiers be compatible

An object, defined with internal linkage in a translation unit, is distinct from any other object in other translation units, even if the definition of an identifier, denoting an object, in a different translation unit has exactly the same spelling (the linkage of the object in the other translation units is irrelevant).

Coding Guidelines

Why would a developer want to have more than one declaration of an identifier, with internal linkage, in one translation unit? There is one case where multiple declarations of the same object, with internal linkage, are necessary— when two or more object definitions recursively refer to each other (such usage is rare). There is also one case where multiple declarations of the same function, with internal linkage, are required—when two or more functions are in a recursive call chain. In this case some of the functions must be declared before they are defined. While it may be necessary to create type definitions that are mutually recursive, the declared identifiers have *none* linkage.

function call 1026
recursive
EXAMPLE 1474
mutually referential structures

Some coding guideline documents recommend that all functions defined in a translation unit be declared at the beginning of the source file, along with all the other declarations of file scope identifiers.

The rationale given for a guideline recommendation that identifiers with external linkage have a single textual declaration included a worthwhile reduction in maintenance costs. This rationale does not apply to declarations of identifiers having internal linkage, because translators are required to diagnose any type incompatibilities in any duplicate declarations and duplicate declarations are not common.

identifier 422.1
declared in one file

Example

```
1 struct T {struct T *next;};
2
3 static struct T q;
4
```

```
5   static struct T p = { &q }; /* Recursive reference. */
6   static struct T q = { &p }; /* Recursive reference. */
7
8   static void g(int);
9
10  static void f(int valu)
11  {
12  if (valu--)
13     g(valu);
14  }
15
16  static void g(int valu)
17  {
18  if (--valu)
19     f(valu);
20  }
```

424 Each declaration of an identifier with *no linkage* denotes a unique entity.

no linkage identifier declaration is unique

Commentary

Here the phrase *no linkage* is used to mean that the linkage is *none*. The term *no linkage* is commonly used to have this meaning. The only entities that can have a linkage other than linkage *none* are objects and functions, so identifiers denoting all other entities have *no linkage*.

Tags are the only identifiers having no linkage that may be declared more than once in the same scope. Other wording in the standard makes it a constraint violation to have more than one such identifier with the same name in the same scope and name space.

432 identifier no linkage
475 incomplete types
1350 declaration only one if no linkage

C++

The C++ *one definition rule* covers most cases:

> *No translation unit shall contain more than one definition of any variable, function, class type, enumeration type or template.* 3.2p1

However, there is an exception:

> *In a given scope, a* **typedef** *specifier can be used to redefine the name of any type declared in that scope to refer to the type to which it already refers. [Example:* 7.1.3p2
>
> ```
> typedef struct s { /* ... */ } s;
> typedef int I;
> typedef int I;
> typedef I I;
> ```
>
> *—end example]*

Source developed using a C++ translator may contain duplicate typedef names that will generate a constraint violation if processed by a C translator.

The following does not prohibit names from the same scope denoting the same entity:

> *A name is said to have linkage when it might denote the same object, reference, function, type, template, namespace or value as a name introduced by a declaration in another scope:* 3.5p2
>
> *— When a name has no linkage, the entity it denotes cannot be referred to by names from other scopes.*

This issue is also discussed elsewhere.

1350 declaration only one if no linkage

static internal linkage

If the declaration of a file scope identifier for an object or a function contains the storage-class specifier **static**, the identifier has internal linkage.[22)] 425

Commentary

no linkage 435 block scope object storage-class 1364 specifier syntax declarator 1547 syntax

If the same declaration occurs in block scope the identifier has no linkage. The keyword **static** is overworked in the C language. It is used to indicate a variety of different properties.

C++

3.5p3

A name having namespace scope (3.3.5) has internal linkage if it is the name of

— an object, reference, function or function template that is explicitly declared ***static*** *or,*

— an object or reference that is explicitly declared ***const*** *and neither explicitly declared* ***extern*** *nor previously declared to have external linkage; or*

```
1  const int glob; /* external linkage */
2                  // internal linkage
```

identifier 422.1 declared in one file identifier 1818.1 definition shall #include

Adhering to the guideline recommendations dealing with textually locating declarations in a header file and including these headers, ensures that this difference in behavior does not occur (or will at least cause a diagnostic to be generated if they do).

Other Languages

Some languages specify that all identifiers declared at file scope are not externally visible unless explicitly stated otherwise (i.e., the identifiers have to be explicitly exported through the use of some language construct).

Coding Guidelines

linkage 420 educating developers

Developers often think in terms of the keyword **static** limiting the visibility of an identifier to a single translation unit. This describes the effective behavior, but not the chain of reasoning behind it.

extern identifier linkage same as prior declaration

For an identifier declared with the storage-class specifier **extern** in a scope in which a prior declaration of that identifier is visible,[23)] if the prior declaration specifies internal or external linkage, the linkage of the identifier at the later declaration is the same as the linkage specified at the prior declaration. 426

Commentary

The C committee were faced with a problem. Historically, use of the keyword **extern** has been sloppy. Different declaration, organizational styles have been used to handle C's relaxed, separate compilation model. This sometimes resulted in multiple declarations of the same identifier using the storage-class specifier **extern**. Allowing the linkage of an object declared using the storage-class specifier **extern** to match the linkage of any previous declaration maintained the conformance status of existing (when C90 was written) source code.

While there may be more than one declaration of the same identifier in a translation unit, if it is used in an expression a definition of it is required to exist. If the identifier has internal linkage, a single definition of it must exist within the translation unit, and if it has external linkage there has to be exactly one definition of it somewhere in the entire program.

definition 1812 one external external 1818 linkage exactly one external definition

C90

The wording in the C90 Standard was changed to its current form by the response to DR #011.

Coding Guidelines

While an identifier might only be textually declared in a single header file, that header may be **#include**d more than once when a source file is translated. A consequence of this multiple inclusion is that the same identifier can be declared more than once during translation (because it is a tentative definition). 1849 tentative definition

An identifier declared using the storage-class specifier **static** that is followed, in the same translation unit, by another declaration of the same identifier containing the storage-class specifier **extern** is considered to be harmless.

Example

```
1  static int si;
2  extern int si; /* si has internal linkage. */
3
4  static int local_func(void)
5  { /* ... */ }
6
7  void f(void)
8  {
9  extern int local_func(void);
10 }
11
12 static int glob; /* Declaration 1 */
13
14 void DR_011(void)
15 {
16 extern int glob; /* Declaration 2.  At this point Declaration 1 is visible. */
17
18    {
19    /*
20     * The following declaration results in an identifier that refers
21     * to the same object having both internal and external linkage.
22     */
23    extern int glob; /* Declaration 3.  Declaration 2 is visible here. */
24    }
25 }
```

---

427 21) There is no linkage between different identifiers. footnote 21

Commentary

Nor is there any linkage between identifiers in different name spaces; only identifiers in the *normal* name space can have linkage. Identifiers whose spelling differ in significant characters are different identifiers. The number of significant characters may depend on the linkage of the identifier. 282 internal identifier significant characters 283 external identifier significant characters

C++

The C++ Standard says this the other way around.

A name is said to have linkage when it might denote the same object, reference, function, type, template, namespace or value as a name introduced by a declaration in another scope: 3.5p2

Coding Guidelines

Translators that support a limited number of significant characters in identifiers may create a linkage where none was intended. For instance, two different identifiers (when compared using all of the characters appearing in their spelling) with external linkage in different translation units may end up referring to each other because the translator used does not compare characters it considers nonsignificant. This issue is discussed elsewhere. 792 identifier number of characters

Example

Because there is no linkage between different identifiers, the following program never outputs any characters:

```
#include <stdio.h>

const int i = 0;
const int j = 0;

int main(void)
{
if (&i == &j)
   printf("Linkage exists between different identifiers\n");
return 0;
}
```

---

footnote 22

22) A function declaration can contain the storage-class specifier **static** only if it is at file scope; see 6.7.1. 428

Commentary

This sentence appears in a footnote and as such has no normative meaning. However, there is other wording in the standard that renders use of the static storage-class at block scope to be undefined behavior.

block scope 1371
storage-class use

C++

7.1.1p4 *There can be no* ***static*** *function declarations within a block, . . .*

This wording does not require a diagnostic, but the exact status of a program containing such a usage is not clear.

A function can be declared as a static member of a **class** (**struct**). Such usage is specific to C++ and cannot occur in C.

Other Languages

Languages in the Pascal/Ada family supports the nesting of function definitions. Such nested definitions essentially have static storage class. Java does not support the nesting of function definitions (although classes may be nested).

Common Implementations

gcc supports nested functions, as an extension, and the static storage-class can be explicitly specified for such functions. The usage is redundant in that they have block scope (inside the function that contains their definition) and are not visible outside of that block.

---

prior declaration not

If no prior declaration is visible, or if the prior declaration specifies no linkage, then the identifier has external linkage. 429

Commentary

A prior declaration might not be visible because it does not exist or because a block scope declaration of the same identifier (in the same name space) hides it. Here the term *no linkage* is used to mean that a linkage of external or internal was not assigned (using the rules of the standard to interpret a prior declaration).

outer scope 413
identifier hidden

C90

The wording in the C90 Standard was changed to its current form by the response to DR #011.

Coding Guidelines

If a prior declaration exists, the situation involves more than one declaration of the same identifier. As such, it is covered by the guideline recommendation dealing with multiple declarations of the same identifier.

object 422
external linkage denotes same

Example

```
1  extern int doit_1(void); /* external linkage. */
2  static int doit_2(void); /* internal linkage. */
3
4  void f(void)
5  {
6  int doit_1, /* no linkage. */
7      doit_2; /* no linkage. */
8
9     {
10    extern int doit_1(void); /* external linkage. */
11    extern int doit_2(void); /* external linkage. */
12    }
13 }
```

430 If the declaration of an identifier for a function has no storage-class specifier, its linkage is determined exactly as if it were declared with the storage-class specifier **extern**.

function no storage-class

Commentary

A significant amount of existing code omits the **extern** specifier in function definitions. The Committee could not create a specification that required **extern**s to be inserted into long-existent source code. The behavior is as-if **extern** had appeared in the declaration. This does not automatically give the function external linkage (there could be a prior declaration that gives it internal linkage). This behavior is different from that used for object declarations in the same circumstances.

426 extern identifier linkage same as prior declaration
431 object file scope no storage-class

Other Languages

Languages that use some sort of specifier to denote the visibility of file scope identifiers usually apply the same rules to functions and objects.

Coding Guidelines

Developers generally believe that a function declaration that does not include a storage-class specifier has external linkage. While this belief is not always true, the consequences of it being wrong are not far-reaching (i.e., a program may fail to link because a call was added in a different source file to a function having internal linkage when the developer believed it had external linkage). There does not appear to be a worthwhile benefit in a guideline recommendation that changes the existing practice of not including **extern** in function definitions.

426 extern identifier linkage same as prior declaration

A future revision of the standard may require a storage-class specifier to appear in the declaration if a previous declaration of the identifier had internal linkage.

2035 identifier linkage future language directions

Example

```
1  static int f2(void);
2  int f2(void); /* Same behavior as-if extern int f2(void) had been written. */
3
4  extern int f(void)
5  { return 22; }
6
7  int g(void)
8  { return 23; }
```

431 If the declaration of an identifier for an object has file scope and no storage-class specifier, its linkage is external.

object file scope no storage-class

Commentary

function 430 no storage-class tentative definition 1849 tentative definition 1849 object 1354 reserve storage

There is no as-if here; the object is given external linkage. The behavior differs in more than one way from that for functions. If no storage-class specifier is given, the declaration is also a tentative definition. One possible reason for wanting to omit the storage-class specifier in the declaration of a file scope object is that such a declaration is also a definition (actually a tentative definition unless an explicit initializer is given). Another way of creating a definition at file scope with external linkage is to explicitly specify an initializer; in this case it does not matter if the storage-class specifier **extern** is or is not given.

Prior to C90, many implementations treated object declarations that contained both an **extern** storage-class specifier and an explicit initializer as a constraint violation. There was, and continues to be, a significant amount of existing code that omits the specification of any linkage on object declarations unless internal linkage is required. Without breaking existing code, the Committee continues to be in the position of not being able to change the specification, other than to make external linkage the default (when a storage-class specifier is not explicitly specified).

identifier 2035 linkage future language directions

Support for declaring an identifier with internal linkage at file scope without the storage-class specifier **static** may be withdrawn in a future revision of the standard.

Coding Guidelines

external declaration 1810 syntax

The issue of what linkage objects at file scope should be declared to have is discussed elsewhere.

Example

```
1  static int si1; /* internal linkage. */
2  int si1;        /* external linkage, previous was internal, linkage mismatch. */
3
4  int ei1;        /* No explicit storage-class given, so it is external.        */
5
6  extern int ei2; /* Same linkage as any prior declaration, otherwise external. */
```

---

identifier no linkage

The following identifiers have no linkage: 432

Commentary

no linkage 424 identifier declaration is unique

Here the phrase *no linkage* is used to mean that the linkage is *none*.

---

member no linkage

an identifier declared to be anything other than an object or a function; 433

Commentary

This list includes tags, typedefs, labels, macros, and a member of a structure, union, or enumeration.

C++

3.5p3 *A name having namespace scope (3.3.5) has internal linkage if it is the name of*

— a data member of an anonymous union.

While the C Standard does not support anonymous unions, some implementations support it as an extension.

3.5p4 *A name having namespace scope (3.3.5) has external linkage if it is the name of*

— a named class (clause 9), or an unnamed class defined in a typedef declaration in which the class has the typedef name for linkage purposes (7.1.3); or

— a named enumeration (7.2), or an unnamed enumeration defined in a typedef declaration in which the enumeration has the typedef name for linkage purposes (7.1.3); or

— an enumerator belonging to an enumeration with external linkage; or

Names not covered by these rules have no linkage. Moreover, except as noted, a name declared in a local scope (3.3.2) has no linkage. 3.5p8

The following C definition may cause a link-time failure in C++. The names of the enumeration constants are not externally visible in C, but they are in C++. For instance, the identifiers `E1` or `E2` may be defined as externally visible objects or functions in a header that is not included by the source file containing this declaration.

```
extern enum T {E1, E2} glob;
```

There are also some C++ constructs that have no meaning in C, or would be constraint violations.

```
void f()
{
union {int a; char *p; }; /* not an object */
                          // an anonymous union object

/*
 * The following all have meaning in C++
 *
   a=1;
 *
   p="Derek";
 */
}
```

---

434 an identifier declared to be a function parameter; parameter linkage

Commentary

A parameter in a function definition is treated as a block scope object with automatic storage duration. A parameter in a function declaration has function prototype scope.

Other Languages

Some languages allow arguments to be passed to a function in any order. This is achieved by specifying the parameter identifier that a particular argument is being passed to at the point of call. The identifiers denoting the function parameters are thus visible outside of the function body. In such languages parameter identifiers can only occur in the context of an argument list to a call of the function that defines them.

Many languages do not permit identifiers to be specified for function declarations that are not also definitions. In these cases only the types of the parameters may be specified.

---

435 a block scope identifier for an object declared without the storage-class specifier **`extern`**. no linkage block scope object

Commentary

Block scope identifiers are only intended to be visible within the block that defines them. The linkage mechanism is not needed to resolve multiple declarations. Use of the storage-class specifier **`extern`** at block scope is needed to support existing (when the C90 was first created) code. Use of the storage-class specifier **`static`** at block scope creates an identifier with linkage none (the purpose of using the keyword in this context is to control storage duration, not linkage).

1645 identifier linkage at block scope
455 static storage duration

C++

3.5p8 *Moreover, except as noted, a name declared in a local scope (3.3.2) has no linkage. A name with no linkage (notably, the name of a class or enumeration declared in a local scope (3.3.2)) shall not be used to declare an entity with linkage.*

The following conforming C function is ill-formed in C++.

```
1  void f(void)
2  {
3  typedef int INT;
4
5  extern INT a; /* Strictly conforming */
6                // Ill-formed
7
8  enum E_TAG {E1, E2};
9
10 extern enum E_TAG b; /* Strictly conforming */
11                      // Ill-formed
12 }
```

Other Languages

Few languages provide any mechanism for associating declarations of objects in block scope with declarations in other translation units.

Coding Guidelines

identifier declared in one file 422.1

The guideline recommendation dealing with textually locating declarations in a header file is applicable here.

---

linkage both internal/external

If, within a translation unit, the same identifier appears with both internal and external linkage, the behavior is undefined. 436

Commentary

EXAMPLE linkage 1852

There are a few combinations of declarations where it is possible to give the same identifier both internal and external linkage. There are no combinations of declarations that can give the same identifier two other kinds of linkage.

C++

The C++ Standard does not specify that the behavior is undefined and gives an example (3.5p6) showing that the behavior is defined.

Common Implementations

Some translators issue a diagnostic for all cases where the same identifier appears with both internal and external linkage.

Coding Guidelines

An instance of this undefined behavior is most likely to occur when a `.c` file includes a header containing the declaration of an identifier for an object, where this `.c` file also contains a declaration using the storage-class specifier **`static`** for the same identifier (that is intended to be distinct from the identifier in the header). The situation occurs because the developer was not aware of all the identifiers declared in the header (one solution is to rename one of the identifiers). The same identifier is rarely declared with both internal and external linkage and a guideline recommendation is not considered worthwhile.

Example

```
1  extern int glob_0; /* external linkage. */
2  static int glob_0; /* internal linkage (prior declaration not considered). */
3
4  static int glob_1, glob_2; /* internal linkage. */
5         int         glob_2; /* Linkage is specified by the prior declaration. */
6
7  void f(void)
8  {
9  extern int glob_1; /* Same linkage as one visible at file scope. */
10
11        {
12        /*
13         * We need to enter another block to exhibit this problem.
14         * Now the visible declaration is in block scope, so the
15         * wording in clause 6.1.2.2 does not apply and we take the
16         * linkage from the declaration here, not the linkage from
17         * the outer scope declaration.
18         */
19         extern int glob_1; /* external and internal linkage. */
20         }
21 }
```

Usage

The translated form of this book's benchmark programs contained 27 instances of identifiers declared, within the same translation unit, with both internal and external linkage.

---

437 **Forward references:** declarations (6.7), expressions (6.5), external definitions (6.9), statements (6.8).

6.2.3 Name spaces of identifiers

---

438 If more than one declaration of a particular identifier is visible at any point in a translation unit, the syntactic context disambiguates uses that refer to different entities. name space

Commentary

At a particular point in the source it is possible to have the same identifier declared and visible as a label, object/function/typedef/enumeration constant, enum/structure/union tag, and a potentially infinite number of member names. Syntactic context in C is much more localized than in human languages. For instance, in "There is a sewer near our home who makes terrific suites," the word *sewer* is not disambiguated until at least four words after it occurs. In C the token before an identifier (`->`, `.`, **`struct`**, **`union`**, and **`enum`**) disambiguates some name spaces. Identifiers used as labels require a little more context because the following `:` token can occur in several other contexts.

C++

This C statement is not always true in C++, where the name lookup rules can involve semantics as well as syntax; for instance, in some cases the **`struct`** can be omitted. 441 tag name space

Common Implementations

The amount of sufficient syntactic context needed to determine uses that refer to typedef names and other kinds of identifiers is greater than most implementors of translators want to use (for efficiency reasons most existing parser generators only use a lookahead of one token). Translators handle this by looking up identifiers in a symbol table prior to passing them on to be syntactically processed. For instance, the sequence `int f(a, b)` could be declaring `f` to be an old-style function definition (where `a` and `b` are the identifier names) or a function prototype (where `a` and `b` are the types of the parameters). Without accessing the symbol table, a translator would not know which of these cases applied until the token after the closing right parenthesis was seen.

Coding Guidelines

syntactic context
belief maintenance 0

Syntactic context is one source of information available to developers when reading source code. Another source of information are their existing beliefs (e.g., obtained from reading other source code related to what they are currently reading). Note: There is a syntactic context where knowledge of the first token does not provide any information on the identity a following identifier; a declaration defines a new identifier and the spelling of this identifier is not known until it is seen.

semantic priming 792

Many studies have found that people read a word (e.g., doctor) more quickly and accurately when it is preceded by a related word (e.g., nurse) than when it is preceded by an unrelated word (e.g., toast). This effect is known as *semantic priming*. These word pairs may be related because they belong to the same category, or because they are commonly associated with each other (often occurring in the same sentence together). Does the syntactic context of specific tokens (e.g., `->`) or keywords (e.g., **`struct`**) result in semantic priming? For such priming to occur there would need to be stronger associations in the developer's mind between identifiers that can occur in these contexts, and those that cannot. There have been no studies investigating how developers store and access identifiers based on their C language properties. It is not known if, for instance, an identifier appearing immediately after the keyword **`struct`** will be read more quickly and accurately if its status as a tag is known to the developer.

It is possible for identifiers denoting different entities, but with the same spelling, to appear closely together in the source. For instance, an identifier with spelling `kooncliff` might be declared as both a structure tag and an object of type **`float`** and appear in an expression in both contexts. Is syntactic context the dominant factor in such cases, or will the cost of comprehension be measurably greater than if the identifiers had different spellings?[438.1]

A study by McKoon and Ratcliff[920] looked at contextual aspects of meaning when applied to the same noun. Subjects were read a paragraph and then asked to reply *true* or *false* to three test questions (see the following discussion). Some of the questions involved properties that were implicit in the paragraph. For instance, an interest in painting a tomato implicitly involves its color. The results showed that subjects verified the property of a noun more quickly (1.27 seconds vs. 1.39) and with a lower error rate (4.7% vs. 9.7%), in a context in which the property was relevant than in a context in which it was not relevant.

> Paragraph 1
>
> This still life would require great accuracy. The painter searched many days to find the color most suited to use in the painting of the ripe tomato.
>
> Paragraph 2
>
> The child psychologist watched the infant baby play with her toys. The little girl found a tomato to roll across the floor with her nose.
>
> Test sentences
>
> 1) Tomatoes are red.
>
> 2) Balloons are heavy.
>
> 3) Tomatoes are round.

The results of this study show that the (category) context in which a name is used affects a subject's performance. However, until studies using C language constructs have been performed, we will not know the extent to which these context dependencies affect developer comprehension performance.

word frequency 792
identifier 792
tip-of-the-tongue

Are there situations where there might be a significant benefit in using identifiers with the same spelling, to denote different entities? Studies of word recall have found a frequency effect; the more concepts associated with a word, the fewer tip-of-the-tongue cases occur. Tag and typedef names denote very similar concepts, but they are both ways of denoting types.

[438.1] No faults can be introduced into the source through misuse of these identifiers because all such uses will result in a translator issuing a diagnostic.

```
1  typedef struct SOME_REC {int mem;} SOME_REC;
```

In the above case, any confusion on the developers' part will not result in unexpected affects (the name can appear either with or without the **struct** keyword— it is fail-safe).

Dev 792.3 A newly declared identifier denoting a tag may have the same spelling as a typedef name denoting the same type.

Macros provide a mechanism for hiding the syntactic context from readers of the visible source; for instance, the `offsetof` macro takes a tag name and a member name as arguments. This usage is rare and is not discussed further here.

Table 438.1: Identifiers appearing immediately to the right of the given token as a percentage of all instances of the given token. An identifier appearing to the left of a **:** could be a label or a **case** label. However, C syntax is designed to be parsed from left to right and the presence, or absence, of a **case** keyword indicates the entity denoted by an identifier. Based on the visible form of the `.c` files.

Token	.c file	.h file	Token	.c file	.h file
goto identifier	99.9	100.0	**struct** identifier	99.0	88.4
#define identifier	99.9	100.0	**union** identifier	65.5	75.8
. identifier	100.0	99.8	**enum** identifier	86.6	53.6
-> identifier	100.0	95.5	**case** identifier	71.3	47.2

439 Thus, there are separate *name spaces* for various categories of identifiers, as follows:

Commentary

In C each name space is separate from other name spaces. As the name suggests this concept can be viewed as a space within which names exist. This specification was introduced in C90 so that existing code was not broken. There is also a name space for macro names.

1928 macro one name space

The standard specifies various identifiers, having particular spellings, as being reserved for various purposes. The term *reserved name space* is sometimes used to denote identifiers belonging to this set. However, this term does not occur in the C Standard; it is an informal term used by the committee and some developers.

C++

C++ uses **namespace** as a keyword (there are 13 syntax rules associated with it and an associated keyword, **using**) and as such it is denotes a different concept from the C name space. C++ does contain some of the name space concepts present in C, and even uses the term namespace to describe them (which can be somewhat confusing). These are dealt with under the relevant sentences that follow.

Other Languages

Most languages have a single name space, which means that it is not necessary to talk about a name space as such. A few languages have a mechanism for separate translation that requires identifiers to be imported into a translation unit before they can be referenced. This mechanism is sometimes discussed in terms of being a name space.

Common Implementations

Some very early implementations of C did not always fully implement all of the name spaces defined in the C Standard. In particular early implementations treated the members of all structure and union types as belonging to the same name space[723] (i.e., once a member name was used in one structure type, it could not be used in another in the same scope).

Table 439.1: Occurrence of various kinds of declarations of identifiers as a percentage of all identifiers declared in all the given contexts. Based on the translated form of this book's benchmark programs.

Declaration Context	%	Declaration Context	%
block scope objects	23.7	file scope objects	4.4
macro definitions	19.3	macro parameters	4.3
function parameters	16.8	enumeration constants	2.1
struct/union members	9.6	**typedef** names	1.2
function declarations	8.6	tag names	1.0
function definitions	8.1	label names	0.9

label name space

— *label names* (disambiguated by the syntax of the label declaration and use); 440

Commentary

labeled statements 1722 syntax label name 394

Labels represent statement locations within a function body. Putting label names in their own name space represents a language design decision. It enables uses such as `if (panic) goto panic`.

C++

6.1p1 *Labels have their own name space and do not interfere with other identifiers.*

Other Languages

In Pascal and Ada labels must be declared before use. In Pascal they are numeric, not alphanumeric, character sequences. Some languages (e.g., Algol 60, Algol 68) do put label names in the same name space as ordinary identifiers.

Common Implementations

Some early implementations of C placed labels in the same name space as ordinary identifiers.

tag name space

— the *tags* of structures, unions, and enumerations (disambiguated by following any[24)] of the keywords **struct**, **union**, or **enum**); 441

Commentary

tag declarations 1459 different scope

The original definition of C[1170] did not include support for typedef names. Tags were the mechanism by which structure, union, and enumerated types could be given a name that could be referred to later. Putting tags in a different name space removed the possibility of a tag name clashing with an ordinary identifier. It also has the advantage on large projects of reducing the number of possible naming conflicts, and allowing declarations such as the following to be used:

```
1   typedef struct listitem listitem;
```

C++

Tags in C++ exist in what is sometimes known as *one and a half name spaces*. Like C they can follow the keywords **struct**, **union**, or **enum**. Under certain conditions, the C++ Standard allows these keywords to be omitted.

3.4p1 *The name lookup rules apply uniformly to all names (including `typedef-names` (7.1.3), `namespace-names` (7.3) and `class-names` (9.1)) wherever the grammar allows such names in the context discussed by a particular rule.*

In the following:

```
struct T {int i;};
struct S {int i;};
int T;

void f(T p); // Ill-formed, T is an int object
             /* Constraint violation */

void g(S p); // Well-formed, C++ allows the struct keyword to be omitted
             // There is only one S visible at this point
             /* Constraint violation */
```

C source code migrated to C++ will contain the **struct/union** keyword. C++ source code being migrated to C, which omits the *class-key*, will cause a diagnostic to be generated.

The C++ rules for tags and typedefs sharing the same identifier are different from C.

3.4.4p2

If the name in the elaborated-type-specifier is a simple identifier, and unless the elaborated-type-specifier has the following form:

class-key identifier ;

the identifier is looked up according to 3.4.1 but ignoring any non-type names that have been declared. If this name lookup finds a typedef-name, the elaborated-type-specifier is ill-formed.

The following illustrates how a conforming C and C++ program can generate different results:

```
extern int T;

int size(void)
{
struct T {
         double mem;
         };

return sizeof(T);   /* sizeof(int) */
                    // sizeof(struct T)
}
```

The following example illustrates a case where conforming C source is ill-formed C++.

```
struct TAG {int i;};
typedef float TAG;

struct TAG x; /* does not affect the conformance status of the program */
              // Ill-formed
```

Other Languages

Tags are unique to C (and C++).

Coding Guidelines

A tag name always appears to the right of a keyword. Its status as a tag is clearly visible to the reader. The issue of tag naming conventions is discussed elsewhere.

792 tag naming conventions

Example

```
typedef struct X_REC {
                      int mem1;
                      } X_REC;
```

members name space

— the *members* of structures or unions; 442

Commentary

base document 1

In the base document, all members of structure and union types occupied the same name space (an idea that came from BCPL). Such member names were essentially treated as symbolic forms for offsets into objects.

```
1  struct {
2          char mem_1;
3          long mem_2;
4         } x;
5  struct {
6         char mem_3;
7         char mem_4;
8         } y;
9
10 void f(void)
11 {
12 /*
13  * Under the original definition of C the following would zero a char
14  * sized object in x that had the same offset as mem_4 had in y.
15  */
16 x.mem_4 = 0;
17 }
```

This language specification prevented structures and unions from containing a particular member name once it had been used in a previous definition as a member name. The idea of member names representing offsets was a poor one and quickly changed. A consequence of this history is that structure and union definitions are thought of as creating a name space, not in terms of members existing in a scope (a usage common to many other languages, including C++).

C++

3.3.6p1 *The following rules describe the scope of names declared in classes.*

In C++ members exist in a scope, not a name space.

```
1  struct {
2         enum E_TAG { E1, E2}  /* C identifiers have file scope */
3                               // C++ identifiers have class scope
4                               m1;
5         } x;
6
7  enum E_TAG y; /* C conforming */
8                // C++ no identifier names E_TAG is visible here
```

Other Languages

Many languages treat the contents of what C calls a structure or union as a scope. The member-selection operator opening this scope to make the members visible (in C this operator makes the unique name space visible).

member namespace

each structure or union has a separate name space for its members (disambiguated by the type of the expression used to access the member via the . or -> operator); 443

Commentary

Although each structure or union type definition creates its own unique name space, no new scope is created. The declarations contained within these definitions have the scope that exists at the point where the structure or union is defined.

406 identifier scope determined by declaration placement

C++

The name of a class member shall only be used as follows: 3.3.6p2

. . .

— *after the* `.` *operator applied to an expression of the type of its class (5.2.5) or a class derived from its class,*

— *after the* `->` *operator applied to a pointer to an object of its class (5.2.5) or a class derived from its class,*

```
1  struct {
2         enum {E1, E2} m;
3         } x;
4
5  x.m = E1; /* does not affect the conformance status of the program */
6            // ill-formed. X::E1 is conforming C++ but a syntax violation in C
```

Coding Guidelines

Given that one of two tokens immediately precedes a member name its status as a member is immediately obvious to readers of the source (the only time when this context may not be available is when a member name occurs as an argument in a macro invocation). Because of the immediate availability of this information there is no benefit in a naming convention intended to flag the status of an identifier as a member.

Members in different structure types may hold the same kind of information; for instance, a member named `next` might always point to the next element in a linked list, its type being a pointer to the structure type containing its definition. Members named `x_coord` and `y_coord` might occur in several structure types dealing with coordinate systems.

The underlying rationale for the guideline recommendation dealing with reusing the same identifier name, confusion cased by different semantic associations, is only applicable if the semantic associations are different. If they are the same, then there is a benefit in reusing the same name when dealing with different members that are used for the same purpose.

792.3 identifier reusing names

Dev 792.3

A newly declared member may have the same spelling as a member in a different structure/union type provided they both share the same semantic associations; and if they both have an arithmetic type, their types are the same.

The term *same semantic associations* is somewhat ill-defined and subject to interpretation (based on the cultural background and education of the person performing the evaluation, an issue that is discussed in more detail elsewhere). While guideline recommendation wording should normally aim to be precise, it should also try to be concise. It is not clear that this guideline would be improved by containing more words.

792 semantic associations enumerating

Members having arithmetic types could be interchanged in many situations without any diagnostic being issued. A member having type **`int`** in one structure and type **`float`** in another, for instance, may represent the same semantic concept; but the way they need to be handled is different. Inappropriately interchanging nonarithmetic types is much more likely to result in a diagnostic being generated.

A study by Neamtiu, Foster, and Hicks[998] of the release history of a number of large C programs, over 3-4 years (and a total of 43 updated releases), found that in 79% of releases one or more existing structure

or union types had one or more fields added to them, while structure or union types had one or more fields deleted in 51% of releases and had one or more of their field names changed in 37% of releases. One or more existing fields had their types changed in 35% of releases.[997]

A study by Anquetil and Lethbridge[47] analyzed 2 million lines of Pascal (see Table 443.1 and Table 443.2). Members that shared the same name were found to be much more likely to share the same type than members having different names.

Table 443.1: Number of matches found when comparing between pairs of members contained in different Pascal records that were defined with the same type name. Adapted from Anquetil and Lethbridge.[47]

	Member Types the Same	Member Types Different	Total
Member names the same	73 (94.8%)	4 (5.2%)	77
Member names different	52 (11 %)	421 (89 %)	473

Table 443.2: Number of matches found when comparing between pairs of members contained in different Pascal records (that were defined with the any type name). Adapted from Anquetil and Lethbridge.[47]

	Member Types the Same	Member Types Different	Total
Member names the same	7,709 (33.7%)	15,174 (66.3%)	22,883
Member names different	158,828 (0.2%)	66,652,062 (99.8%)	66,710,890

Example

```
1  struct {
2          int m;
3         } x;
4  struct {
5          int m;
6          struct {
7                  int n;
8                 } n;
9         } y;
```

the two members, named `m`, are each in a different name space. In the definition of `y` the two members, named `n`, are also in different name spaces.

ordinary identifiers
name space ordinary identifiers

— all other identifiers, called *ordinary identifiers* (declared in ordinary declarators or as enumeration constants). 444

Commentary

This defines the term *ordinary identifiers*. These ordinary identifiers include objects, functions, typedef names and enumeration constants. Macro names and macro parameters are not included in this list. Keywords are part of the language syntax. Identifiers with the spelling of a keyword only stop being identifier preprocessing tokens and become keyword tokens in phase 7. Literals are not in any name space.

C++

The C++ Standard does not define the term *ordinary identifiers*, or another term similar to it.

Coding Guidelines

Naming conventions that might be adopted to distinguish between these ordinary identifiers, used for different purposes, are discussed in more detail in their respective sentences.

enumeration 792 constant naming conventions
typedef 792 naming conventions
macro 792 naming conventions
function 792 naming conventions

Forward references: enumeration specifiers (6.7.2.2), labeled statements (6.8.1), structure and union specifiers (6.7.2.1), structure and union members (6.5.2.3), tags (6.7.2.3), the **goto** statement (6.8.6.1). 445

446 23) As specified in 6.2.1, the later declaration might hide the prior declaration. footnote 23

Example

```
1  extern int glob;
2
3  void f(void)
4  {
5  int glob; /* Hide prior declaration. */
6     {
7     extern int glob;
8     }
9  }
```

447 24) There is only one name space for tags even though three are possible. footnote 24

Commentary

The additional functionality, if three had been specified, would be to enable the same identifier spelling to be used after each of the three keywords. There is little to be gained from this and the possibility of much confusion.

C++

There is no separate name space for tags in C++. They exist in the same name space as object/function/typedef *ordinary identifiers*.

Common Implementations

Early translators allowed the **`struct`** and **`union`** keywords to be intermixed.

```
1  union Tag {
2            int mem;
3            };
4
5  int main(void)
6  {
7  struct Tag *ptr;   /* Acceptable in K&R C. */
8  }
```

6.2.4 Storage durations of objects

448 An object has a *storage duration* that determines its lifetime. storage duration object

Commentary

Storage duration is a property unique to objects. In many cases it mirrors an object's scope (not its visibility) and developers sometimes use the term *scope* when *lifetime* would have been the correct term to use.

C++

An object has a storage duration (3.7) which influences its lifetime (3.8). 1.8p1

In C++ the initialization and destruction of many objects is handled automatically and in an undefined order (exceptions can alter the lifetime of an object, compared to how it might appear in the visible source code). For these reasons an object's storage duration does not fully determine its lifetime, it only influences it.

Other Languages

Most languages include the concept of the lifetime for an object.

There are three storage durations: static, automatic, and allocated. 449

Commentary

One of the uses of the overworked keyword **`static`** is to denote objects that have static storage duration (there are other ways of denoting this storage duration).

C90

The term *allocated* storage duration did not appear in the C90 Standard. It was added by the response to DR #138.

C++

3.7p1 *The storage duration is determined by the construct used to create the object and is one of the following:*

— *static storage duration*

— *automatic storage duration*

— *dynamic storage duration*

The C++ term *dynamic storage* is commonly used to describe the term *allocated storage*, which was introduced in C99.

Common Implementations

stack

Objects having particular storage durations are usually held in different areas of the host address space. The amount of static storage duration is known at program startup, while the amounts of automatic and allocated storage varies during program execution. The most commonly seen division of available storage is to have the two variable-size storage durations growing toward each other. Objects having static storage duration are often located at the lowest address rather than the highest. This design decision may make it possible to access these objects with a single instruction using a register + offset addressing mode (provided one is available).

register + offset 1000

A few implementations do not have separate stack and heap areas. They allocate stack space on the heap, on an as-needed basis. This usage is particularly common in realtime, multiprocess environments, without hardware memory management support to map logical addresses to different physical addresses. The term *cactus stacks* is sometimes used.

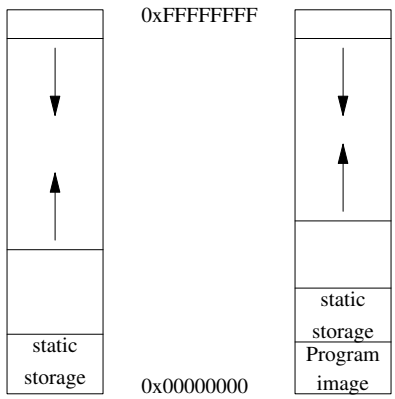

Figure 449.1: The location of the stack invariably depends on the effect of a processor's pop/push instructions (if they exist). The heap usually goes at the opposite end of available storage. The program image may, or may not, exist in the same address space.

Some processors (usually those targeted at embedded systems[612]) support a variety of different kinds of addressable storage. This storage may be disjoint in that two storage locations can have the same address, accesses to them being disambiguated either by the instruction used or a flag specifying the currently active storage bank. Optimally allocating declared objects to these storage areas is an active research topic.[66, 1250] One implementation[66] distributes the stack over several storage banks.

Coding Guidelines

In resource-constrained environments there can be space and efficiency issues associated with the different kinds of storage durations. These are discussed for each of the storage durations later.

The term *allocated storage* is not commonly used by developers (in the sense of being a noun). The use of the word *allocated* as an adjective is commonly heard. The terms *dynamically allocated* or *allocated on the heap* are commonly used to denote this kind of storage duration. There does not seem to be any worthwhile benefit in trying to educate developers to use the technically correct term in this case.

Usage

In the translated form of this book's benchmark programs 37% of defined objects had static storage duration and 63% had automatic storage duration (objects with allocated storage duration were not included in this count).

Table 449.1: Total number of objects allocated (in thousands), the total amount of storage they occupy (in thousands of bytes), their average size (in bytes) and the high water mark of these values (also in thousands). Adapted from Detlefs, Dosser and Zorn.[349]

Program	Total Objects	Total Bytes	Average Size	Maximum Objects	Maximum Bytes
sis	63,395	15,797,173	249.2	48.5	1,932.2
perl	1,604	34,089	21.3	2.3	116.4
xfig	25	1,852	72.7	19.8	1,129.3
ghost	924	89,782	97.2	26.5	2,129.0
make	23	539	23.0	10.4	208.1
espresso	1,675	107,062	63.9	4.4	280.1
ptc	103	2,386	23.2	102.7	2,385.8
gawk	1,704	67,559	39.6	1.6	41.0
cfrac	522	8001	15.3	1.5	21.4

450 Allocated storage is described in 7.20.3.

Commentary

Allocated storage is not implicitly handled by the implementation. It is controlled by calling library functions.

Other Languages

In some languages handle allocated storage is part of the language, not the library. For instance, C++ contains the **new** operator (where the amount of storage to allocate is calculated by the translator, based on deducing the type of object required). Pascal also contains new, but calls is a *required function*.

451 The *lifetime* of an object is the portion of program execution during which storage is guaranteed to be reserved for it.

lifetime of object

Commentary

This defines the term *lifetime*. The storage reserved for an object may exist outside of its guaranteed lifetime. However, this behavior is specific to an implementation and cannot be relied on in a program.

C90

The term *lifetime* was used twice in the C90 Standard, but was not defined by it.

C++

3.8p1 *The lifetime of an object is a runtime property of the object. The lifetime of an object of type T begins when:*

. . .

The lifetime of an object of type T ends when:

The following implies that storage is allocated for an object during its lifetime:

3.7p1 *Storage duration is the property of an object that defines the minimum potential lifetime of the storage containing the object.*

Common Implementations

An implementation may be able to deduce that it is only necessary to reserve storage for an object during a subset of the lifetime required by the standard. For instance, in the following example the accesses to the objects `loc_1` and `loc_2` occur in disjoint portions of program execution. This usage creates an optimization opportunity (having the two objects share the same storage during disjoint intervals of their lifetime).

```
1  void f(void)
2  {
3  int loc_1,
4      loc_2;
5  /*
6   * Portion of program execution that accesses loc_1, but not loc_2.
7   */
8
9  /*
10  * Portion of program execution that accesses loc_2, but not loc_1.
11  */
12 }
```

Reuse of storage is usually preceded by some event; for instance, a function return followed by a call to another function (for automatic storage duration, the storage used by the previous function is likely to be used by different objects in the newly called function). There are many possible algorithms[9, 17, 96, 375, 484, 1144, 1174] that an implementation can use to manage allocated storage and no firm prediction on reuse can be made about objects having this storage duration.

A study by Bowman, Ratliff, and Whalley[148] optimized the storage lifetimes of the static data used by 15 Unix utilities (using the same storage locations for objects accessed during different time intervals; they all had static storage duration). They were able to make an overage saving of 7.4%. By overlaying data storage with instruction storage (the storage for instructions not being required after their last execution) they achieved an average storage saving of 22.8%.

object 1354
reserve storage

The issue of where storage is allocated for objects is discussed elsewhere.

Coding Guidelines

The lifetime of objects having static or automatic storage durations are easy to deduce from looking at the source code. The lifetime of allocated storage is rarely easy to deduce. Coding techniques to make it easier to demark the lifetime of allocated storage are outside the scope of this book (the Pascal `mark`/`release` functionality sometimes encouraged developers to develop algorithms to treat heap allocation in a stack-like fashion).

Example

The following coding fault is regularly seen:

```
1  struct list *p;
2    /* ... */
3  free(p);
4  p = p->next;
```

452 An object exists, has a constant address,[25)] and retains its last-stored value throughout its lifetime.[26)]

Commentary

At first glance the phrase *constant address* appears to prevent a C implementation from using a garbage collector that moves objects in storage. But what is an address? An implementation could choose to represent object addresses as an index into an area of preallocated storage. This indexed element holds the real address in memory of the object's representation bits. The details of this extra indirection operation is dealt with by the translator (invisible to the developer unless a disassembled listing of the generated code is examined). A garbage collector would only need to update the indexed elements after storage had been compacted, and the program would know nothing about what had happened.

The last-stored value may have occurred as a result of an assignment operator, external factors for an object declared with the **volatile** storage-class, or another operator that updates the value held in an object.

C++

There is no requirement specified in the C++ Standard for an object to have a constant address. The requirements that are specified include:

> *Such an object exists and retains its last-stored value during the execution of the block and while the block is suspended (by a call of a function or receipt of a signal).* 1.9p10

> *All objects which neither have dynamic storage duration nor are local have static storage duration. The storage for these objects shall last for the duration of the program (3.6.2, 3.6.3).* 3.7.1p1

Common Implementations

In most implementations objects exist in either RAM or ROM. The value of an object whose address is never taken may only ever exist in a processor register; the only way to tell is by looking at a listing of the generated machine code. In all commercial implementations known to your author an object's address has a direct correspondence to its actual address in storage. There is no indirection via other storage performed by the implementation, although the processor's memory-management unit may perform its own mappings into physical memory.

Coding Guidelines

An implementation that performs garbage collection may have one characteristic that is visible to the developer. The program may appear to stop executing periodically because garbage collection is taking place. There are implementation techniques that perform incremental garbage collection, which avoids this problem to some degree.[689] However, this problem is sufficiently rare that it is considered to be outside the scope of these coding guidelines.

A program running in a sufficiently hostile environment that the last-stored value of an object may be corrupted requires the use of software development techniques that are outside the scope of this book.

Example

The two values output on each iteration of the loop are required to be equal. However, there is no requirement that the values be the same for different iterations of the loop.

```
1  #include <stdio.h>
2
3  int main(void)
4  {
5  for (int loop=0; loop < 10; loop++)
6     {
7     int nested_obj;
8
9     printf("address is=%p", &nested_obj);
10    printf(", and now it is=%p\n", &nested_obj);
11    }
12 }
```

If an object is referred to outside of its lifetime, the behavior is undefined. 453

Commentary

Such a reference is possible through

- the address of a block scope object assigned to a pointer having a greater lifetime, and
- an object allocated by the memory-allocation library functions that has been freed.

C++

The C++ Standard does not unconditionally specify that the behavior is undefined (the cases associated with pointers are discussed in the following C sentence):

3.8p3 *The properties ascribed to objects throughout this International Standard apply for a given object only during its lifetime. [Note: in particular, before the lifetime of an object starts and after its lifetime ends there are significant restrictions on the use of the object, as described below, in 12.6.2 and in 12.7. describe the behavior of objects during the construction and destruction phases.]*

Common Implementations

object 458
lifetime from entry to exit of block

On entry to a function it is common for the total amount of stack storage for that invocation to be allocated. The extent to which the storage allocated to objects, defined in nested blocks, is reused will depend on whether their lifetime is disjoint from objects defined in other nested blocks. In other words, is there an opportunity for a translator to reuse the same storage for different objects?

Most implementations' undefined behavior is to continue to treat the object as if it was still live. The storage location referenced may contain a different object, or even some internal information used by the runtime system. Values read from that location may be different from the last-stored value written into the original object. Stores to that location could affect the values of other objects and the effects of modifying internal, housekeeping information can cause a program to abort abnormally. The situation with allocated storage is much more complex.

Coding Guidelines

object reference outside lifetime

When the lifetime of an object ends, nothing usually happens to the last-stored value (or indeed any subsequent ones) held at that location. Programs that access the storage location that held the object, soon after the object's lifetime has ended, often work as expected (such an access can only occur via a pointer dereference; if an identifier denoting a declared object is visible the object it denotes cannot be outside of its lifetime). Accessing an object outside of its lifetime is unlikely to cause the implementation to issue a diagnostic. However, accessing an object outside of its lifetime sometimes does result in unexpected behavior. A coding guideline recommending that "an object shall not be referenced outside of its lifetime." is a special case of the guideline stating that programs shall not contain faults. The general aim of guideline recommendations in

guidelines 0
not faults

this area is to prevent the address of an object being available outside of its lifetime.

Although some implementations provide a mechanism to initialize newly created objects with some unusual value (this often helps to catch uninitialized objects quickly during testing), an equivalent mechanism at the end of an object's lifetime is unknown (to your author).

---

454 The value of a pointer becomes indeterminate when the object it points to reaches the end of its lifetime.

pointer indeterminate

Commentary

It is not the object pointed at, but the value of pointers pointing at it that become indeterminate. Once its value becomes indeterminate, the value of the pointer cannot even be read; for instance, compared for equality with another pointer.

An object having a pointer type has an indeterminate value at the start of its lifetime, like any other object (even if that lifetime starts immediately after it was terminated; for instance, an object defined in the block scope of a loop).

461 object initial value indeterminate

C++

The C++ Standard is less restrictive; if does not specify that the value of the pointer becomes indeterminate.

> *Before the lifetime of an object has started but after the storage which the object will occupy has been allocated[34)] or, after the lifetime of an object has ended and before the storage which the object occupied is reused or released, any pointer that refers to the storage location where the object will be or was located may be used but only in limited ways. Such a pointer refers to allocated storage (3.7.3.2), and using the pointer as if the pointer were of type* `void*`*, is well-defined. Such a pointer may be dereferenced but the resulting lvalue may only be used in limited ways, as described below. If the object will be or was of a class type with a nontrivial destructor, and the pointer is used as the operand of a* `delete-expression`*, the program has undefined behavior.*

3.8p5

Source developed using a C++ translator may contain pointer accesses that will cause undefined behavior when a program image created by a C implementation is executed.

Other Languages

Languages in the Pascal/Ada family only allow pointers to refer to objects with allocated storage lifetime. These objects can have their storage freed. In this case the same issues as those in C apply.

Common Implementations

Some processors load addresses into special registers (sometimes called address registers; for instance, the Motorola 68000[968]). Loading a value into such an address register may cause checks on its validity as an address to be made by the processor. If the referenced address refers to storage that is no longer available to the program, a trap may be generated.

pointer cause undefined behavior

Coding Guidelines

One way to ensure that pointers never refer to objects whose lifetime has ended is to ensure they are never assigned the address of an object whose lifetime is greater than their own. Scope is a concept that developers are more familiar with than lifetime and a guideline recommendation based on scope is likely to be easier to learn. The applicable recommendations is given elsewhere.

1088.1 object address assigned

Returning the address of a block scope object, in a **`return`** statement, is a fault. Although other guidelines sometimes recommend against this usage, these coding guidelines are not intended to recommend against the use of constructs that are obviously faults.

0 guidelines not faults

---

455 An object whose identifier is declared with external or internal linkage, or with the storage-class specifier **`static`** has *static storage duration*.

static storage duration

Commentary

This defines the term *static storage duration*. Objects have storage duration, identifiers have linkage. The visibility of an identifier defined with internal linkage may be limited to the block that defined it, but its lifetime extends from program startup to program termination.

Objects declared in block scope can have static storage duration. The **extern** or **static** storage-class specifiers can occur on declarations in block scope. In the former case it refers to a definition outside of the block. In the latter case it is the definition.

string literal 903
static storage duration

All file scope objects have static storage duration. String literals also have static storage duration.

C++

The wording in the C++ Standard is not based on linkage and corresponds in many ways to how C developers often deduce the storage duration of objects.

3.7.1p1 *All objects which neither have dynamic storage duration nor are local have static storage duration.*

3.7.1p3 *The keyword* **static** *can be used to declare a local variable with static storage duration.*

Common Implementations

The total number of bytes of storage required for static storage duration objects is usually written into the program image in translation phase 8. During program startup this amount of storage is requested from the host environment. Objects and literals that have static storage duration are usually placed in a fixed area of memory, which is reserved on program startup. This is possible because the amount of storage needed is known prior to program execution and does not change during execution.

Coding Guidelines

There can be some confusion, in developers' minds, between the keyword **static**, static storage duration, and *declared static*— a term commonly used to denote internal linkage. There are even more uses of the keyword **static** discussed elsewhere. There is little to be done, apart from being as precise as possible, to reduce the number of possible alternatives when using the word static.

declarator syntax 1547

Objects in block scope, having static storage duration, retain their last-stored value between invocations of the function that contains their definition. Mistakes are sometimes made on initializing such objects; the developer forgets that initialization via a statement, rather than via an initialization expression in the definition, will be executed every time the function is called. Assigning a value to such an object as its first usage suggests that either static storage duration was not necessary or that there is a fault in the code. While this usage might be flagged by a lint-like tool, neither of them fall within the remit of guideline recommendations.

Example

Here are three different objects, all with static storage duration.

```
1  static int vallu;
2
3  void f(void)
4  {
5  static int valyou = 99;
6
7     {
8     static int valu;
9
10    valu = 21;
11    }
12 }
```

Usage

In the visible form of the `.c` files approximately 5% of occurrences of the keyword **static** occurred in block scope.

456 Its lifetime is the entire execution of the program and its stored value is initialized only once, prior to program startup.

static storage duration when initialized

Commentary

The storage is allocated and initialized prior to calling the function `main`. A recursive call to `main` does not cause startup initialization to be performed again.

150 program startup

Other Languages

Java loads modules on an as-needed basis. File scope objects only need be allocated storage when each module is loaded, which may be long after the program execution started.

Common Implementations

Implementations could use the as-if rule to delay creating storage for an object, with static storage duration, until the point of its first access. There were several development environments in the 1980s that used incremental linkage at the translation unit level. These environments were designed to aid the testing and debugging of programs, even if the entire source base was not available.

Coding Guidelines

In environments where storage is limited, developers want to minimize the storage footprint of a program. If some objects with static storage duration are only used during part of a program's execution, more efficient storage utilization schemes may be available; in particular making use of allocated storage.

Use of named objects makes it easier for a translator, or static analysis tool, to detect possible defects in the source code. Use of pointers to objects requires very sophisticated points to analysis just to be able to do the checks performed for named objects (without using sophisticated analysis).

A technique that uses macros to switch between referencing named objects during development and allocated storage during testing and deployment offers a degree of independent checking. If this technique is used, it is important that testing be carried out using the configuration that will ship in the final product. Using named objects does not help with checking the lifetimes of the allocated objects used to replace them. However, discussion of techniques for controlling a program's use of storage is outside the scope of this book.

457 An object whose identifier is declared with no linkage and without the storage-class specifier **`static`** has *automatic storage duration*.

automatic storage duration

Commentary

These objects occur in block scope and are commonly known as *local variables*. The storage-class specifier **`auto`** can also be used in the definition of such objects. Apart from translator test programs, this keyword is rarely used, although some developers use it as a source layout aid.

C++

3.7.2p1

> *Local objects explicitly declared* **`auto`** *or* **`register`** *or not explicitly declared* **`static`** *or* **`extern`** *have automatic storage duration.*

Other Languages

Nearly all languages have some form of automatic storage allocation for objects. Use of a language keyword to indicate this kind of storage allocation is very rare. Cobol does not support any form of automatic storage allocation.

Common Implementations

Storage for objects with automatic storage duration is normally reserved on a stack. This stack is frequently the same one used to pass arguments to functions and to store function return addresses and other housekeeping information associated with a function invocation (see Figure 1000.1).

Recognizing the frequency with which such automatic storage duration objects are accessed (at least while executing within the function that defines them), many processor instruction sets have special operations, or addressing modes, for accessing storage within a short offset from an address held in a register.

register 1000 + offset

The Dynamic C implementation for Rabbit Semiconductor[1499] effectively assigns the static storage class to all objects declared with no linkage (this default behavior, which does not support recursive function calls, may be changed using the compiler **`#class auto`** directive).

Coding Guidelines

The terminology *automatic storage duration* is rarely used by developers. Common practice is to use the term *block scope* to refer to such objects. The special case of block scope objects having static storage duration is called out in the infrequent cases it occurs.

---

object lifetime from entry to exit of block

For such an object that does not have a variable length array type, its lifetime extends from entry into the block with which it is associated until execution of that block ends in any way. 458

Commentary

While the lifetime of an object may start on entry into a block, its scope does not start until the completion of the declarator that defines it (an objects scope ends at the same place as its lifetime).

identifier 418 scope begins
block scope 408 terminates

C++

3.7.2p1 *The storage for these objects lasts until the block in which they are created exits.*

5.2.2p4 *The lifetime of a parameter ends when the function in which it is defined returns.*

6.7p2 *Variables with automatic storage duration declared in the block are destroyed on exit from the block (6.6).*

Which is a different way of phrasing 3.7.2p1.

3.8p1 *The lifetime of an object of type T begins when:*

— storage with the proper alignment and size for type T is obtained, and

. . .

The lifetime of an object of type T ends when:

— the storage which the object occupies is reused or released.

The C++ Standard does not appear to completely specify when the lifetime of objects created on entry into a block begins.

Other Languages

All arrays in Java, Awk, Perl, and Snobol 4 have their length decided during program execution (in the sense that the specified size is not used during translation even if it is a constant expression). As such, the lifetime of array in these languages does not start until the declaration, or statement, that contains them is executed.

Common Implementations

Most implementations allocate the maximum amount of storage required, taking into account definitions within nested blocks, on function entry. Such a strategy reduces to zero any storage allocation overhead associated with entering and leaving a block, since it is known that once the function is entered the storage requirements for all the blocks it contains are satisfied. Allocating and deallocating storage on a block-by-block basis is usually considered an unnecessary overhead and is rarely implemented. In:

```
void f(void)
{               /* block 1 */
int loc_1;

   {            /* block 2 */
   long loc_2;
   }

   {            /* block 3 */
   double loc_3;
   }
}
```

the storage allocated for `loc_2` and `loc_3` is likely to overlap. This is possible because the blocks containing their definitions are not nested within each other, and their lifetimes are disjoint. On entry to `f` the total amount of storage required for developer-defined automatic objects (assuming `sizeof(long) <= sizeof(double)`) is `sizeof(int)+padding_for_double_alignment+sizeof(double)`.

Coding Guidelines

Where storage is limited, defining objects in the closest surrounding block containing accesses to them, can reduce the maximum storage requirements (because objects defined with disjoint lifetimes can share storage space). It is safer to let the translator perform the housekeeping needed to handle such shared storage than to try to do it manually (by using of the same objects for disjoint purposes). The issues surrounding the uses to which an object is put are discussed elsewhere. The issues involved in deciding which block an identifier should be defined in, if it is only referenced within a nested block, are also discussed elsewhere.

1352.1 object used in a single role
1348 identifier definition close to usage

Example

```
int glob;
int *pi = &glob;

void f(void)
{ /* Lifetime of loc starts here. */

block_start:;

*pi++; /* The identifier loc is not visible here. */

if (*pi == 1)
   goto skip_definition; /* Otherwise we always execute initializer. */

int loc = 1;

skip_definition:;

pi=&loc;

if (loc != 7)
   goto block_start;

/* Lifetime of loc ends here. */ }
```

(Entering an enclosed block or calling a function suspends, but does not end, execution of the current block.) 459

Commentary

Execution of a block ends when control flow within that block transfers execution to a block at the same or lesser block nesting, or causes execution of the function in which it is contained to terminate (i.e., by executing a **return** statement, or calling one of the `longjmp`, `exit`, or `abort` functions).

C is said to be a *block structured* language.

C++

1.9p10 *Such an object exists and retains its last-stored value during the execution of the block and while the block is suspended (by a call of a function or receipt of a signal).*

3.7.2p1 *The storage for these objects lasts until the block in which they are created exits.*

Other Languages

This behavior is common to block structured languages.

Coding Guidelines

It would be incorrect to assume that objects defined with the **volatile** qualifier can only be modified by the implementation while the block that defines them is being executed. Such objects can be modified at any point in their lifetime.

---

block entered recursively

If the block is entered recursively, a new instance of the object is created each time. 460

Commentary

function call 1026 recursive

This can only happen through a recursive call to the function containing the block. A jump back to the beginning of the block, using a **goto** statement, is not a recursive invocation of that block.

C90

The C90 Standard did not point this fact out.

C++

object 458 lifetime from entry to exit of block

As pointed out elsewhere, the C++ Standard does not explicitly specify when storage for such objects is created. However, recursive instances of block scope declarations are supported.

5.2.2p9 *Recursive calls are permitted, except to the function named `main` (3.6.1).*

6.7p2 *Variables with automatic storage duration (3.7.2) are initialized each time their `declaration-statement` is executed. Variables with automatic storage duration declared in the block are destroyed on exit from the block (6.6).*

Other Languages

This behavior is common to block structured languages. Recursion was not required in the earlier versions of the Fortran Standard, although some implementations provided it.

Common Implementations

There are some freestanding implementations where storage is limited and recursive function calls are not supported (such implementations are not conforming). The problem is not usually one of code generation, but the storage optimizations performed by the linker. To minimize storage usage in memory limited environments linkers build program call graphs to deduce which objects can have their storage overlaid. The storage optimization algorithms do not terminate if there are loops in the call graph (a recursive call would create such a loop). Thus, recursion is not supported because programs containing it would never get past translation phase 8.

1000 call graph

Allocating storage for all objects defined in a function, on a per function invocation basis, may cause inefficient use of storage when recursive invocations occur. In practice both recursive invocations and objects defined in nested blocks are rare.

---

461 The initial value of the object is indeterminate.

object initial value indeterminate

Commentary

This statement applies to all object declarations having no linkage, whether they have initializers or not (it is explicitly stated for objects having a VLA type elsewhere).

466 object initial VLA value indeterminate

C++

8.5p9

If no initializer is specified for an object, and the object is of (possibly cv-qualified) non-POD class type (or array thereof), the object shall be default-initialized; if the object is of const-qualified type, the underlying class type shall have a user-declared default constructor.

Otherwise, if no initializer is specified for an object, the object and its subobjects, if any, have an indeterminate initial value[90]; if the object or any of its subobjects are of const-qualified type, the program is ill-formed.

C does not have constructors. So a const-qualified object definition, with a structure or union type, would be ill-formed in C++.

```
1  struct T {int i;};
2
3  void f(void)
4  {
5  const struct T loc; /* very suspicious, but conforming */
6                      // Ill-formed
7  }
```

Other Languages

This behavior is common to nearly every block scoped language. Some languages (e.g., awk) provide an initial value for all objects (usually zero, or the space character).

Common Implementations

Some implementations assign a zero value to automatic and allocated storage when it is created. They do this to increase the likelihood that programs containing accesses to uninitialized objects will work as intended. They are *application user friendly* by helping to protect against errors in the source code. (Many objects are initially set to zero by developers and this implicit implementation value assignment mimics what is likely to be the behavior intended by the author of the code.)

Some implementations (e.g., the Diab Data compiler[353] supports the `-Xinit-locals-mask` option) implicitly assign some large value, or a trap representation, to freshly allocated storage. The intent is to be *developer friendly* by helping to detect faults, created by use of uninitialized objects, as quickly as possible. Assigning an unusual value is likely to have the effect of causing the reads from uninitialized objects to

have an unintended effect and to be quickly detected. The Burroughs B6700 (a precursor of the Unisys A Series[1389]) initialized its 48-bit words to 0xbadbadbadbad. The value 0xdeadbeef is used in a number of environments supported by IBM.

Coding Guidelines

It is surprising how often uninitialized objects contain values that result in program execution producing reasonable results. Having the implementation implicitly initialize objects to some *unfriendly* value helps to track down these kinds of faults much more quickly and helps to prevent reasonable results from hiding latent problems in the source code.

---

initialization performed every time declaration reached

If an initialization is specified for the object, it is performed each time the declaration is reached in the execution of the block; 462

Commentary

object 1711 initializer evaluated when

The sequence of operations is specified in more detail elsewhere in the C Standard.

If flow of control jumps over the declaration, for instance by use of a **goto** statement, the initialization is not performed; however, the lifetime of the object is not affected (the storage will already have been allocated on entry into the block).

object 458 lifetime from entry to exit of block

Because initializations are performed during program execution, it is possible for the evaluation of a floating constant to cause an exception to be raised. This can occur even if the floating constant appears to have the same type as the object it is being assigned to. An implementation is at liberty to evaluate the initialization expression in a wider format, which will then need to be converted to the object type. It is the conversion from any wider format to the type of the object type that may raise the exception.

FLT_EVAL_METHOD 354

```
1  #include <math.h>
2
3  void f(void)
4  {
5  static float w = 1.1e75; /* Performed at translation time, no exception raised. */
6  /*
7   * The following may all require conversions at execution time.
8   * Therefore they can all raise exceptions.
9   */
10 float x_1 = 1.1e75;
11 double x_2 = 1.1e75;
12 float x_3 = 1.1e75f;
13
14 /*
15  * The following do not require any narrowing conversions and cannot raise exceptions.
16  */
17 long double x_4 = 1.1e75;
18 double_t x_5 = 1.1e75;
19
20 /*
21  * For constant expressions we have (the final value of y and z is undefined)...
22  */
23 static double y = 0.0/0.0;  /* Performed at translation time, no exception raised. */
24 auto double z = 0.0/0.0;    /* Performed at execution time, may raise exception.   */
25 }
```

C90

If an initialization is specified for the value stored in the object, it is performed on each normal entry, but not if the block is entered by a jump to a labeled statement.

Support for mixing statements and declarations is new in C99. The change in wording is designed to ensure that the semantics of existing C90 programs is unchanged by this enhanced functionality.

Other Languages

Some languages do not allow object definitions to contain an initializer. Those that do usually follow the same initialization rules as C.

Common Implementations

For objects having a scalar type the machine code generated for the initializer will probably look identical to that generated for an assignment statement. For derived types implementations have all the information needed to generate higher-quality code. For instance, for array types, the case of all elements having a zero value is usually a special case and a machine code loop is generated to handle it.

Example

```
1  void f(int x)
2  {
3  switch(x)
4     {
5     int i=33; /* This initialization never occurs. */
6
7     case 1: x--;
8             break;
9     }
10 }
```

Usage

Usage information on initializers is given elsewhere.

1652 object value indeterminate

---

463 otherwise, the value becomes indeterminate each time the declaration is reached.

object indeterminate each time declaration reached
1711 object initializer evaluated when

Commentary

An indeterminate value is stored in the object each time the declaration is reached in the order of execution.

Other Languages

Most languages follow the model of giving an object an indeterminate value when it is first defined.

Common Implementations

If no other objects are assigned the same storage location, it is very likely that the last-stored value will be available in the object every time its declaration is reached.

Example

```
1  extern int glob;
2
3  _Bool f(void)
4  {
5  for (int i=0; i<5; i++)
6     {
7     int loc;
8
9     if (i > 0)
10       loc -= i; /* loc always has an indeterminate value here. */
11    else
12       loc=23;
13    }
14
15 goto do_work;
16    {
17    start_block:;
```

```
18      int count;
19
20      return (count == glob); /* count always has an indeterminate value here. */
21      /*
22       * The above return statement exhibits undefined behavior,
23       * because of the access to count.
24       */
25      do_work:;
26      count = glob % 4;
27
28      goto start_block;
29      }
30  }
```

VLA lifetime starts/ends

For such an object that does have a variable length array type, its lifetime extends from the declaration of the object until execution of the program leaves the scope of the declaration.[27)] 464

Commentary

The lifetime of a VLA starts at its point of declaration, not at the point of entry into the block containing its definition. This means it is possible to control the number of elements in the VLA through side effects within the block containing its definition. The intent of the Committee was for it to be possible to implement VLAs using the same stack used to allocate storage for local objects. Although their size varies, the requirements are such that it is possible to allocate storage for VLAs in a stack-like fashion. C does not define any out-of-storage signals and is silent on the behavior if the implementation cannot satisfy the requested amount of storage.

C90

Support for variable length arrays is new in C99.

C++

C++ does not support variable length arrays in the C99 sense; however, it does support containers:

23.1p1 *Containers are objects that store other objects. They control allocation and deallocation of these objects through constructors, destructors, insert and erase operations.*

The techniques involved, templates, are completely different from any available in C and are not discussed further here.

Other Languages

The lifetime of arrays in some languages (e.g., Java, Awk, Perl, and Snobol 4) does not start until the declaration, or statement, that contains them is executed. An array definition in Java does not allocate storage for the array elements; it only allocates storage for a reference to the object. The storage for the array elements is created by the execution of an *array access expression*. This can occur at any point where the identifier denoting the declared array is visible. Fortran and Pascal allow variable-size arrays to be passed as arguments. However, this is a subset of the functionality involved in allowing the number of elements in an array definition to be decided during program execution. In PL/1 the storage for arrays whose size is computed during program execution is not allocated at the point of definition, but within the executable statements via the use of the **allocate** statement.

```
1  declare
2       (k, l) fixed bin,
3       a dim (k) char (l) controlled;
4
5  k = 10;
```

```
6   l = 10;
7   allocate a;
8   free a;
```

Common Implementations

Because the size of an object having VLA type is not known at translation time, the storage has to be allocated at execution time. A commonly used technique involves something called a *descriptor*. Storage for this descriptor, one for each object having VLA type, is allocated in the same way as locally defined objects having other types, during translation. The descriptor contains one or more members that will hold information on the actual storage allocated and for multidimensional arrays the number of elements in each dimension. When the definition of an object having a VLA type is encountered during program execution, storage is allocated for it (often on the stack), and the descriptor members are filled in.

```
1   extern void G(void);
2
3   void f(int n)
4   {
5   long l;
6   char a[n];
7   float f_l;
8
9   G();
10  double d[11][n+8];
11  int i_l;
12  /* ... */
13  }
```

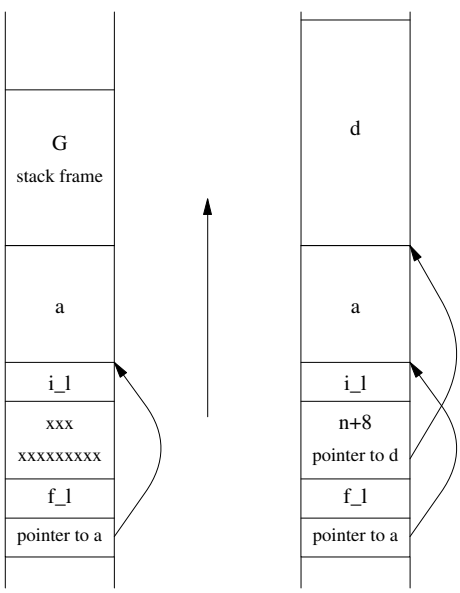

Figure 464.1: Storage for objects not having VLA type is allocated on block entry, plus storage for a descriptor for each object having VLA type. By the time `G` has been called, the declaration for `a` has been reached and storage allocated for it. After `G` returns, the declaration for `d` is reached and is storage allocated for it. The descriptor for `d` needs to include a count of the number of elements in one of the array dimensions. This value is needed for index calculations and is not known at translation time. No such index calculations need to be made for `a`.

Once execution leaves the scope of the object definition, having a VLA type, its lifetime terminates and the allocated storage can be freed up. This involves the implementation keeping track of all constructs that can cause this to occur (e.g., **goto** statements, as well as normal block termination).

One technique for simplifying the deallocation of VLA stack storage is to save the current value of the stack pointer on entry into a block containing VLA object definitions and to restore this value when the block terminates. There are situations where this technique might not be considered applicable (e.g., when a **goto** statement jumps to before a VLA object definition in the same block, an implementation either has to perform deallocation just prior to the **goto** statement or accept additional stack growth).

Coding Guidelines

object 458
lifetime from entry
to exit of block

For objects that don't have a VLA type, jumping over their definition may omit any explicit initialization, but storage for that object will still have been allocated. If the object has a VLA type the storage is only allocated if the definition is executed.

It is not expected that the use of VLA types will cause a change in usage patterns of the **goto** statement. A guideline recommendation dealing with this situation is not considered to be worthwhile.

Example

```
1  extern int n;
2  extern char gc;
3  extern char *pc = &gc;
4
5  void f(void)
6  {
7  block_start:;
8  /*
9   * At this point the lifetime of ca has not yet started.  Jumping back to
10  * this point, from a point where the lifetime has started, will terminate
11  * the lifetime.
12  */
13 n++;
14
15 /*
16  * First time around the loop pc points at storage allocated for gc.
17  * On second and subsequent iterations pc will have been pointing at an
18  * object whose lifetime has terminated (giving it an indeterminate value).
19  */
20 pc[0]='z';
21
22 char ca[n]; /* Lifetime of ca starts here. */
23 pc=ca;
24
25 if (n < 11)
26    goto block_start;
27 }
```

---

object
new instance
for recursion

If the scope is entered recursively, a new instance of the object is created each time. 465

Commentary

block 460
entered recursively

A scope can only be entered recursively through a recursive function call. This behavior is the same as for objects that don't have a VLA type. Functions containing VLAs are reentrant, just like functions containing any other object type.

The functions in the standard library are not guaranteed to be reentrant.

Other Languages

This behavior is common to all block scoped languages.

Common Implementations

In practice few function definitions are used in a way that requires their implementation to be reentrant. Some implementations[1340] assume that functions need not be reentrant unless explicitly specified as such (e.g., by using a keyword such as **`reentrant`**).

---

466 The initial value of the object is indeterminate.

object initial VLA value indeterminate

Commentary

Objects having a VLA type are no different from objects having any other type.

461 object initial value indeterminate

Common Implementations

The usage patterns of objects having a VLA type are not known. Whether they are less likely to have their values from a previous lifetime in a later lifetime than objects having other types is not known.

---

467 **Forward references:** statements (6.8), function calls (6.5.2.2), declarators (6.7.5), array declarators (6.7.5.2), initialization (6.7.8).

---

468 25) The term "constant address" means that two pointers to the object constructed at possibly different times will compare equal.

footnote 25

Commentary

The standard does not specify how addresses are to be represented in a program; it only specifies the results of operations on them. In between their construction and being compared, it is even possible that they are written out and read back in again.

C++

The C++ Standard is silent on this issue.

Other Languages

This statement is true of nearly all classes of languages, although some don't support the construction of pointers to objects. Functional languages (often used when formally proving properties of programs) never permit two pointers to refer to the same object. Assignment of pointers always involves making a copy of the pointed-to object (and returning a pointer to it).

Common Implementations

In some implementations the address of an object is its actual address in the processes (executing the program) address space. With memory-mapping hardware (now becoming common in high-end freestanding environments) it is unlikely to be the same as its physical address. Its logical address may remain constant, but its physical address could well change during the execution of the program.

---

469 The address may be different during two different executions of the same program.

Commentary

It is possible to write a pointer out to a file using the `%p` conversion specifier during one execution of the program and read it back in during a subsequent execution of the program. While the address read back, during the same execution of the program, will refer to the same object (assuming the object lifetime has not ended); however, during a different execution of the program the address is not guaranteed to refer be the same object (or storage allocated for any object).

Addresses might be said to having two kinds of representation details associated with them. There is the bit pattern of the value representation and there is the relative location of one address in relation to another address. Some applications make use of the relationship between addresses for their own internal algorithms. For instance, some garbage collectors for Lisp interpreters depend on low addresses being used for allocated storage. Low address are required because the garbage collector use higher order bits within the address value to indicate certain properties (assuming they can be zeroed out when used in a pointer dereference).

1354 object reserve storage

C++

The C++ Standard does not go into this level of detail.

Other Languages

Most high-level languages do not make visible, to the developer, the level of implementation detail specified in the C Standard.

Common Implementations

Programs running in hosted environments that use a memory-management unit to map logical to physical addresses are likely to use the same logical addresses, to hold the same objects, every time they are executed. It is only when other programs occupy some of the storage visible to a program that the address of its objects is likely to vary.

---

footnote 26 — 26) In the case of a volatile object, the last store need not be explicit in the program. 470

Commentary

volatile 1482 last-stored value — The fact that a volatile object may be mapped to an I/O port, not a storage location, does not alter its lifetime. As far as a program is concerned, the lifetime of an object having a given storage-class is defined by the C Standard.

C++

7.1.5.1p8 *[Note: **volatile** is a hint to the implementation to avoid aggressive optimization involving the object because the value of the object might be changed by means undetectable by an implementation. See 1.9 for detailed semantics. In general, the semantics of **volatile** are intended to be the same in C++ as they are in C.]*

---

footnote 27 — 27) Leaving the innermost block containing the declaration, or jumping to a point in that block or an embedded block prior to the declaration, leaves the scope of the declaration. 471

Commentary

The scope of the declaration is the region of program text in which the identifier is visible using a top-down, left-to-right parse of the source code.

C90

Support for VLAs is new in C99.

Common Implementations

An implementation is required to track all these possibilities. It can choose not to free-up allocated storage in some cases, perhaps because it can deduce that the same amount of storage will be allocated when the definition is next executed. There is little practical experience with the implementation and VLA types at the moment. The common cases can be guessed at, but are not known with certainty.

6.2.5 Types

---

types — The meaning of a value stored in an object or returned by a function is determined by the *type* of the expression used to access it. 472

Commentary

Without a type, the object representation is simply a pattern of bits. A type creates a value representation from an object representation.

Other Languages

There is a standard for data types: *ISO/IEC 11404:1996 Information Technology— Programming languages, their environments and system software interfaces – Language-independent datatypes*. Quoting from the scope of this standard "This International Standard specifies the nomenclature and shared semantics for a collection of datatypes commonly occurring in programming languages and software interfaces, . . . ".

Some languages, for instance Visual Basic, tag objects with information about their type. When accessed, the implementation uses the tag associated with an object to determine its type, removing the need for the developer to explicitly specify a type for an object before program execution. Some languages (e.g., Algol 68 and CHILL) use the term *mode* rather than *type*.

Coding Guidelines

Accessing the same object using more than one type is making use of representation information and is discussed elsewhere.

569.1 representation information using
948 effective type

---

473 (An identifier declared to be an object is the simplest such expression;

Commentary

Such an expression is a *primary-expression*. Both the form and value of an integer constant determines its type, so an integer constant is not simpler than an identifier.

975 primary-expression syntax
835 integer constant type first in list

---

474 the type is specified in the declaration of the identifier.)

Commentary

C99 does not support the implicit declaration of any identifier. Labels may be used before they are defined, but they must still be defined.

1379 declaration at least one type specifier

Common Implementations

The behavior of some implementations on encountering an identifier that has not been declared is to provide a default declaration (as well as issuing the required diagnostic). Declaring the identifier to be an object of type **int** often prevents cascading diagnostics from being generated. A more sophisticated error-recovery strategy is to examine the token immediately to the left of identifier (adding the identifier as a member of the structure or union type if it is a selection operator).

---

475 Types are partitioned into *object types* (types that fully describe objects), *function types* (types that describe functions), and *incomplete types* (types that describe objects but lack information needed to determine their sizes).

types partitioned
object types
incomplete types

Commentary

This defines the terms *object types*, *function types*, and *incomplete types*. Function types can never be transformed into another type, although a pointer-to function type is an object type. When an incomplete type is completed, it becomes an object type. In the case of array types it is possible for its complete/incomplete status to alternate. For instance:

```
1  extern int ar[];   /* ar has an incomplete type here.  */
2
3  void f_1(void)
4  {
5  extern int ar[10]; /* ar has a complete type here.    */
6  }
7                     /* ar has an incomplete type here. */
```

Structure and union types can only be completed in the same scope as the original, incomplete declaration.

C++

3.9p6 *Incompletely-defined object types and the void types are incomplete types (3.9.1).*

So in C++ the set of incomplete types and the set of object types overlap each other.

3.9p9 *An object type is a (possibly cv-qualified) type that is not a function type, not a reference type, and not a* ***void*** *type.*

A sentence in the C++ Standard may be word-for-word identical to one appearing in the C Standard and yet its meaning could be different if the term *object type* is used. The aim of these C++ subclauses is to point out such sentences where they occur.

Other Languages

Many languages only have object types. Some languages support pointers to function types, but don't necessarily refer to a function definition as a function type. Incomplete types, in C, were originally needed to overcome the problems associated with defining mutually recursive structure types. Different languages handle this issue in different ways. The Java class method can be viewed as a kind of function type.

_Bool large enough to store 0 and 1

An object declared as type **_Bool** is large enough to store the values 0 and 1. 476

Commentary

Many existing programs contain a type defined, by developers, with these properties. The C committee did not want to break existing code by introducing a new keyword for an identifier that was likely to be in widespread use. **_Bool** was chosen. The header **<stdbool.h>** was also created and defined to contain more memorable identifiers. Like other scalar types, **_Bool** is specified in terms to the values it can hold, not the number of bits in its representation.

While an object of type **_Bool** can only hold the values 0 and 1, its behavior is not the same as that of an **unsigned int** bit-field of width one. In the case of **_Bool** the value being assigned to an object having this type is first compared against zero. In the case of a bit-field the value is cast to an unsigned type of the appropriate width. An example of the difference in behavior is that even, positive values will always cause 1 to be assigned to an object of type **_Bool**, while the same values will cause a 0 to be assigned to the object having the bit-field type. The standard does not prohibit an object of type **_Bool** from being larger than necessary to store the values 0 and 1. The only way of storing a value other than 0 or 1 into such a *larger object* depends on undefined behavior (i.e., two members of a union type, or casting pointer types). Whether, once stored, such a value may be read from the object using its **_Bool** type will also depend on the implementation (which may simply load a byte from storage, or may extract the value of a single bit from storage).

The term *boolean* is named after George Boole whose book, "An investigation of the laws of thought",[137] introduced the concept of Boolean algebra (or *logic* as it is commonly known, a term that is something of an overgeneralization).

C90

Support for the type **_Bool** is new in C99.

C++

3.9.1p6 *Values of type* ***bool*** *are either* ***true*** *or* ***false****.*

An rvalue of type **bool** *can be converted to an rvalue of type* **int**, *with* **false** *becoming zero and* **true** *becoming one.*

A **bool** *value can successfully be stored in a bit-field of any nonzero size.* 9.6p3

Other Languages

Many languages, including Java, support a boolean type; however, they don't usually get involved in specifying representation details. Fortran calls its equivalent type **LOGICAL**.

Common Implementations

Only a few processors contain instructions for loading and storing individual bits— from/to storage. Most implementations have to generate multiple instructions to achieve the required effect. Representing the type **_Bool** using a byte of storage simplifies (shorter, faster code) the loading and storing of its values. Many implementations make this choice.

The Intel 8051[625] has a 16-byte internal data-storage area and supports bit-level accesses to it. Several implementations (e.g., Keil,[717] Tasking[20]) include support for the type specifier **bit**, which enables objects to be declared that denote specific bits in this data area.

Coding Guidelines

George Boole intended his work to " . . . investigate the fundamental laws of those operations of the mind by which reasoning is performed.". It was some time before people realized that the reasoning carried out by the human mind is based on principles other than mathematical logic.

Experience with character types has shown that developers sometimes overlook the effects of promotion, of operands, to the type **int**. It remains to be seen whether objects of type **_Bool** will be used in contexts where such oversights, if made, will be significant. 653 operand convert automatically

Existing programs that define their own boolean type often use the type **unsigned char** as the underlying representation type. Given that implementations are likely to use this representation, internally, for the type **_Bool**, there would not appear to be any worthwhile benefits to changing the underlying type of the developer-defined boolean type. However, translators and static analysis tools are becoming more sophisticated and use of the type **_Bool** provides them with more tightly specified information on the range of possible intended values.

The type **_Bool** is based on concepts derived from boolean algebra and mathematical logic. Other than defining this type, the concept is not discussed again in the standard. Some languages (including C++) specify the result of some operators as having a boolean type. This is not the case in C99 (largely for backwards compatibility with C90). There are 10 kinds of developers, those that understand boolean roles and those that don't.

While the C Standard does not use **_Bool** in the specification of any other constructs, the concept of a boolean role is invariably part of a developer's comprehension of source code. Other terms used by developers when discussing boolean roles include *flag*, *indicator*, *switch*, *toggle*, and *bit*. These terms are usually associated with situations having two different states, or values. True and false, or 0 and 1, are simply different ways of representing these states. Mathematically the representation values could just as well be 222 and 4,567, or 0 and any number except 0. However, in practice the representation does play a part and the minimalist approach is often used (the values 0 and 1 are also representable a bit). 1112 logical negation result type 51 bit

Should the concept of boolean be interpreted in its broadest sense, with any operation that can only ever deliver one of two results be considered as boolean? Or should the C definition of the type **_Bool** be used as the sole basis for how the concept of boolean is interpreted? The former interpretation probably corresponds more closely with how developers think about boolean concepts, while the latter avoids subtle problems with different representations of the two values used in the representation. However, there is no evidence to suggest that either interpretation is unconditionally better than the other.

At the source code level the difference in specification of behavior for boolean and the other arithmetic types can be a small one. In all but the first case C defines the result of the following operations have an integer type (which differs from C++ where some of them have type **bool**):

- Cast of an expression to type **_Bool**.
- The result of a relational, equality, or logical operator.
- The definition of an enumerated type containing two enumeration constants.
- The definition of a bit-field of width one.
- The result of the remainder operator when the denominator has a value of 2.

Is there a worthwhile benefit in a guideline recommendation that classifies certain kinds of operations as delivering a result that has a boolean role and places restrictions on the subsequent use of these results?

The type **_Bool** is new in C99, and there is little experience available on the kinds of developer comprehension costs associated with in its use. However, a boolean type has long been supported in other languages. Is there anything to be learned from this other language usage? The other languages containing a boolean type, known to your author, do not promote operands (having this type) to an integer type. Because the operands retain their boolean type, some of the operations (e.g., addition) available to the C developer are not permitted (without explicitly casting to an integer type). Creating a stricter type system for C which treated the type **_Bool** as being distinct from the integer types and specified a result type of **_Bool** for some operators (e.g., logical negation, relational, equality, logical-AND, and logical-OR), is likely to be a nontrivial exercise that will touch nearly all aspects of the language specification. The approach taken in these coding guidelines is to introduce the concept of roles (leaving the C type system alone) and provide guideline recommendations on the contexts in which objects having these roles may occur.

typedef 1633 is synonym
logical negation 1111 result is
relational operators 1211 result type
equality operators 1220 result type
&& 1252 result type
|| 1260 result type
object 1352 role
boolean role
identifier 792 selecting spelling

An object having an integer type integer type has a boolean role if it is only expected to hold one of two possible values or it is assigned objects that have a boolean role.

The semantic associations implied by boolean usage could suggest spellings of identifiers denoting states that only ever take on one of two values. This issue is discussed elsewhere.

Example

```
#include <stdio.h>

extern _Bool E;

void f(void)
{
if (((E ? 1 : 0) != (!(!E))) ||
    ((E += 2) != 1)          ||
    ((--E, --E, E) != E))
   printf("This is not a conforming implementation\n");
}

void g(void)
{
_Bool Q;
struct {
        unsigned int u_bit :1;
       } u;
#define U (u.ubit)

Q = 0;     U = 0;   // sets both to 0
Q = 1;     U = 1;   // sets both to 1
Q = 4;     U = 4;   // sets Q to 1, U to 0
```

```
24  Q = 0.5;   U = 0.5; // sets Q to 1, U to 0
25  Q++;       U++;     // sets Q to 1; sets U to 1-U
26  Q--;       U--;     // sets Q to 1-Q; sets U to 1-U
27  }
```

---

477 An object declared as type **char** is large enough to store any member of the basic execution character set.

char hold any member of execution character set

Commentary

This requirement on the implementation is not the same as that for byte. One is based on storage and the other on type. The values of the CHAR_MIN and CHAR_MAX macros delimit the range of integer values that can be stored into an object of type **char**.

53 byte addressable unit
311 CHAR_MIN
312 CHAR_MAX

C++

> *Objects declared as characters (**char**) shall be large enough to store any member of the implementation's basic character set.* 3.9.1p1

The C++ Standard does not use the term character in the same way as C.

59 character single-byte

Other Languages

Many languages have some form of type **char**. Objects declared to have this type are capable of representing the value of a single character.

Coding Guidelines

The terms *char* (a type) and *character* (a bit representation) are often interchanged by developers. While technically they have different meanings in C (but not C++), there does not appear to be anything to be gained by educating developers about the correct C usage.

59 character single-byte

---

478 If a member of the basic execution character set is stored in a **char** its value is guaranteed to be ~~positive~~non-negative.

basic character set positive if stored in char object

Commentary

This guarantee only applies during program execution (i.e., it does not apply during preprocessing). The nonnegative value is also representable in a byte. No standardized character set specifies a negative value for its member representations. However, this is not a requirement on the character set an implementation may use. It is a requirement on an implementation that its representation of the type **char** be capable of supporting its chosen basic execution character set.

1883 basic character set may be negative
222 basic character set fit in a byte

The wording was changed by the response to DR #216.

C++

The following is really a tautology since a single character literal is defined to have the type **char** in C++.

> *If a character from this set is stored in a character object, the integral value of that character object is equal to the value of the single character literal form of that character.* 3.9.1p1

The C++ does place a requirement on the basic execution character set used.

> *For each basic execution character set, the values of the members shall be non-negative and distinct from one another.* 2.2p3

Other Languages

Few languages say anything about the values of character set members. But they invariably use the same character sets as C, so the above statement is also likely to be true for them.

Common Implementations

Although the basic execution character set has less than 127 members, it is possible for a character set to use values outside of the range 0 to 127 to represent members (and EBCDIC does).

Coding Guidelines

Dev 569.1 A program may rely on the value of a member of the basic execution character set stored in an object of type **char** being positive.

If any other character is stored in a **char** object, the resulting value is implementation-defined but shall be within the range of values that can be represented in that type. 479

Commentary

This is a requirement on the implementation. They cannot, for instance, specify the implementation-defined value of `'@'` as 999 when objects of type **char** can only represent values between -128 and 127 (but such an implementation-defined value would be possible if the type **char** supported a range of values that included 999).

An implementation supporting a character set containing a member whose value was greater than 127, assuming an 8-bit **char**, would have to chose a representation for the type **char** that had the same range as type **unsigned char**. Such character sets occur within mainstream European languages. The numeric values assigned, by ISO 10646, to characters in the ISO 8859–1 (Latin-1) standard fall in the range 32 to 255.

ISO 8859 24

C90

If other quantities are stored in a ***char*** *object, the behavior is implementation-defined: the values are treated as either signed or nonnegative integers.*

The implementation-defined behavior referred to in C90 was whether the values are treated as signed or nonnegative, not the behavior of the store. This C90 wording was needed as part of the chain of deduction that the plain char type behaved like either the signed or unsigned character types. This requirement was made explicit in C99. In some cases the C90 behavior for storing *other characters* in a **char** object could have been undefined (implicitly). The effect of the change to the C99 behavior is at most to turn undefined behavior into implementation-defined behavior. As such, it does not affect conforming programs.

char 516 range, representation and behavior

Issues relating to this sentence were addressed in the response to DR #040, question 7.

C++

2.2p3 *The values of the members of the execution character sets are implementation-defined, and any additional members are locale-specific.*

glyph 58 The only way of storing a particular character (using a glyph typed into the source code) into a char object is through a character constant, or a string literal.

2.13.2p1 *An ordinary character literal that contains a single* `c-char` *has type* ***char****, with value equal to the numerical value of the encoding of the* `c-char` *in the execution character set.*

2.13.4p1

An ordinary string literal has type "array of n `const char`*" and static storage duration (3.7), where n is the size of the string as defined below, and is initialized with the given characters.*

If a character from this set is stored in a character object, the integral value of that character object is equal to the value of the single character literal form of that character. 3.9.1p1

Taken together these requirements are equivalent to those given in the C Standard.

Other Languages

Few language specifications get involved in the representational details of character set members. In most strongly typed languages character literals have type **char**, so by definition they can be represented in a **char** object.

Coding Guidelines

569.1 representation information using

The guideline recommendation dealing with the use of representation information is applicable here. An example of a situation where implicit assumptions on representation may be made is array indexing. A positive value is always required, and the guarantee on positive values only applies to members of the basic execution character set.

Example

```
1   char ch_1 = '@';
```

Usage

In the visible form of the `.c` files 2.1% (`.h` 2.9%) of characters in character constants are not in the basic execution character set (assuming the Ascii character set representation is used for escape sequences).

---

480 There are five *standard signed integer types*, designated as **signed char**, **short int**, **int**, **long int**, and **long long int**.

standard signed integer types

Commentary

This defines the term *standard signed integer types*. Having five different types does not mean that there are five different representations (in terms of number of bits used). Multiple integer types, based on processor implementation characteristics, are part of the fabric of C. An implementation could choose to implement all types in 64 bits. They would still be different types, irrespective of the underlying representation. On processors that do not support 32- or 64-bit (needed for **long** and **long long** respectively) integer operations in hardware, there is a strong incentive not to use types requiring this number of representation bits.

There are three real floating types.

497 floating types three real

C90

Support for the type **long long int** (and its unsigned partner) is new in C99.

C++

Support for the type **long long int** (and its unsigned partner) is new in C99 and is not available in C++. (It was discussed, but not adopted by the C++ Committee.) Many hosted implementations support these types.

Other Languages

Many languages only support a single integer type. Some implementations of these languages, for instance Fortran, include extensions that allow the size of the integer type to be specified. Fortran 90 contains the intrinsic function `SELECT_INT_KIND` which enables the developer to specify the range of powers of 10 that an integer should be able to represent. The intrinsic `SELECT_REAL_KIND` allows the decimal precision and exponent range to be specified.

The Ada Standard gives permission for an implementation to support the optional predefined types **SHORT_INTEGER** and **LONG_INTEGER**. Java contains the types **short**, **int**, and **long**. It also specifies that **long** is represented in 64 bits, so there is no need (at least yet) to specify a **long long** that may be larger than a **long**.

Common Implementations

There are commonly at least four bit widths used to represent these types— 8, 16, 32, and 64. On processors that do not support a 64-bit data type (needed for the type **long long**) an implementation will perform 64-bit operations via calls to internal library functions. Some processors do not even support 32-bit operations. Like the 64-bit case, the support is provided via calls to internal library functions.

Coding Guidelines

The fact that there are at least five (four in C90) integer types in C, and not one, is a cause of great misunderstanding, by developers and unintentional behavior, in programs. The existence of these different types causes implicit conversions to become an important issue.

operand 653 convert automatically

There is a simple solution: Restrict programs to using a single integer type. The argument against this solution is often based on a perceived lack of resources (additional time to execute a program and greater storage requirements). The quest for efficiency is often uppermost in developers' minds when deciding on which integer type to use. For instance, an object taking on a small range of values, less than 128 say, is almost automatically given a character type. On RISC- and Intel Pentium-based processors the time taken to load or store an 8- or 32-bit quantity is usually the same. Once the value is loaded into a register, it is often operated on as a 32-bit quantity. There are 8-bit operations available on the Pentium, but they are not often generated by translators because of the extra complication needed for what can be small savings.

On the low-cost processors found in many freestanding environments, there are often resource limitations. Use of a narrower integer type can result in worthwhile performance improvements and storage savings. Implementations for such environments usually use the same representation for the types **int** and **short**. In a hosted environment the representation for the type **int** is usually the same as for the type **long**. The choice of representation for the type **int** is intended to be natural to the execution environment.

int 485 natural size

Rev 480.1 The type specifiers **char**, **short**, and **long** shall not appear in the visible source, or be used via developer-defined macros or via developer-defined typedef names.

Dev 480.1 When resources are constrained and where a worthwhile benefit has been calculated a character type whose promoted type is **int** may be used.

Dev 480.1 If a program needs to represent an integer value that is outside the representable range of the type **int** the type **long** or **long long** type may be used.

Dev 480.1 If a program needs to represent an integer value that is outside the representable range of the type **int**, resources are constrained and where a worthwhile benefit has been calculated, the type **unsigned int** may be used.

Developers rarely have any control over the contents of system headers. These may contain typedefs, for instance `size_t`, that have an integer type other than **int**. While use of these system-defined typedefs has many advantages, they do provide an alternative route for operands having different integer types to appear within expressions.

It is possible for values of different types to occur in an expression, other than via accesses to declared objects. For instance, an operand might be a wide character constant, the result of the **sizeof** operator, or the result of subtracting two pointers.

wide character constant 887 type of sizeof 1127 result type pointer 1175 subtract result type integer types 303 sizes

The minimum range of values that can be represented in these integer types is specified by the standard. An algorithm may depend on some object being able to represent a particular range of values. Use of a typedef name, in declarations of objects, provides a single point of control for the underlying representation

(the typedef name definition). The issue of encoding this range information in the typedef name is discussed elsewhere.

792 typedef naming conventions

Some coding guideline documents recommend that these keywords not be used directly in declarations (e.g., MISRA rule 13). Instead, it is recommended that typedef names denoting integer types of specific widths be defined and used. Such typedefs can be applicable in some situations. However, the number of programs where it is necessary to be concerned about the widths of all integer object representations is small. A much more important association is implied by the semantics associated with typedef names, this is discussed elsewhere.

0 MISRA

673 typedef assumption of no integer promotions

Usage

It is possible to specify many of the integer types, in C, using more than one sequence of keywords. Usage information on integer types is given elsewhere (see Table 1378.1).

1629 typedef name syntax

---

481 (These and other types may be designated in several additional ways, as described in 6.7.2.)

Commentary

Useful for developers who are lazy typists, entrants to the Obfuscated C contest,[43] and writers of coding guideline recommendations who want to pad out their material.

1378 type specifier syntax

Other Languages

Most languages define a single way of specifying every type.

---

482 There may also be implementation-defined *extended signed integer types*.[28)]

extended signed integer types

Commentary

The Committee recognized that new processors are constantly being developed to fill niche markets. These markets do not always require the characteristics normally expected of a general-purpose processor. Sometimes special-purpose uses result in unusual architectural designs. Rather than have vendors extending the language in different kinds of ways, the Committee has attempted to provide a standard framework for extended integer types. The **<stdint.h>** header is one place where these extended integer types may be defined.

Is using " . . . implementation-defined extended signed integer types." making use of an extension or is it implementation-defined behavior? It is listed as an implementation-defined behavior in annex J.3.5.

An implementation may also define new keywords to denote the existing types specified in the standard.

512 footnote 34

C90

The C90 Standard never explicitly stated this, but it did allow extensions. However, the response to DR #067 specified that the types of `size_t` and `ptrdiff_t` must be selected from the list of integer types specified in the standard. An extended type cannot be used.

C++

The C++ Standard does not explicitly specify an implementation's ability to add extended signed integer types, but it does explicitly allow extensions (1.4p8).

Other Languages

The Pascal/Ada language family allows developer-specified subranges (lower and upper bounds on the possible values) of integer types to be defined. These subranges provide information to the translator that enable it to select the appropriate underlying, processor, integer type to use.

Coding Guidelines

If the guideline recommendation dealing with using a single integer type is followed, any extended types will not occur in the source.

480.1 object int type only

Having occurrences of a nonstandard type, supported by a particular implementation, scattered throughout the visible source code creates portability problems. A method of minimizing the number of visible occurrences is needed. Use of a typedef name does not necessarily offer the best solution:

```
/*
 * Assuming vendor_int is a keyword denoting an extended
 * integer type supported by some implementation.
 */
#if USING_VENDOR_X
typedef vendor_int INT_V;
#else
typedef int INT_V;
#endif

unsigned INT_V glob; /* Syntax violation. */
```

type specifier syntax 1378

C syntax does not allow a declaration to include both a typedef name and another type specifier. Using a macro name to cover the implementation-defined keyword would avoid this problem.

---

signed integer types

The standard and extended signed integer types are collectively called *signed integer types*.[29)] 483

Commentary

This defines the term *signed integer types*. Unlike the integer types, other types do not have unsigned versions (floating-point types are always signed) and are not thought of in terms of being signed or unsigned. Hence the term commonly used is *signed types* rather than *signed integer types*.

C90

Explicitly including the extended signed integer types in this definition is new in C99.

An object declared as type **signed char** occupies the same amount of storage as a "plain" **char** object. 484

Commentary

character types 515

The amount of storage occupied by the two types may be the same, but they are different types and may be capable of representing different ranges of values. The representation of the sign in the type **signed char** is part of the object representation and is not permitted to consume additional bits.

---

int natural size

A "plain" **int** object has the natural size suggested by the architecture of the execution environment (large enough to contain any value in the range **INT_MIN** to **INT_MAX** as defined in the header **<limits.h>**). 485

Commentary

A "plain" **int** is the most commonly used type in source code. The choice of its representation has many important consequences, particularly in the quality of machine code produced by a translator. There may be several interpretations of the term *natural size* for some processor architectures. Efficiency is usually a big consideration. Execution-time performance efficiency is not always the same as storage efficiency for a given architecture. An implementors choice of "plain" **int** also needs to consider its effect on how integer types with lower rank will be promoted.

ABI

The choice of representation need not be decided purely on how the available processor instructions manipulate their operands. In function calls the most commonly passed argument type is "plain" **int**. The organization of the function call stack is an important design issue. In some cases it may have already been specified by a hardware vendor.[613, 1345–1347, 1517] In this case the choice of "plain" **int** representation has already been dictated for all translators targeting that environment.

Other Languages

Most languages say nothing about the representation of integer types; it is left to implementation vendors to decide how best to implement them for a given host. Java is designed to be portable across all environments. This is achieved by specifying the representation of all types in the language standard.

Common Implementations

Historically the "plain" **int** type was usually the same size as either the types **short** or **long**. It is rare to find an **int** type having a size that is between the sizes of these two types. This existing practice has affected

existing code, which is often found to contain implicit assumptions about various integer types having the same widths. 626 width integer type

Coding Guidelines

Developers sometimes want the program they write, or at least large parts of them, to be independent of the host processor (the current market dominance of the Intel/Microsoft platform has caused many development groups to lose interest in portability to other platforms). Having a fundamental integer type whose representation depends on natural features of the host environment does not sound ideal. One solution is to hide implementation decisions behind a typedef name and recommend that developers use this rather than the **int** keyword (moving source code to a new implementation then only requires one change to the typedef definition).

It used to be the case that both 16- and 32-bit processors were commonly encountered in a hosted environment. The migration, for hosted environments, to 32-bit processors is now an established fact. The migration to processors where 64-bit integers are the natural architectural choice has only just started (in 2002). Whether it is yet worth investing effort on enforcing a guideline that recommends using a typedef name rather than the **int** keyword is uncertain (for programs aimed at the desktop environment).

Mobile phones and hand-held organizers are starting to support the execution of programs downloaded by their users. To conserve power and reduce costs, some of the processors used in such devices have a natural integer size of 16 bits. The extent to which a large number of programs will need to be ported from a 32-bit environment to these hosts is unknown.

The processors used in freestanding environments vary enormously in their support for different sized integer types. On some, support for a 16-bit **int** (the minimum standard requirement) does not come naturally. At the time of this writing a large amount of the software written for these processors does not get ported to other processors, it is device-specific (as much driven by the characteristics of the application as by the cost of changing processors). But developer organizations do want to reuse code if possible— it can reduce time to market (but not always total cost). In this development environment, where the size of the type **int** is likely to vary, there are obvious benefits in a guideline recommendation to use a typedef name.

The guideline recommendation dealing with using a single integer type specifies the use of the type **int**. 480.1 object int type only

---

486 For each of the signed integer types, there is a corresponding (but different) unsigned integer type (designated with the keyword **unsigned**) that uses the same amount of storage (including sign information) and has the same alignment requirements. signed integer corresponding unsigned integer

Commentary

This is another case of C providing a construct that mirrors a data type, and associated operations, commonly found in hardware processors. The unsigned integer types can generally represent positive values twice as great as their corresponding signed counterparts.

Other Languages

Few languages support unsigned integer types. Modula-2 uses the term *cardinal* to denote its unsigned integer type. Support for what were called *modular* types was added to Ada 95.

Coding Guidelines

The mixing of operands having unsigned and signed integer type in an expression is a common cause of unexpected program behavior. Developers overlook the effects of performing the integer promotions clauses and usual arithmetic conversions, or are simply unaware that the operands have different signedness. This issue is also discussed elsewhere. 675 integer promotions 706 usual arithmetic conversions 653 operand convert automatically

Following the guideline recommendation that only the type **int** be used implies that no objects having an unsigned type are declared. Does a deviation from this guideline recommendation have a worthwhile benefit? Measurements show (see Table 486.1) that unsigned types are much more common in embedded software than signed types. The fact that some languages do not have an unsigned type might be more of an indication 480.1 object int type only

of the applications written using them than that programs don't need to use such a type. The following are several ways of thinking about unsigned types in relation to signed types:

integer types 303 sizes

integer promotions 675

- Signed types are the *natural type* to use and any usage of unsigned types needs to be justified. In many programs the range of values manipulated is well within the representable range of the integer types used. The ability of signed types to represent negative values frees developers of the need to think about the possibility of having to handle negative values created as the intermediate step during the evaluation of an expression. The type **`int`** is the type to which narrower types are converted by the integer promotions. The type **`int`** is equivalent to the type **`signed int`**. Signed types appear to be the type of least effort (for developers).
- Unsigned types are the *natural type* to use and any usage of signed types needs to be justified. Most quantities that are counted or measured have positive values (mathematicians refused to acknowledge the existence of negative quantities for many centuries[138]). In many cases applications do not deal with negative quantities. Unsigned types appear to share the same *positive quantity* semantics as applications.
- Neither type is considered more natural to use than the other. There does not appear to be any situation where this would be the default position to take.

Using the type **`unsigned int`** only prevents signed/unsigned conversion issues from arising if it is the only type used. Objects declared using a type of less rank will be promoted to the type **`int`**.

Alt 480.1

All objects declared in a program shall have an unsigned type.

Developers often only consider the use an unsigned type when the possible range of values being stored is not representable in the corresponding signed type. There may not be a signed type capable of representing the desired range of values (support for the type **`long long`** is new in C99), or use of this type may be considered to be *inefficient*. Whether signed/unsigned conversion issues are minimized by declaring all objects to have either a signed or unsigned type will have to be decided by the developer.

Usage

Usage information on integer type specifiers is given elsewhere (see Table 1378.1, which does not include uses of integer types specified via typedef names).

Table 486.1: Occurrence of objects having different width integer types (as a percentage of all integer types) for embedded source and the SPECint95 benchmark (separated by a forward slash, e.g.,embedded/SPECint95). Adapted from Engblom.[390]

	8 bits	16 bits	32 bits
unsigned	70.8/1.3	14.0/0.4	2.1/44.9
signed	2.7/0.0	9.4/0.3	1.0/53.1

A study by Engblom[390] compared the use of integer types in embedded source and SPECint95 (see Table 486.1). There are a number of possible reasons of Engblom's results. Most of the difference is due to the use of the type **`unsigned char`**. There can be significant performance advantages in using this type (because of processor characteristics <host processors, introduction>). There is also the observation that measurements of physical quantities are usually positive quantities. Other reasons include the following:

- Developers writing for the desktop are not motivated to spend time tuning the sizes of scalar objects. (The fact that any storage saving from using a smaller type is insignificant and the instruction timings for the different types is often very similar if not identical is not the issue, because many developers believe there are performance differences.) There are often few resources (e.g., developers time, performance-monitoring tools) provided by management to motivate developers to think about performance issues in this environment.

- Processors used for embedded applications usually have instructions specifically designed to efficiently handle 8-bit data. Programs often have storage constraint when executing in such environments. There are real benefits to be had from being able to use an 8- or 16-bit data type. The technical case, showing that performance improvements are available, is visible to developers and their managers. The demands of the application can also require management to make the resources available to consider performance as the application is being designed, coded, and maintained.

It might be claimed that embedded applications are oriented to 8-bit data. The application requirements control the choice of processor, not the other way around. Hardware cost is important (designers worry over pennies, which add up when millions of units are to be manufactured). Processors that handle 8-bit data are usually cheaper to manufacture and the interfacing costs are lower (fewer wires to the outside world).

---

487 The type **_Bool** and the unsigned integer types that correspond to the standard signed integer types are the *standard unsigned integer types*. standard unsigned integer

Commentary

This defines the term *standard unsigned integer type*.

The unsignedness of the type **_Bool** is unlikely to be visible to the developer. The usual arithmetic conversions will always promote objects having this type to the type **int**. 706 usual arithmetic conversions 476 _Bool large enough to store 0 and 1

C90

Support for the type **_Bool** is new in C99.

C++

In C++ the type **bool** is classified as an integer type (3.9.1p6). However, it is a type distinct from the signed and unsigned integer types.

Coding Guidelines

Although the type **_Bool** may, technically, be an integer type, there are benefits to treating it as a distinct type. However, there is a potential cost in doing so. Treating it as a distinct type reinforces the (technically incorrect) developer expectation that implementations will treat it as purely a boolean type, having one of two values. If a value other than 0 or 1 (through use of a construct exhibiting undefined behavior) is stored in such an object, implicit assumptions in a program may no longer hold. These coding guidelines assume that the benefits of treating the type **_Bool** as a distinct type significantly outweigh the potential costs The fact that the type **_Bool** is classified as an unsigned integer type is not of any practical significance to coding guidelines. 476 boolean role

---

488 The unsigned integer types that correspond to the extended signed integer types are the *extended unsigned integer types*. extended unsigned integer

Commentary

This defines the term *extended unsigned integer type*. By definition any unsigned integer type that does not have a corresponding extended signed integer type is not as an *extended unsigned integer type*.

Common Implementations

The concept of extended integer types is still too new to be able to say anything about common implementations. The Motorola AltiVec implementation[971] supports the type **pixel**. This uses 16 bits to represent a display pixel (a 1/5/5/5 bit interpretation of the bits is used, and the type is treated like an **unsigned short**).

Coding Guidelines

The use of extended unsigned integer types violates the guideline recommendation dealing with using extensions and using a single integer type. Such types are not usually provided by implementations. Support for them, by an implementation, implies customer demand. Given such demand it is likely that they will be used, in some cases, by developers. Following coding guidelines is unlikely to take precedence in these cases, and nothing more is said about the issue. 95.1 extensions cost/benefit 480.1 object int type only

unsigned integer types

The standard and extended unsigned integer types are collectively called *unsigned integer types*.[30)] 489

Commentary

This defines the term *unsigned integer types*. It is common practice to use the term *unsigned types* to denote these types.

signed integer types 483

C90

Explicitly including the extended signed integer types in the definition is new in C99.

footnote 28

28) Implementation-defined keywords shall have the form of an identifier reserved for any use as described in 7.1.3. 490

Commentary

An implementation-defined keyword is an extension, however it is spelled. In specifying how new keywords are to be added to the language the Committee is recognizing that this is often done by translator vendors. By listing the identifier spellings that should be used, the Committee is also giving a warning to developers not to use them in their own declarations.

The incentive for vendors to use these spellings is that they can claim their extensions have been added in a standards-conforming way. What do developers gain from it? Existing code is less likely to be broken (because it is not supposed to use these spellings) and the Committee continues to have the option of using nonreserved words in future language enhancements (the Committee never makes extensions).

C90

The C90 Standard did not go into this level of detail on implementation extensions.

C++

The C++ Standard does not say anything about how an implementation might go about adding additional keywords. However, it does list a set of names that is always reserved for the implementation (17.4.3.1.2).

Other Languages

Most languages say nothing about possible extensions to themselves, perhaps in the hope that there will not be any such extensions. Those that do rarely specify a list of reserved identifiers.

Common Implementations

Suggestions about the spelling of additional keywords was not given in C90 and vendors used a variety of identifiers, only a few of them following the usage described in 7.1.3. One of the most commonly seen keyword extensions, **`asm`**, is not in the list of reserved names. The keywords **`near`** and **`far`** (and sometimes **`tiny`** and **`huge`**) were used by translators targeting the Intel x86 processor when many of the applications were predominantly 16 bit. While most applications for this processor are now 32 bit, support for these keywords is kept for backwards compatibility. These keywords have also been adopted by translators targeting other processors, where pointers of various widths need to be supported.

The token sequence **`long long`** was a relatively common extension in C90 implementations. This usage did not introduce a new keyword; it used existing keywords to create a new type.

typing minimization 0

Experience shows that developers prefer keywords that are short and meaningful, and they often complain that having to prefix keywords with underscores is irksome. A solution used by some implementations that have added extra keywords is to define matching macro names (e.g., `gcc` defines the keywords **`__attribute__`** and **`__typeof__`**; It also predefines the macro names `attribute` and `typedef`, which expand to the respective keywords).

The Keil compiler[717] supported the keyword **`bit`**, for some processors, well before the C99 Standard was published.

footnote 29

29) Therefore, any statement in this Standard about signed integer types also applies to the extended signed integer types. 491

Commentary

Because the extended integer types are included in the definition of signed integer types, any statement that refers to the term *signed integer types* also includes any extended integer types.

C++

The C++ Standard does not place any requirement on extended integer types that may be provided by an implementation.

Common Implementations

It remains to be seen whether implementations abide by this non-normative footnote.

Coding Guidelines

Any guideline recommendation that applies to the signed integer types also applies to any extended signed integer types. The additional guidelines that apply to extended signed integer types are those that apply generally to the use of extensions. The additional complexity introduced into the usual arithmetic conversions needs to be considered.

95 implementation extensions
706 usual arithmetic conversions

---

492 30) Therefore, any statement in this Standard about unsigned integer types also applies to the extended unsigned integer types.

footnote 30

Commentary

The discussion on statements that apply to the signed integer types is also applicable here.

491 footnote 29

---

493 The standard signed integer types and standard unsigned integer types are collectively called the *standard integer types*, the extended signed integer types and extended unsigned integer types are collectively called the *extended integer types*.

standard integer types
extended integer types

Commentary

This defines the terms *standard integer types* and *extended integer types*. Note that this definition does not include the type **char** or the enumerated types. These are included in the definition of the term *integer types*.

519 integer types

C++

Types **bool**, **char**, **wchar_t**, *and the signed and unsigned integer types are collectively called integral types.*[43)] *A synonym for integral type is integer type.*

3.9.1p7

43) Therefore, enumerations (7.2) are not integral; however, enumerations can be promoted to **int**, **unsigned int**, **long**, *or* **unsigned long**, *as specified in 4.5.*

Footnote 43

The issue of enumerations being distinct types, rather than integer types, is discussed elsewhere.

864 enumeration constant type

---

494 For any two integer types with the same signedness and different integer conversion rank (see 6.3.1.1), the range of values of the type with smaller integer conversion rank is a subrange of the values of the other type.

integer types relative ranges
rank relative ranges

Commentary

The specification of the sizes of integer types provides a minimum range of values that each type must be able to represent. Nothing is said about maximum values. The specification of rank is based on the names of the types, not their representable ranges. This requirement prevents, for instance, an implementation from supporting a greater range of representable values in an object of type **short** than in an object of type **int**. An implementation could choose to support an integer type, with a given conversion rank, capable of representing the same range of values as an integer type with greater rank. But an integer type cannot be

303 integer types sizes
659 conversion rank
659 conversion rank

capable of representing a greater range of values than another integer type (of the same sign) without also having a greater rank.

The concept of rank is new in C99.

C90

There was no requirement in C90 that the values representable in an unsigned integer type be a subrange of the values representable in unsigned integer types of greater rank. For instance, a C90 implementation could make the following choices:

```
1  SHRT_MAX  ==   32767  /* 15 bits */
2  USHRT_MAX ==  262143  /* 18 bits */
3  INT_MAX   ==   65535  /* 16 bits */
4  UINT_MAX  ==  131071  /* 17 bits */
```

No C90 implementation known to your author fails to meet the stricter C99 requirement.

C++

3.9.1p2 *In this list, each type provides at least as much storage as those preceding it in the list.*

C++ appears to have a lower-level view than C on integer types, defining them in terms of storage allocated, rather than the values they can represent. Some deduction is needed to show that the C requirement on values also holds true for C++:

3.9.1p3 *For each of the signed integer types, there exists a corresponding (but different) unsigned integer type: "**unsigned char**", "**unsigned short int**", "**unsigned int**", and "**unsigned long int**," each of which occupies the same amount of storage and has the same alignment requirements (3.9) as the corresponding signed integer type[40] ;*

They occupy the same storage,

3.9.1p3 *that is, each signed integer type has the same object representation as its corresponding unsigned integer type. The range of nonnegative values of a signed integer type is a subrange of the corresponding unsigned integer type, and the value representation of each corresponding signed/unsigned type shall be the same.*

they have a common set of values, and

3.9.1p4 *Unsigned integers, declared **unsigned**, shall obey the laws of arithmetic modulo 2^n where n is the number of bits in the value representation of that particular size of integer.[41]*

more values can be represented as the amount of storage increases.

QED.

Coding Guidelines

Each integer type's ability to represent values, relative to other integer types, is something developers learn early and have little trouble with thereafter. It is developers' expectation of specific integer types being able to represent the same range of values as other integer types that is often the root cause of faults and portability problems.

In a 16-bit environment there is often an expectation that the type **int** is represented in 16 bits, a width that differs from the type **long** and (sometimes) pointer types. In a 32-bit environment there is often an expectation that the pointer types and the types **int** and **long** are represented using the same amount of storage, each being capable of storing any value that can be represented in the other's type.

The introduction of the type **long long** in C99 uncovered a new expectation— that the type **long** is the widest integer type (and the less reasonable expectation that the type **long** occupies at least the same amount of storage as a pointer). The typedef `intmax_t` was introduced to provide a name for the concept of widest integer type to prevent this issue from causing a problem in the future. However, this typedef name does not solve the problem in existing code.

widest type assumption

---

495 The range of nonnegative values of a signed integer type is a subrange of the corresponding unsigned integer type, and the representation of the same value in each type is the same.[31)]

positive signed integer type subrange of equivalent unsigned type

Commentary

This is a requirement on the implementation (even though it does not use the term *shall*). The standard is doing more than enshrining various, low-level representation issues within the language. If the type of operands differ in their sign only, the result of the usual arithmetic conversions is an unsigned type. This requirement ensures that such a conversion does not lead to any surprises if the operand with signed type is positive. This requirement does rule out implementations using the following:

706 usual arithmetic conversions

- More representation bits in the signed type; for instance, the signed type using 24 bits and the unsigned type 16 bits.
- Combinations of integer representations; for instance, two's complement for a particular signed type and BCD for its corresponding unsigned type (although the use of BCD is ruled out by other requirements).

610 sign bit representation

However, it does not rule out the possibility of an unsigned integer type being able to represent significantly more values than its corresponding signed type.

623 object representation same padding signed/unsigned

Other Languages

Most languages do not specify representation details down to this level.

Common Implementations

Some host processors contain instructions for operating on BCD representations (e.g.,the Intel x86). A few older processors aimed at the business language (Cobol) market had no instructions for performing arithmetic on binary integer representations (e.g., ICL System 25). C on such hardware would be problematic.

---

496 A computation involving unsigned operands can never overflow, because a result that cannot be represented by the resulting unsigned integer type is reduced modulo the number that is one greater than the largest value that can be represented by the resulting type.

unsigned computation modulo reduced

Commentary

The common term for such operations is that they *wrap*.

683 unsigned integer conversion to

This specification describes the behavior of arithmetic operations for the vast majority of existing processors operating on values having unsigned types. Modulo arithmetic is a long-established part of mathematics (number theory). However, mathematicians working in the field of program correctness often frown on reliance on modulo arithmetic operations in programs (they represent a discontinuity). The **%** operator provides another mechanism for obtaining modulo behavior.

1149 % operator result

The LIA (Language Independent Arithmetic) standards[642] treat both nonrepresentable signed and unsigned values in the same way, a mathematical view of the world where values are never intended to exceed their maximum values. C's view is based on how existing processors operate on unsigned quantities.

Other Languages

Languages that support an unsigned integer type usually specify a similar behavior.

Common Implementations

This behavior describes what most processor operations on unsigned values already do. In those rare cases where a processor does not support unsigned operations, calls to internal library functions have to be made.

Coding Guidelines

Are the people working in the field of proving program correctness themselves correct to recommend against the use of modulo arithmetic? It seems to your author that such people are more interested in making programs fit their favorite mathematical theories and algorithms than making the mathematics fit the programs that commercial developers write. In practice the truncation of significant bits (which is how the engineers who originally designed the processor operations thought about it) for operations on unsigned values does not differ from the behavior commonly seen for signed values. However, the standard specifies a well-defined behavior in the former case and undefined behavior in the latter case. However, the difference is not in the commonly seen behaviors, or the specification provided in the standard. The difference is in the commonly seen developer intent.

arithmetic 607 operation
exceptional condition
exception 947 condition

Developers sometimes write code that relies on the modulo behavior of operations on unsigned values. It is very rare for developers to write code that relies on the common processor behavior on signed value overflow. It is not possible to imply from an object having an unsigned type that developers intend operations using it to wrap. The fact that modulo arithmetic is defined by the standard and used by developers some of the time does not mean that this behavior is always intended.

Are there any common cases? Are objects usually defined with unsigned integer types purely to make use of the larger range of values available, or is the modulo behavior on overflow intended? A similar question can be asked of a cast to an unsigned integer type.

It is your author's experience (who has no figures to back his view up) that most operations whose mathematical result is not within the range of the type are not intended by developers. Wanting the result to be modulo-reduced is the less common case. For this reason (and the effects of the mathematical puritans) many coding guideline documents specify that operations on operands having unsigned type should not generate a value that is different from its modulo-reduced value (i.e., operations on unsigned values are not allowed to *overflow*).

Some algorithms depend on modulo arithmetic behavior (e.g., in cryptography). Recommending against all such usage is not constructive. Documenting all such dependencies is a useful aid to readers because they can then assume that in all other cases no such behavior is intended.

Rev 496.1 Those operations involving operands, having an unsigned integer type, where it is known that the result may need to be modulo-reduced shall be commented as such.

---

floating types three real

There are three *real floating types*, designated as **float**, **double**, and **long double**.[32)] 497

Commentary

This defines the term *real floating types*. The possibility of additional floating-point types is listed in future language directions

floating types 2034 future language directions

The organization of the floating types has a similar structure to that commonly seen in the handling of the integer types **short**, **int**, and **long**. The type **double** is often thought of in terms of the floating-point equivalent of **int**. On some implementations it has the same size as the type **float**, on other implementations it has the same size as the type **long double**, and on a few implementations its size lies between these two types. One difference between integer and floating types is that in the latter case an implementation is given much greater freedom in how operations on operands having these types are handled. The header **<math.h>** defines the typedefs `float_t` and `double_t` for developers who want to define objects having types that correspond to how an implementation performs operations.

standard 480 signed integer types
354 FLT_EVAL_METHOD

The type **long double** was introduced in C90. It was not in K&R C.

base document 1

C90

What the C90 Standard calls *floating types* includes complex types in C99. The term *real floating types* is new in C99.

Other Languages

Many languages only support a single floating-point type. Some implementations of these languages, for instance Fortran, include extensions that allow the size of the floating-point type to be specified. The Fortran 90 standard provides a mechanism for developers to specify decimal precision and exponent range. The Ada Standard gives permission for an implementation to support the optional predefined types **SHORT_FLOAT** and **LONG_FLOAT**. Java has the types **float** and **double** type, but does not have a type **long double**.

Common Implementations

The original K&R specification treated the token sequence **long float** as a synonym for **double** (this support was removed during the early evolution of C[1180] although some implementations continue to support it[600]). However, some vendors continue to support this usage.[612]

When floating-point operations are performed using hardware, there are usually two or more different floating-point formats (number of bits). When these operations are carried out in software, sometimes only a single representation is available (in some cases the vendor only provides floating-point support to enable them to claim conformance to the C Standard). The IEC 60559 Standard defines single- and double-precision formats. It also supports an extended precision form for both of these representations.

29 IEC 60559

The Cray processors are unusual in that the types **float** and **double** are both represented in the same number of bits. It is the size of **float** that has been increased to 64 bits, not **double** reduced to 32 bits. The IBM ILE C compiler[617] supports a packed decimal data type. The declaration `decimal(6, 2) x;` declares `x` to have six decimal digits before the decimal point and two after it.

Coding Guidelines

The simple approach of using as much accuracy as possible, declaring all floating-point objects as type **long double**, does not guarantee that algorithms will be well behaved. There is no substitute for careful thought and this is even more important when dealing with floating-point representation.

The type **double** tends to be the floating-point type used by default (rather like the type **int**). Execution time performance is an issue that developers often think about when dealing with floating-point types, sometimes storage capacity (for large arrays) can also be an issue. The type **double** has traditionally been the recommended floating type, for developers to use by default, although in many cases the type **float** provides sufficient accuracy. Given the problems that many developers have in correctly using floating types, a more worthwhile choice of guideline recommendation might be to recommend against their use completely.

It may be possible to trade execution-time performance against accuracy of the final results, but this is not always the case. For instance, some processors perform all floating-point operations to the same accuracy and the operations needed to convert between types (less/more accurate) can decrease execution performance. For processors that operate on formats of different sizes, it is likely that operations on the smaller size will be faster. The question is then whether enough is understood, by the developer, about the algorithm to know if the use a floating-point type with less accuracy will deliver acceptable results.

353 floating-point architectures

In practice few algorithms, let alone applications, require the stored precision available in the types **double** or **long double**. However, a minimum amount of accuracy may be required in the intermediate result of expression evaluation. In some cases the additional range supported by the exponents used in wider types is required by an application.

354 FLT_EVAL_ME
334 exponent

Given the degree of uncertainty about the costs and benefits in using any floating types, this coding guideline subsection does not make any recommendations.

Table 497.1: Occurrence of floating types in various declaration contexts (as a percentage of all floating types appearing in all of these contexts). Based on the translated form of this book's benchmark programs.

Type	Block Scope	Parameter	File Scope	**typedef**	Member	Total
float	35.2	15.1	8.3	0.7	21.0	80.3
double	8.5	7.9	0.5	0.7	2.2	19.7
long double	0.0	0.0	0.0	0.0	0.0	0.0
Total	43.6	22.9	8.8	1.5	23.2	

The set of values of the type **float** is a subset of the set of values of the type **double**; 498

Commentary

This is a requirement on the implementation. There are no special values that can be represented in the type **float** that cannot also be represented in the type **double**.

Common Implementations

In IEC 60559 the significand, in double-precision, contains more representation bits than in single-precision (assuming these representations are chosen for the types **float** and **double**). Similarly, the exponent can represent a greater range of powers of 2.

Coding Guidelines

With 30 additional bits of significand in IEC 60559, there is a 1 in 10^9 chance of a value represented in double-precision having an exact value presentation in single-precision (leaving aside the possible extra exponent range available in the type **double**).

double values subset of long double

the set of values of the type **double** is a subset of the set of values of the type **long double**. 499

Commentary

This is a requirement on the implementation. There are no special values that can be represented in the type **double** that cannot also be represented in the type **long double**.

Common Implementations

On an Intel x86-based host the type **double** is usually 64 total bits. Some implementations also choose this representation for the type **long double**. Others make use of the extended precision mode supported by the floating-point unit, which is used for performing all floating-point operations. In these cases the type **long double** is often represented by 80 or 96 bits.

For 128-bit **long double** most IEC 60559 implementations use the format of 1–15–113 bits for sign-exponent-significand (and a hidden bit just like single and double).

floating types 330 characteristics

Some implementations use two contiguous **double**s to represent the type **long double**. This format has problems near DBL_MIN in that no extra precision, than available in the type **double**, is available. Also, while it can represent 2*DBL_MAX, there is normally no additional range available. There is also the issue of the interpretation of LDBL_EPSILON.

*_EPSILON 377

complex types

There are three *complex types*, designated as **float _Complex**, **double _Complex**, and **long double _Complex**.[33] 500

Commentary

The introduction of complex types in C99 was based on a marketing decision. The Committee wanted to capture the numerical community, which was continuing to use Fortran. The Committee was told that one of the major reasons engineers and scientists prefer Fortran is that it does a better job of supporting their requirements for numerical computation, support for complex types being one of these requirements. Fortran does not support complex integer types and there did not seem to be sufficient utility to introduce such types in C99.

A new header, **<complex.h>**, has been defined for performing operations on objects having the type **_Complex**. Annex G (informative) specifies IEC 60559-compatible complex arithmetic.

C90

Support for complex types is new in C99.

C++

In C++ complex is a template class. Three specializations are defined, corresponding to each of the floating-point types.

The header **<complex>** *defines a template class, and numerous functions for representing and manipulating complex numbers.*

The effect of instantiating the template `complex` *for any type other than float, double, or long double is unspecified.* 26.2p2

The C++ syntax for declaring objects of type **complex** is different from C.

```
#ifdef __cplusplus

#include <complex>

typedef complex<float> float_complex;
typedef complex<double> double_complex;
typedef complex<long double> long_double_complex;

#else

#include <complex.h>

typedef float complex float_complex;
typedef double complex double_complex;
typedef long double complex long_double_complex;
#endif
```

Other Languages

Fortran has contained complex types since an early version of that standard. Few other languages specify a built-in complex type (e.g., Ada, Common Lisp, and Scheme).

Common Implementations

Very few processors support instructions that operate on complex types. Implementations invariably break down the operations into their constituent real and imaginary parts, and operate on those separately.

`gcc` supports integer complex types. Any of the integer type specifiers may be used.

Coding Guidelines

The use of built-in language types may offer some advantages over developer-defined representations (optimizers have more information available to them and may be able to generate more efficient code). However, the cost involved in changing existing code to use this type is likely to be larger than the benefits reaped.

---

501 The real floating and complex types are collectively called the *floating types*. floating types

Commentary

This defines the term *floating types*.

C90

What the C90 Standard calls *floating types* includes complex types in C99.

Coding Guidelines

There is plenty of opportunity for confusion over this terminology. Common developer usage did not use to distinguish between complex and real types; it did not need to. Developers who occasionally make use of floating-point types will probably be unaware of the distinction, made by the C Standard between real and complex. The extent to which correct terminology will be used within the community that uses complex types is unknown.

For each floating type there is a *corresponding real type*, which is always a real floating type. 502

Commentary

This defines the term *corresponding real type*. The standard does not permit an implementation to support a complex type that does not have a matching real type. Given that a complex type is composed of two real components, this may seem self-evident. However, this specification prohibits an implementation-supplied complex integer type.

For real floating types, it is the same type. 503

Commentary

It is the same type in that the same type specifier is used in both the real and complex declarations.

For complex types, it is the type given by deleting the keyword **_Complex** from the type name. 504

Commentary

The keyword **_Complex** cannot occur as the only type specifier, because it has no implicit real type. One of the real type specifiers has to be given.

C++

In C++ the complex type is a template class and declarations involving it also include a floating-point type bracketed between < > tokens. This is the type referred to in the C99 wording.

complex type representation

Each complex type has the same representation and alignment requirements as an array type containing exactly two elements of the corresponding real type; 505

Commentary

This level of specification ensures that C objects, having a complex type, are likely to have the same representation as objects of the same type in Fortran within the same host environment. Such shared representations simplifies the job of providing an interface to library functions written in either language.

Rationale

The underlying implementation of the complex types is Cartesian, rather than polar, for overall efficiency and consistency with other programming languages. The implementation is explicitly stated so that characteristics and behaviors can be defined simply and unambiguously.

C++

The C++ Standard defines `complex` as a template class. There are no requirements on an implementation's representation of the underlying values.

Other Languages

Other languages that contain complex as a predefined type do not usually specify how the components are represented in storage. Fortran specifies that the type **complex** is represented as an ordered pair of real data.

Common Implementations

Some processors have instructions capable of loading and storing multiple registers. Such instructions usually require adjacent registers (based on how registers are named or numbered). Requiring adjacent registers can significantly complicate register allocation and an implementation may chose not to make use of these instructions.

Coding Guidelines

This requirement does more than imply that the **sizeof** operator applied to a complex type will return a value that is exactly twice that returned when the operator is applied to the corresponding real type. It exposes other implementation details that developers might want to make use of. The issues involved are discussed in the following sentence.

Example

```
#include <stdlib.h>

double _Complex *f(void)
{
/*
 * Not allocating an even number of doubles.  Suspicious?
 */
return (double _Complex *)malloc(sizeof(double) * 3);
}
```

506 the first element is equal to the real part, and the second element to the imaginary part, of the complex number.

complex component representation

Commentary

This specification lists additional implementation details that correspond to the Fortran specification. This requirement means that complex types are implemented using Cartesian coordinates rather than polar coordinates. A consequence of the choice of Cartesian coordinates (rather that polar coordinates) is that there are four ways of representing 0 and eight ways of representing infinity (where n represents some value):

+0 + i*0	-0 + i*0	-0 - i*0	+0 - i*0
$+\infty + i*n$	$+\infty + i*\infty$	$n + i*\infty$	$-\infty + i*\infty$
$-\infty + i*n$	$-\infty - i*\infty$	$n - i*\infty$	$+\infty - i*\infty$

The library functions `creal` and `cimag` provide direct access to these components.

C++

Clause 26.2.3 lists the first parameter of the complex constructor as the real part and the second parameter as the imaginary part. But, this does not imply anything about the internal representation used by an implementation.

Other Languages

Fortran specifies the Cartesian coordinate representation.

Coding Guidelines

The standard specifies the representation of a complex type as a two-element array of the corresponding real types. There is nothing implementation-defined about this representation and the guideline recommendation against the use of representation information is not applicable.

569.1 representation information using

One developer rationale for wanting to make use of representation information, in this case, is efficiency. Modifying a single part of an object with complex type invariably involves referencing the other part; for instance, the assignment:

```
val = 4.0 + I * cimag(val);
```

may be considered as too complicated for what is actually involved. A developer may be tempted to write:

```
*(double *)&val = 4.0;
```

as it appears to be more efficient. In some cases it may be more efficient. However, use of the address-of operator is likely to cause translators to be overly cautious, only performing a limited set of optimizations on expressions involving `val`. The result could be less efficient code. Also, the second form creates a dependency on the declared type of `val`. Until more experience is gained with the use of complex types in C, it is not possible to evaluate whether any guideline recommendation is worthwhile.

Example

It is not possible to use a typedef name to parameterize the kind of floating-point type used in the following function.

```
1  double f(double _Complex valu, _Bool first)
2  {
3  double *p_c = (double *)&valu;
4
5  if (first)
6     return *p_c;       /* Real part. */
7  else
8     return *(p_c + 1); /* Imaginary part. */
9  }
```

---

basic types

The type **char**, the signed and unsigned integer types, and the floating types are collectively called the *basic types*. 507

Commentary

footnote 34 512

This defines the term *basic types* (only used in this paragraph and footnote 34) which was also defined in C90. The term *base types* is sometimes used by developers.

C++

The C++ Standard uses the term *basic types* three times, but never defines it:

3.9.1p10 *[Note: even if the implementation defines two or more basic types to have the same value representation, they are nevertheless different types.]*

13.5p7 *The identities among certain predefined operators applied to basic types (for example, `++a` ≡ `a+=1`) need not hold for operator functions. Some predefined operators, such as `+=`, require an operand to be an lvalue when applied to basic types; this is not required by operator functions.*

Footnote 174 *174) An implicit exception to this rule are types described as synonyms for basic integral types, such as `size_t` (18.1) and `streamoff` (27.4.1).*

Coding Guidelines

This terminology is not commonly used outside of the C Standard's Committee.

---

types different even if same representation

Even if the implementation defines two or more basic types to have the same representation, they are nevertheless different types.[34)] 508

Commentary

The type checking rules are independent of representation (which can change between implementations). A type is a property in its own right that holds across all implementations. For example, even though the type **char** is defined to have the same range and representation as either of the types **signed char** or **unsigned char**, it is still a different type from them.

char separate type 537

Other Languages

Some languages go even further and specify that all user defined types, even of scalars, are different types. These are commonly called strongly typed languages.

Common Implementations

Once any type compatibility requirements specified in the standard have been checked, implementations are free to handle types having the same representation in the same way. Deleting casts between types having the same representation is so obvious it hardly merits being called an optimization. Some optimizers use type information when performing alias analysis— for instance, in the following definition:

1491 alias analysis

```
1  void f(int *p1, long *p2, int *p3)
2  { /* ... */ }
```

It might be assumed that the objects pointed to by `p1` and `p2` do not overlap because they are pointers to different types, while the objects pointed to by `p1` and `p3` could overlap because they are pointers to the same type.

Coding Guidelines

C does not provide any mechanism for developers to specify that two typedef names, defined using the same integer type, are different types. The benefits of such additional type-checking machinery are usually lost on the C community.

1633 typedef is synonym

Example

```
1  typedef int APPLES;
2  typedef int ORANGES;
3
4  APPLES coxes;
5  ORANGES jafa;
6
7  APPLES totals(void)
8  {
9  return coxes + jafa; /* Adding apples to oranges is suspicious. */
10 }
```

---

509 31) The same representation and alignment requirements are meant to imply interchangeability as arguments to functions, return values from functions, and members of unions.

footnote 31

Commentary

This interchangeability does not extend to being considered the same for common initial sequence purposes. The sentence that references this footnote does not discuss any alignment issues. This footnote is identical to footnote 39.

1038 common initial sequence

565 footnote 39

Prior to C90 there were no function prototypes. Developers expected to be able to interchange arguments that had signed and unsigned versions of the same integer type. Having to cast an argument, if the parameter type in the function definition had a different signedness, was seen as counter to C's easy-going type-checking system and a little intrusive. The introduction of prototypes did not completely do away with the issue of interchangeability of arguments. The ellipsis notation specifies that nothing is known about the expected type of arguments.

1601 ellipsis supplies no information

Similarly, for function return values, prior to C99 it was explicitly specified that if no function declaration was visible the translator provided one. These implicit declarations defaulted to a return type of **`int`**. If the actual function happened to return the type **`unsigned int`**, such a default declaration might have returned an unexpected result. A lot of developers had a casual attitude toward function declarations. The rest of us have to live with the consequences of the Committee not wanting to break all the source code they wrote. The interchangeability of function return values is now a moot point, because C99 requires that a function declaration be visible at the point of call (a default declaration is no longer provided).

Having slid further down the slippery slope, we arrive at union types. From the efficiency point of view, having to assign a member of a union to another member, having the corresponding (un)signed integer type, knowing that the value is representable, seems overly cautious. If the value is representable in both types, it is a big simplification not to have to be concerned about which member was last assigned to.

This footnote does not explicitly discuss casting pointers to the same signed/unsigned integer type. If objects of these types have the same representation and alignment requirements, which they do, and the value pointed at is within the range common to both types, everything ought to work. However, *meant to imply* does not explicitly apply in this case.

DR #070 *The program is not strictly conforming. Since many pre-existing programs assume that objects with the same representation are interchangeable in these contexts, the C Standard encourages implementors to allow such code to work, but does not require it.*

The program referred to, in this DR, was very similar to the following:

```
1  #include <stdio.h>
2
3  void output(c)
4  int c;
5  {
6  printf("C == %d\n", c);
7  }
8
9  void DR_070(void)
10 {
11 output(6);
12 /*
13  * The following call has undefined behavior.
14  */
15 output(6U);
16 }
```

Other Languages

Few languages support unsigned types as such. Languages in the Pascal family allow subranges to be specified, which could consist of nonnegative values only. However, such subrange types are not treated any differently by the language semantics than when the subrange includes negative values. Consequently, other languages tend to say nothing about the interchangeability of objects having the corresponding signed and unsigned types.

Common Implementations

The standard does not require that this interchangeability be implemented. But it gives a strong hint to implementors to investigate the issue. There are no known implementations that don't do what they are *imply*ed to do.

Coding Guidelines

function declaration use prototype 1810.1 If the guideline recommendation dealing with use of function prototypes is followed, the visible prototype will cause arguments to be cast to the declared type of the parameter. The function return type will also always be known. However, for arguments corresponding to the ellipsis notation, translators will not perform any implicit conversions. If the promoted type of the argument is not compatible with the type that appears in any invocation of the `va_arg` macro corresponding to that argument, the behavior is undefined. Incompatibility between an argument type and its corresponding parameters type (when no prototype is visible) is known to be a source of faults (hence the guideline recommendation dealing with the use of prototypes). So it is to be expected that the same root cause will also result in use of the `va_arg` macro having the same kinds of fault. However, use of the `va_arg` macro is relatively uncommon and for this reason no guideline recommendation is made here.

function declaration use prototype 1810.1

Signed and unsigned versions of the same type may appear as members of union types. However, this footnote does not give any additional access permissions over those discussed elsewhere. Interchangeability of union members is rarely a good idea. 589 union member when written to

What about a pointer-to objects having different signed types? Accessing objects having different types, signed or otherwise, may cause undefined behavior and is discussed elsewhere. The interchangeability being discussed applies to values, not objects. 948 effective type

Example

```
union {
       signed int m_1;
       unsigned int m_2;
      } glob;

extern int g(int, ...);

void f(void)
{
glob.m_2=3;
g(2, glob.m_1);
}
```

---

510 32) See “future language directions” (6.11.1). footnote 32

---

511 33) A specification for imaginary types is in informative annex G. footnote 33

Commentary

This annex is informative, not normative, and is applicable to IEC 60559-compatible implementations. 18 Normative references

C++

There is no such annex in the C++ Standard.

---

512 34) An implementation may define new keywords that provide alternative ways to designate a basic (or any other) type; footnote 34

Commentary

Some restrictions on the form of an identifier used as a keyword are given elsewhere. A new keyword, provided by an implementation as an alternative way of designating one of the basic types, is not the same as a typedef name. Although a typedef name is a synonym for the underlying type, there are restrictions on how it can be used with other type specifiers (it also has a scope, which a keyword does not have). For instance, a vendor may supply implementations for a range of processors and chose to support the keyword **__int_32**. On some processors this keyword is an alternative representation for the type **long**, on others an alternative for the type **int**, while on others it may not be an alternative for any of the basic types. 490 footnote 28
1633 typedef is synonym
1378 type specifier syntax

C90

Defining new keywords that provide alternative ways of designating basic types was not discussed in the C90 Standard.

C++

The object-oriented constructs supported by C++ removes most of the need for implementations to use additional keywords to designate basic (or any other) types

Other Languages

Most languages do not give explicit permission for new keywords to be added to them.

Common Implementations

Microsoft C supports the keyword **__int64**, which specifies the same type as **long long**.

Coding Guidelines

Another difference between an implementation-supplied alternative designation and a developer-defined typedef name is that one is under the control of the vendor and the other is under the control of the developer. For instance, if __int_32 had been defined as a typedef name by the developer, then it would be the developer's responsibility to ensure that it has the appropriate definition in each environment. As an implementation-supplied keyword, the properties of **__int_32** will be selected for each environment by the vendor.

The intent behind supporting new keywords that provide alternative ways to designate a basic type is to provide a mechanism for controlling the use of different types. In the case of integer types the guideline recommendation dealing with the use of a single integer type, through the use of a specific keyword, is applicable here.

object int type only 480.1

Example

```
/*
 * Assume vend_int is a new keyword denoting an alternative
 * way of designating the basic type int.
 */
typedef int DEV_INT;

unsigned DEV_INT glob_1;  /* Syntax violation. */
unsigned vend_int glob_2; /* Can combine with other type specifiers. */
```

---

this does not violate the requirement that all basic types be different. 513

Commentary

The implementation-defined keyword is simply an alternative representation, like trigraphs are an alternative representation of some characters.

Implementation-defined keywords shall have the form of an identifier reserved for any use as described in 7.1.3. 514

Commentary

footnote 28 490

This sentence duplicates the wording in footnote 28.

---

character types The three types **char**, **signed char**, and **unsigned char** are collectively called the *character types*. 515

Commentary

This defines the term *character types*.

C++

Clause 3.9.1p1 does not explicitly define the term *character types*, but the wording implies the same definition as C.

Other Languages

Many languages have a character type. Few languages have more than one such type (because they do not usually support unsigned types).

Coding Guidelines

This terminology is not commonly used by developers who sometimes refer to *char types* (plural), a usage that could be interpreted to mean the type **char**. The term *character type* is not immune from misinterpretation either (as also referring to the type **char**). While it does have the advantage of technical correctness, there is no evidence that there is any cost/benefit in attempting to change existing, sloppy, usage.

Table 515.1: Occurrence of character types in various declaration contexts (as a percentage of all character types appearing in all of these contexts). Based on the translated form of this book's benchmark programs.

Type	Block Scope	Parameter	File Scope	**typedef**	Member	Total
char	16.4	3.6	1.2	0.1	6.6	28.0
signed char	0.2	0.3	0.0	0.1	0.3	1.0
unsigned char	18.1	10.6	0.4	0.8	41.2	71.1
Total	34.7	14.6	1.5	1.0	48.2	

516 The implementation shall define **char** to have the same range, representation, and behavior as either **signed char** or **unsigned char**.[35)]

char range, representation and behavior

Commentary

This is a requirement on the implementation. However, it does not alter the fact that the type **char** is a different type than **signed char** or **unsigned char**.

C90

This sentence did not appear in the C90 Standard. Its intent had to be implied from wording elsewhere in that standard.

C++

3.9.1p1

*A **char**, a **signed char**, and an **unsigned char** occupy the same amount of storage and have the same alignment requirements (3.9); that is, they have the same object representation.*

. . .

*In any particular implementation, a plain **char** object can take on either the same values as **signed char** or an **unsigned char**; which one is implementation-defined.*

In C++ the type **char** can cause different behavior than if either of the types **signed char** or **unsigned char** were used. For instance, an overloaded function might be defined to take each of the three distinct character types. The type of the argument in an invocation will then control which function is invoked. This is not an issue for C code being translated by a C++ translator, because it will not contain overloaded functions.

517 An *enumeration* comprises a set of named integer constant values.

enumeration set of named constants

Commentary

There is no phase of translation where the names are replaced by their corresponding integer constant. Enumerations in C are tied rather closely to their constant values. The language has never made the final jump to treating such names as being simply that— an abstraction for a list of names.

Rationale

The C89 Committee considered several alternatives for enumeration types in C:

1. leave them out;

2. include them as definitions of integer constants;
3. include them in the weakly typed form of the UNIX C compiler;
4. include them with strong typing as in Pascal.

The C89 Committee adopted the second alternative on the grounds that this approach most clearly reflects common practice. Doing away with enumerations altogether would invalidate a fair amount of existing code; stronger typing than integer creates problems, for example, with arrays indexed by enumerations.

base document 1

Enumeration types were first specified in a document listing extensions made to the base document.

Other Languages

symbolic name 822

Enumerations in the Pascal language family are distinct from the integer types. In these languages, enumerations are treated as symbolic names, not integer values (although there is usually a mechanism for getting at the underlying representation value). Pascal does not even allow an explicit value to be given for the enumeration names; they are assigned by the implementation. Java did not offer support for enumerated types until version 1.5 of its specification.

Coding Guidelines

symbolic name 822

The benefits of using a name rather than a number in the visible source to denote some property, state, or attribute is discussed elsewhere. Enumerated types provide a mechanism for calling attention to the association between a list (they may also be considered as forming a set) of identifiers. This association is a developer-oriented one. From the translators point of view there is no such association (unlike many other languages, which treat members as belonging to their own unique type). The following discussion concentrates on the developer-oriented implications of having a list of identifiers defined together within the same enumeration definition.

While other languages might require stronger typing checks on the use of enumeration constants and objects defined using an enumerated type, there are no such requirements in C. Their usage can be freely intermixed, with values having other integer types, without a diagnostic being required to be generated. Enumerated types were not specified in K&R C and a developer culture of using macros has evolved. Because enumerated types were not seen to offer any additional functionality, in particular no additional translator checking, that macros did not already provide, they have not achieved widespread usage.

Some coding guideline documents recommend the use of enumerated types over macro names because of the motivation that "using of the preprocessor is poor practice".[798] Other guideline documents specify ways of indicating that a sequence of macro definitions are associated with each other (by, for instance, using comments at the start and end of the list of definitions). The difference between such macro definition usage and enumerations is that the latter has an explicit syntax associated with it, as well as established practices from other languages.

The advantage of using enumerated types, rather than macro definitions, is that there is an agreed-on notation for specifying the association between the identifiers. Static analysis tools can (and do) use this information to perform a number of consistency checks on the occurrence of enumeration constants and objects having an enumerated type in expressions. Without tool support, it might be claimed that there is no practical difference between the use of enumerated types and macro names. Tools effectively enforce stricter type compatibility requirements based on the belief that the definition of identifiers in enumerations can be taken as a statement of intent. The identifiers and objects having a particular enumerated type are being treated as a separate type that is not intended to be mixed with literals or objects having other types.

It is not known whether defining a list of identifiers in an enumeration type rather than as a macro definition affects developer memory performance (e.g., whether developers more readily recall them, their associated properties, or fellow group member names with fewer errors). The issue of identifier naming conventions based on the language construct used to define them is discussed elsewhere

identifier 792
learning a list of
source code 792
context
identifier

The selection of which, if any, identifiers should be defined as part of the same enumeration is based on

concepts that exist within an application (or at least within a program implementing it), or on usage patterns of these concepts within the source code. There are a number of different methods that might be used to measure the extent to which the concepts denoted by two identifiers are similar. The human-related methods of similarity measuring, and mathematical methods based on concept analysis, are discussed elsewhere. Resnick[1158] describes a measure of semantic similarity based on the *is-a* taxonomy that is based on the idea of shared information content.

0 categorization
1821 concept analysis

While two or more identifiers may share a common set of attributes, it does not necessarily mean that they should, or can, be members of the same enumerated type. The C Standard places several restrictions on what can be defined within an enumerated type, including:

- The same identifier, in a given scope, can only belong to one enumeration (Ada allows the same identifier to belong to more than one enumeration in the same scope; rules are defined for resolving the uses of such overloaded identifiers).
- The value of an enumeration constant must be representable in the type **`int`** (identifiers that denote floating-point values or string literals have to be defined as macro names).
- The values of an enumeration must be translation-time constants.

1440 enumeration constant representable in int

Given the premise that enumerated types have an interpretation for developers that is separate from the C type compatibility rules, the kinds of operations supported by this interpretation need to be considered. For instance, what are the rules governing the mixing of enumeration constants and integer literals in an expression? If the identifiers defined in an enumeration are treated as symbolic names, then the operators applicable to them are assignment (being passed as an argument has the same semantics); the equality operators; and, perhaps, the relational operators, if the order of definition has meaning within the concept embodied by the names (e.g, the baud rates that follow are ordered in increasing speed).

The following two examples illustrate how symbolic names might be used by developers (they are derived from the clause on device- and class-specific functions in the POSIX Standard[636]). They both deal with the attributes of a serial device.

- A serial device will have a single data-transfer rate (for simplicity, the possibility that the input rate may be different from the output rate is ignored) associated with it (e.g., its baud rate). The different rates might be denoted using the following definition:

```
enum baud_rates {B_0, B_50, B_300, B_1200, B_9600, B_38400};
```

  where the enumerated constants have been ordered by data-transfer rate (enabling a test using the relational operators to return meaningful information).

- The following definition denotes various attributes commonly found in serial devices:

```
enum termios_c_iflag {
              BRKINT, /* Signal interrupt on break */
              ICRNL,  /* Map CR to NL on input     */
              IGNBRK, /* ignore break condition    */
              IGNCR,  /* Ignore CR                 */
              IGNPAR, /* Ignore characters with parity errors */
              INLCR,  /* Map NL to CR on input     */
              INPCK,  /* Enable input parity check */
              ISTRIP, /* Strip character           */
              IXOFF,  /* Enable start/stop input control  */
              IXON,   /* Enable start/stop output control */
              PARMRK  /* Mark parity errors               */
};
```

where it is possible that more than one of them can apply to the same device at the same time. These enumeration constants are members of a set. Given the representation of enumerations as integer constants, the obvious implementation technique is to use disjoint bit-patterns as the value of each identifier in the enumeration (POSIX requires that the enumeration constants in `termios_c_iflag` have values that are bitwise distinct, which is not met in the preceding definition). The bitwise operators might then be used to manipulate objects containing these values.

The order in which enumeration constants are defined in an enumerated type has a number of consequences, including:

- If developers recognize the principle used to order the identifiers, they can use it to aid recall.
- The extent to which relational operators may be applied.
- Enhancements to the code need to ensure that any ordering is maintained when new members are added (e.g., if a new baud rate, say 4,800, is introduced, should `B_4800` be added between `B_1200` and `B_9600` or at the end of the list?).

The extent to which a meaningful ordering exists (in the sense that subsequent readers of the source would be capable of deducing, or predicting, the order of the identifiers given a description in an associated comment) and can be maintained when applications are enhanced is an issue that can only be decided by the author of the code.

Rev 517.1 When a set of identifiers are used to denote some application domain attribute using an integer constant representation, the possibility of them belonging to an enumeration type shall be considered.

Cg 517.2 The value of an enumeration constant shall be treated as representation information.

Cg 517.3 If either operand of a binary operator has an enumerated type, the other operand shall be declared using the same enumerated type or be an enumeration constant that is part of the definition of that type.

If an enumerated type is to be used to represent elements of a set, it is important that the values of all of its enumeration constants be disjoint. Adding or removing one member should not affect the presence of any other member.

Usage

A study by Gravley and Lakhotia[517] looked at ways of automatically deducing which identifiers, defined as object-like macros denoting an integer constant, could be members of the same enumerated type. The heuristics used to group identifiers were based either on visual clues (block of **`#define`**s bracketed by comments or blank lines), or the value of the macro body (consecutive values in increasing or decreasing numeric sequence; bit sequences were not considered).

macro object-like 1931

The 75 header files analyzed contained 1,225 macro definitions, of which 533 had integer constant bodies. The heuristics using visual clues managed to find around 55 groups (average size 8.9 members) having more than one member, the value based heuristic found 60 such groups (average size 6.7 members).

enumeration different type

Each distinct enumeration constitutes a different *enumerated type*. 518

Commentary

Don't jump to conclusions. Each enumerated type is required to be compatible with some integer type. The C type compatibility rules do not always require two types to be the same. This means that objects declared to have an enumerated type effectively behave as if they were declared with the appropriate, compatible integer type.

1447 enumeration type compatible with

631 compatible type if

C++

The C++ Standard also contains this sentence (3.9.2p1). But it does not contain the integer compatibility requirements that C contains. The consequences of this are discussed elsewhere.

1447 enumeration type compatible with

Other Languages

Languages that contain enumerated types usually also treat them as different types that are not compatible with an integer type (even though this is the most common internal representation used by implementations).

Coding Guidelines

These coding guidelines maintain this specification of enumerations being different enumerated types and recommends that the requirement that they be compatible with some integer type be ignored.

1447 enumeration type compatible with

---

519 The type **char**, the signed and unsigned integer types, and the enumerated types are collectively called *integer types*.

integer types

Commentary

This defines the term *integer types*. Some developers also use the terminology *integral types* as used in the C90 Standard.

C90

In the C90 Standard these types were called either *integral types* or *integer types*. DR #067 lead to these two terms being rationalized to a single term.

C++

> *Types* **bool**, **char**, **wchar_t**, *and the signed and unsigned integer types are collectively called integral types.*[43)] *A synonym for integral type is integer type.*

3.9.1p7

In C the type **_Bool** is an unsigned integer type and `wchar_t` is compatible with some integer type. In C++ they are distinct types (in overload resolution a **bool** or **wchar_t** will not match against their implementation-defined integer type, but against any definition that uses these named types in its parameter list).

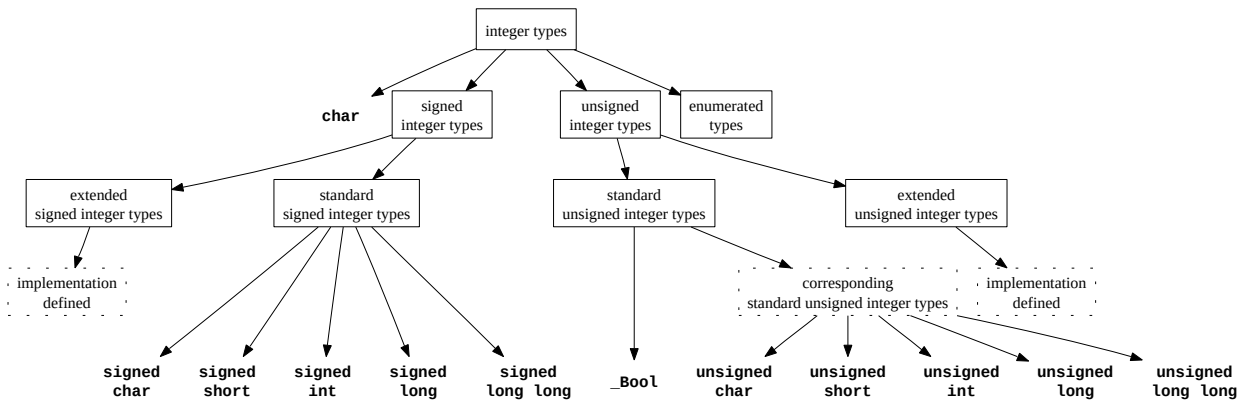

Figure 519.1: The integer types.

standard integer types 493

In C++ the enumerated types are not integer types; they are a compound type, although they may be converted to some integer type in some contexts.

Other Languages

Many other languages also group the character, integer, boolean, and enumerated types into a single classification. Other terms used include *discrete types* and *ordinal types*.

Coding Guidelines

Both of the terms *integer types* and *integral types* are used by developers. Character and enumerated types are not always associated, in developers' minds with this type category.

Table 519.1: Occurrence of integer types in various declaration contexts (as a percentage of those all integer types appearing in all of these contexts). Based on the translated form of this book's benchmark programs.

Type	Block Scope	Parameter	File Scope	`typedef`	Member	Total
`char`	1.8	0.4	0.1	0.0	0.7	3.1
`signed char`	0.0	0.0	0.0	0.0	0.0	0.1
`unsigned char`	2.0	1.2	0.0	0.1	4.6	7.9
`short`	0.7	0.3	0.0	0.0	0.4	1.4
`unsigned short`	2.3	0.8	0.1	0.1	3.2	6.5

---

real types

The integer and real floating types are collectively called *real types*. 520

Commentary

This defines the term *real types*.

C90

C90 did not include support for complex types and this definition is new in C99.

C++

The C++ Standard follows the C90 Standard in its definition of integer and floating types.

Coding Guidelines

This terminology is not commonly used outside of the C Standard. Are there likely to be any guideline recommendations that will apply to real types but not arithmetic types? If there are, then writers of coding guideline documents need to be careful in their use of terminology.

---

arithmetic type

Integer and floating types are collectively called *arithmetic types*. 521

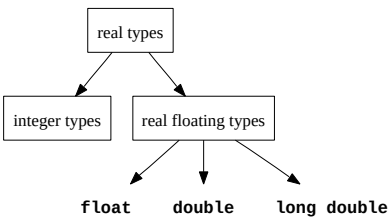

Figure 520.1: The real types.

Commentary

This defines the term *arithmetic types*, so-called because they can appear as operands to the binary operators normally thought of as arithmetic operators.

C90

Exactly the same wording appeared in the C90 Standard. Its meaning has changed in C99 because the introduction of complex types has changed the definition of the term floating types.

497 floating types
three re

C++

The wording in 3.9.1p8 is similar (although the C++ complex type is not a basic type).
The meaning is different for the same reason given for C90.

Coding Guidelines

It is important to remember that pointer arithmetic in C is generally more commonly used than arithmetic on operands with floating-point types (see Table 1154.1, and Table 985.1). There may be coding guidelines specific to integer types, or floating types, however, the category arithmetic type is not usually sufficiently general. Coding guidelines dealing with expressions need to deal with the general, type independent cases first, then the scalar type cases, and finally the more type specific cases.

544 scalar types

Writers of coding guideline documents need to be careful in their use of terminology here. C90 is likely to be continued to be used for several years and its definition of this term does not include the complex types.

---

522 Each arithmetic type belongs to one *type domain*: the *real type domain* comprises the real types, the *complex type domain* comprises the complex types.

type domain

Commentary

This defines the terms *real type domain* and *complex type domain*. The concept of type domain comes from the mathematics of complex variables. Annex G describes the properties of the *imaginary type domain*. An implementation is not required to support this type domain. Many operations and functions return similar results in both the real and complex domains; for instance:

$$finite / ComplexInf \Rightarrow ComplexZero \tag{522.1}$$
$$finite * ComplexInf \Rightarrow ComplexInf \tag{522.2}$$

However, some operations and functions may behave differently in each domain; for instance:

$$\exp(Inf) \Rightarrow Inf \tag{522.3}$$
$$\exp(-Inf) \Rightarrow 0.0 \tag{522.4}$$
$$\exp(ComplexInf) \Rightarrow ComplexNaN \tag{522.5}$$

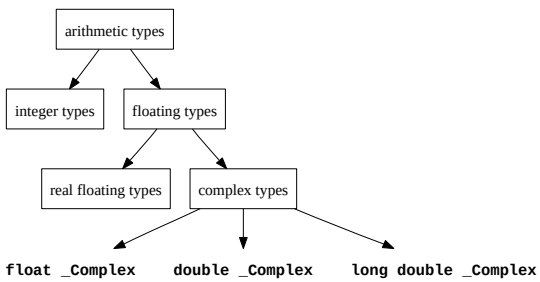

Figure 521.1: The arithmetic types.

Both Inf and $-Inf$ can be viewed as the complex infinity under the Riemann sphere, making the result with an argument of complex infinity nonunique (it depends on the direction of approach to the infinity).

C90

Support for complex types and the concept of type domain is new in C99.

C++

In C++ `complex` is a class defined in one of the standard headers. It is treated like any other class. There is no concept of type domain in the C++ Standard.

Other Languages

While other languages containing a built-in complex type may not use this terminology, developers are likely to use it (because of its mathematical usage).

Coding Guidelines

Developers using complex types are likely to be familiar with the concept of *domain* from their mathematical education.

---

void is incomplete type

The **`void`** type comprises an empty set of values; 523

Commentary

Because types are defined in terms of values they can represent and operations that can be performed on them, the standard has to say what the **`void`** type can represent.

The **`void`** keyword plays many roles. It is the placeholder used to specify that a function returns no value, or that a function takes no parameters. It provides a means of explicitly throwing a value away (using a cast). It can also be used, in association with pointers, as a method of specifying that no information is known about the pointed-to object (pointer to a so-called *opaque* type).

operator () 1000

The use of **`void`** in function return types and parameter definitions was made necessary because nothing appearing in these contexts had an implicit meaning— function returning **`int`** (not supported in C99) and function taking unknown parameters, respectively.

C90

base document 1

The **`void`** type was introduced by the C90 Committee. It was not defined by the base document.

Other Languages

The keyword **`void`** is unique to C (and C++). Some other languages fill the role it plays (primarily in the creation of a generic pointer type) by specifying that no keyword appear. CHILL defines a different keyword, **`PTR`**, for use in this pointer role. Other languages that support a generic pointer type, or have special rules for handling pointers for recursive data structures use concepts that are similar to those that apply to the void type.

Coding Guidelines

generic pointer

The **`void`** type can be used to create an anonymous pointer type or a generic pointer type. The difference between these is intent. In one case there is the desire to hide information and in the other a desire to be able to accept any pointer type in a given context. It can be very difficult, when looking at source code, to tell the difference between these two uses.

coupling 1810

Restricting access to implementation details (through information-hiding) is one way of reducing low-level coupling between different parts of a program. The authors of library functions (either third-party or project-specific) may want to offer a generalized interface to maximize the likelihood of meeting their users' needs without having to provide a different function for every type. Where the calling source code is known, is the use of pointers to **`void`** a lazy approach to passing information around or is it good design practice for future expansion? These issues are higher-level design issues that are outside of the scope of this book.

Usage

Information on keyword usage is given elsewhere (see Table 539.1, Table 758.1, Table 788.1, Table 1003.1, Table 1005.1, and Table 1134.1).

524 it is an incomplete type that cannot be completed.

Commentary

The concept of an incomplete type was not defined in the base document, it was introduced in C90. 1 base document

Defining **void** to be an incomplete type removes the need for lots of special case wording in the standard. A developer defining an object to have the **void** type makes no sense (there are situations where it is of use to the implementation). But because it is an incomplete type, the wording that disallows objects having an incomplete type comes into play; there is no need to introduce extra wording to disallow objects being declared to have the **void** type. Being able to complete the **void** type would destroy the purpose of defining it to be incomplete in the first place. 1818 external linkage exactly one external definition

525 Any number of *derived types* can be constructed from the object, function, and incomplete types, as follows: derived type

Commentary

This defines the term *derived types*. The rules for deciding whether two derived types are compatible are discussed in the clauses for those types.

The translation limits clause places a minimum implementation limit on the complexity of a type and the number of external and block scope identifiers. However, there is no explicit limit on the number of types in a translation unit. Anonymous structure and union declarations, which don't declare any identifiers, in theory consume no memory; a translator can free up all the storage associated with them (but such issues are outside the scope of the standard). 276 translation limits 279 limit type complexity

C++

C++ has derived classes, but it does not define derived types as such. The term *compound types* fills a similar role:

3.9.2p1

> *Compound types can be constructed in the following ways:*

Other Languages

Most languages allow some form of derived types to be built from the basic types predefined by the language. Not all languages support the range of possibilities available in C, while some languages define kinds of derived types not available in C— for instance, sets, tuples, and lists (as built-in types).

Common Implementations

The number of derived types is usually limited by the amount of storage available to the translator. In most cases this is likely to be large.

Coding Guidelines

The term *derived type* is not commonly used by developers. It only tends to crop up in technical discussions involving the C Standard by the Committee.

Derived types are not necessary for the implementation of any application; in theory, an integer type is sufficient. What derived types provide is a mechanism for more directly representing both how an application domain organizes its data and the data structures implied by algorithms (e.g., a linked list) used in implementing an application. Which derived types to define is usually a high-level design issue and is outside the scope of this book. Here we limit ourselves to pointing out constructions that have been known to cause problems in the past.

Table 525.1: Occurrence of derived types in various declaration contexts (as a percentage of all derived types appearing in all of these contexts, e.g., `int **ap[2]` is counted as two pointer types and one array type). Based on the translated form of this book's benchmark programs.

Type	Block Scope	Parameter	File Scope	`typedef`	Member	Total
`*`	30.4	37.6	3.1	0.8	5.6	77.5
array	3.3	0.0	4.4	0.0	3.0	10.8
`struct`	3.7	0.1	2.4	2.3	2.6	11.2
`union`	0.2	0.0	0.0	0.1	0.2	0.5

array type
array
contiguously allocated set of objects

— An *array type* describes a contiguously allocated nonempty set of objects with a particular member object type, called the *element type*.[36)] 526

Commentary

This defines the terms *array type* and *element type*.

Although array types can appear in declarations, they do not often appear as the types of operands. This is because an occurrence, in an expression context, of an object declared to have an array type is often converted into a pointer to its first element. Because of this conversion, arrays in C are often said to be second-class citizens (types). Note that the element type cannot be an incomplete or function type. The standard also specifies a lot of implementation details on how arrays are laid out in storage.

additive 1165
operators
pointer to object

array 994
row-major
storage order

Other Languages

Nearly every language in existence has arrays in one form or another. Many languages treat arrays as having the properties listed here. A few languages simply treat them as a way of denoting a list of locations that may hold values (e.g., Awk and Perl allow the index expression to be a string); it is possible for each element to have a different type and the number of elements to change during program execution. A few languages restrict the element type to an arithmetic type— for instance, Fortran (prior to Fortran 90). The Java reference model does not require that array elements be contiguously allocated. In the case of multidimensional arrays there are implementation advantages to keeping each slice separate (in a garbage collected storage environment it keeps storage allocation requests small).

Coding Guidelines

array type
when to use

The decision to use an array type rather than a structure type is usually based on answers to the following questions:

- Is more than one element of the same type needed?
- Are the individual elements anonymous?
- Do all the elements represent the same applications-domain concept?
- Will individual elements be accessed as a sequence (e.g., indexed with a loop-control variable).

If the individual elements are not anonymous, they might better be represented as a structure type containing two members, for instance, the x and y coordinates of a location. The names of the members also provide a useful aid to remembering what is being represented. In those cases where array elements are used to denote different kinds of information, macros can be used to hide the implementation details. In the following an array holds color and height information. Using macros removes the need to remember which element of the array holds which kind of information. Using enumeration constants is another technique, but it requires the developer to remember that the information is held in an array (and also requires a greater number of modifications if the underlying representation changes):

```
1  #define COLOR(x) (x[0])
2  #define HEIGHT(x) (x[1])
3
4  enum {i_color, i_height};
5
6  extern int abc_info[2];
7
8  void f(void)
9  {
10 int cur_color = COLOR(abc_info);
11 int this_color = abc_info[i_color];
12 }
```

Array types are sometimes the type of choice when sharing data between different platforms (that may use different processors) or between applications written in different languages. The relative position of each element is known, making it easy to code access mechanisms to.

---

527 Array types are characterized by their element type and by the number of elements in the array.

Commentary

This, along with the fact that the first element is indexed from zero, is the complete set of information needed to describe an array type.

989 array subscript identical to

C++

The two uses of the word *characterized* in the C++ Standard do not apply to array types. There is no other similar term applied to array types (8.3.4) in the C++ Standard.

Other Languages

Languages in the Pascal family require developers to specify the lower bound of an array type; it is not implicitly zero. Also the type used to index the array is part of the array type information; the index, in an array access, must have the same type as that given in the array declaration.

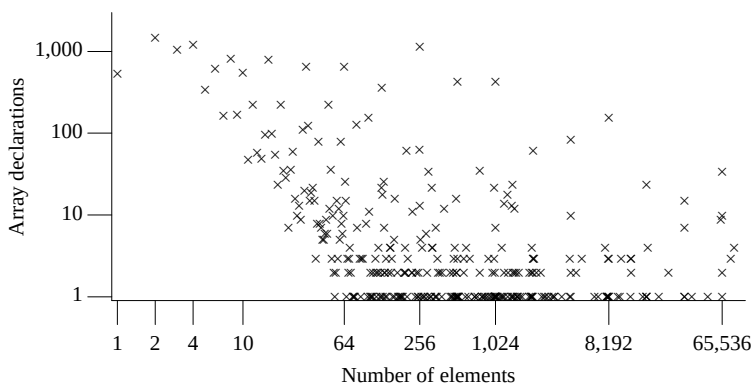

Figure 527.1: Number of arrays defined to have a given number of elements. Based on the translated form of this book's benchmark programs.

Table 527.1: Occurrence of arrays declared to have the given element type (as a percentage of all objects declared to have an array type). Based on the translated form of this book's benchmark programs.

Element Type	%	Element Type	%
`char`	17.2	`struct *`	3.7
`struct`	16.6	`unsigned int`	2.7
`float`	14.6	`enum`	2.5
other-types	10.4	`unsigned short`	2.0
`int`	8.5	`float []`	1.9
`const char`	8.0	`const char * const`	1.3
`char *`	5.1	`short`	1.1
`unsigned char`	4.4		

An array type is said to be derived from its element type, and if its element type is *T*, the array type is sometimes called "array of *T*". 528

Commentary

The term *array of T* is the terminology commonly used by developers and is almost universally used in all programming languages.

C++

This usage of the term *derived from* is not applied to types in C++; only to classes. The C++ Standard does not define the term *array of T*. However, the usage implies this meaning and there is also the reference:

3.9p7 *("array of unknown bound of T" and "array of N T")*

The construction of an array type from an element type is called "array type derivation". 529

Commentary

The term *array type derivation* is used a lot in the standard to formalize the process of type creation. It is rarely heard in noncompiler writer discussions.

C++

This kind of terminology is not defined in the C++ Standard.

Other Languages

Different languages use different forms of words to describe the type creation process.

Coding Guidelines

This terminology is not commonly used outside of the C Standard, and there is rarely any need for its use.

structure type sequentially allocated objects

— A *structure type* describes a sequentially allocated nonempty set of member objects (and, in certain circumstances, an incomplete array), each of which has an optionally specified name and possibly distinct type. 530

Commentary

This defines the term *structure type*. Structures differ from arrays in that their members

- are sequentially allocated, not contiguously allocated (there may be holes, unused storage, between them);
- may have a name;
- are not required to have the same type.

member 1422 address increasing

There are two ways of implementing sequential allocation; wording elsewhere reduces this to one.

C90

Support for a member having an incomplete array type is new in C99.

C++

C++ does not have structure types, it has class types. The keywords **struct** and **class** may both be used to define a class (and *plain old data* structure and union types). The keyword **struct** is supported by C++ for backwards compatibility with C.

Nonstatic data members of a (non-union) class declared without an intervening `access-specifier` *are allocated so that later members have higher addresses within a class object.* 9.2p12

C does not support static data members in a structure, or access-specifiers.

— classes containing a sequence of objects of various types (clause 9), a set of types, enumerations and functions for manipulating these objects (9.3), and a set of restrictions on the access to these entities (clause 11); 3.9.2p1

Support for a member having an incomplete array type is new in C99 and not is supported in C++.

In such cases, and except for the declaration of an unnamed bit-field (9.6), the `decl-specifier-seq` *shall introduce one or more names into the program, or shall redeclare a name introduced by a previous declaration.* 7p3

The only members that can have their names omitted in C are bit-fields. Thus, taken together the above covers the requirements specified in the C90 Standard.

Other Languages

Some languages (e.g., Ada and CHILL) contain syntax which allows developers to specify the layout of members in storage (including having relative addresses that differ from their relative textual positions). Languages in the Pascal family say nothing about field ordering. Although most implementations of these languages allocate storage for fields in the order in which they were declared, some optimizers do reorder fields to optimize (either performance, or amount of generated machine code) access to them. Java says nothing about how members are laid out in a class (C structure).

Common Implementations

Some implementations provide constructs that give the developer some control over how members within a structure are laid out. The **#pack** preprocessing directive is a common extension. For example, it may simply indicate that padding between members is to be minimized, or it may take additional tokens to specify the alignments to use. While use of such extensions does not usually affect the type of a structure, developers have to take care that the same types in different translation units are associated with equivalent **#pack** preprocessing directives.

Coding Guidelines

C specifies some of the requirements on the layout of members within a structure, but not all. Possible faults arise when developers make assumptions about member layout which are not guaranteed by the standard (but happen to be followed by the particular implementation they are using). Use of layout information can also increase the effort needed to comprehend source code by increasing the amount of information that needs to be considered during the comprehension process.

Member layout is part of the representation of a structure type and the applicable guideline is the one recommending that no use be made of representation information. In practice developers use representation information to access members in an array-like fashion, and to treat the same area of storage as having different types. 569.1 representation information using

The reason for defining a member as being part of a larger whole rather than an independent object is that it has some form of association with the other members of a structure type. This association may be

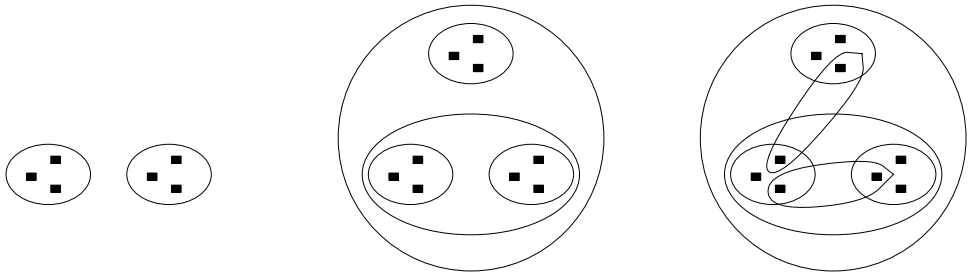

Figure 530.1: Three examples of possible member clusterings. In (a) there are two independent groupings, (b) shows a hierarchy of groupings, while in (c) it is not possible to define two C structure types that share a subset of common member (some other languages do support this functionality). The member c, for instance, might be implemented as a pointer to the value, or it may simply be duplicated in two structure types.

derived from the organization of the application domain, the internal organization of the algorithms used to implement the program, or lower-level implementation details (i.e., if several objects are frequently passed as parameters, or manipulated together the source code can be simplified by passing a single parameter or writing specific functions for manipulating these members). Deciding which structure type (category) a member belongs in is more complicated than the enumeration constant case. Structure types need not be composed of a simple list of members, they can contain instances of other structure types. It is possible to organize structure types into a hierarchy. Organizing the members of structure types is a categorization problem.

categorization 0
enumeration 517
set of named constants
categorization 0

Reorganizing existing structure type declarations to move common member subsets into a new structure definition can be costly (e.g., lots of editing of existing source to change referencing expressions). Your author's experience is that such reorganizations are rarely undertaken. The following are some of the issues that need to be considered in deciding which structure type a member belongs in:

- Is it more important to select a type based on the organization of the application's domain, on the existing internal organization of the source code, or on the expected future organization of the application domain or source code?
- Increasing the nesting of structure definitions will increase the complexity of expressions needed to access some members (an extra selection operator and member name). How much additional cognitive effort is needed to read and comprehend a longer expression containing more member names? This issue is discussed elsewhere.

member selection 1031

- Should the number of members be limited to what is visible on a single screen or printed page? Such a limit implies that the members are somehow related, other than being in the same definition, and that developers would need to refer to different parts of the definition at the same time. If different parts of a definition do need to be viewed at the same time, then comments and blank lines need to be taken into account. It is the number of lines occupied by the definition, not the number of members, that becomes important. The issues involved in laying out definitions are discussed elsewhere. A subset of members sharing an attribute that other members do not have might be candidates for putting in another structure definition.

declaration syntax 1348

- Does it belong to a common subset of members sharing the same attributes and types occurring within two or more structure types? Creating a common type that can be referenced, rather than duplicating members in each structure type, removes the possibility that a change to one of the common members will not be reflected in every type.

Usage

Usage information on the number of members in structure and union types and their types is given elsewhere.

limit 297
members in struct/union
struct 1403
member type

531 — A *union type* describes an overlapping nonempty set of member objects, each of which has an optionally specified name and possibly distinct type.

union type
overlapping
members

Commentary

This defines the term *union type*. The members of a union differ from a structure in that they all share the same start address; they overlap in storage. Unions are often used to interpret a storage location in different ways. There are a variety of reasons for wanting to do this, including the next two:

1207 pointer to union members compare equal

- Reducing the number of different objects and functions needed for accessing information in different parts of a program; for instance, it may be necessary to operate on objects having structure types that differ in only a few members. If three different types are defined, it is necessary to define three functions, each using a different parameter type:

```
struct S1 {
           int m1;
           float m2;
           long d1[3];
          };
struct S2 {
           int m1;
           float m2;
           char d2[4];
          };
struct S3 {
           int m1;
           float m2;
           long double d3;
          };

extern void f1(struct S1 *);
extern void f2(struct S2 *);
extern void f3(struct S3 *);
```

If objects operating on these three types had sufficient commonality, it could be worthwhile to define a single type and to reduce the three function definitions to a single, slightly more complicated (it has to work out which member of the union type is currently active) function:

```
struct S4 {
          int m1;
          float m2;
          union {
                long d1[3];
                char d2[4];
                long double d3;
                } m3;
          };

extern void f(struct S4 *);
```

The preceding example relies on the code knowing which union member applies in a given context. A more flexible approach is to use a member to denote the active member of the union:

```
struct node {
            enum {LEAF, UNARY, BINARY, TERNARY} type;
            struct node *left,
                        *right;
            union {
                   struct {
                          char *ident;
```

```
                        } leaf;
                struct {
                        enum {UNARYPLUS, UNARYMINUS} op;
                        struct node *operand;
                        } unary;
                struct {
                        enum {PLUS, MINUS, TIMES, DIVIDE} op;
                        struct node *left,
                                    *right;
                        } binary;
                struct {
                        struct node *test;
                        struct node *iftrue;
                        struct node *iffalse;
                        } ternary;
                } operands;
        };
```

- Another usage is the creation of a visible type punning interface:

```
union {
      int m1; /* Assume int is 24 bits. */
      struct {
              char c1; /* Assumes char is 8 bits and similarly aligned. */
              char c2;
              char c3;
             } m2;
      } x;
```

Here the three bytes of an object, having type **int**, may be manipulated by referencing `c1`, `c2`, and `c3`. The same effect could have been achieved by using pointer arithmetic. In both cases the developer is making use of implementation details, which may vary considerably between implementations.

C++

9.5p1 *Each data member is allocated as if it were the sole member of a struct.*

This implies that the members overlap in storage.

3.9.2p1 *— unions, which are classes capable of containing objects of different types at different times, 9.5;*

7p3 *In such cases, and except for the declaration of an unnamed bit-field (9.6), the* `decl-specifier-seq` *shall introduce one or more names into the program, or shall redeclare a name introduced by a previous declaration.*

The only members that can have their names omitted in C are bit-fields. Thus, taken together the preceding covers the requirements specified in the C Standard.

Other Languages

Pascal does not have an explicit **union** type. However, it does support something known as a *variant record*, which can only occur within a **record** (**struct**) definition. These variant records provide similar, but more limited, functionality (only one variant record can be defined in any record, and it must occur as the last field).

Java's type safety system would be broken if it supported the functionality provided by the C union type and it does not support this form of construct (although the Java library does contain some functions

for converting values of some types, to and from their bit representation— e.g., `floatToIntBits` and `intBitsToFloat`).

The Fortran **EQUIVALENCE** statement specifies that a pair of identifiers share storage. It is possible to equivalence a variable having a scalar type with a particular array element of another object, and even for one array's storage to start somewhere within the storage of a differently named array. This is more flexible than C, which requires that all objects start at the same storage location.

Algol 68 required implementations to track the last member assigned to during program execution. It was possible for the program to do a runtime test, using something called a conformity clause, to find out the member last assigned to.

Coding Guidelines

Union types are created for several reasons, including the following:

- Reduce the number of closely related functions by having one defined with a parameter whose union type includes all of the types used by the corresponding, related functions.
- Access the same storage locations using different types (often to access individual bytes).
- Reduce storage usage by overlaying objects having different types whose access usage is mutually exclusive in the shared storage locations.

Merging closely related functions into a single function reduces the possibility that their functionality will diverge. The extent to which this benefit exceeds the cost of the increase in complexity (and hence maintenance costs) of the single function can only be judged by the developer.

type punning union

Accessing the same storage locations using different types depends on undefined and implementation-defined behaviors. The standard only defines the behavior if the member being read from is the same member that was last written to. Performing such operations is often unconditionally recommended against in coding guideline documents. However, use of a union type is just one of the ways of carrying out type punning. In this case the recommendation is not about the use of union types; it is either about making use of undefined and implementation-defined behaviors, or the use of type punning. (The guideline recommendation on the use of representation information is applicable here.)

589 union member when written to

569.1 representation information using

If developers do, for whatever reason, want to make use of type punning, is the use of a union type better than the alternatives (usually casting pointers)? When a union type is used, it is usually easy to see which different types are involved by looking at the definitions. When pointers are used, it is usually much harder to obtain a complete list of the types involved (all values, and the casts involved, assigned to the pointer object need to be traced). Union types would appear to make the analysis of the code much easier than if pointer types are used.

Using union types to reduce storage usage by overlaying objects having different types is a variation of using the same object to represent different semantic values. The same guideline recommendations are applicable in both cases.

1352 declaration interpretation of identifier

A union type containing two members that have compatible type might be regarded as suspicious. However, the types used in the definition of the members may be typedef names (one of whose purposes is to hide details of the underlying type). Instances of a union type containing two or more members having a compatible type, where neither is a typedef name, are not sufficiently common to warrant a guideline.

Example

```
1  union U_1 {
2              int m_1;
3              int m_2;
4             };
5
6  typedef int APPLES;
```

```
7   typedef int ORANGES;
8
9   union U_2 {
10             APPLES a_count;
11             ORANGES o_count;
12            };
13
14  union U_3 {
15             float f1;
16             unsigned char f_bytes[sizeof(float)];
17            };
```

Commentary

function 1821 definition syntax
This defines the term *function type*. A function type is created either by a function definition, the definition of an object or typedef name having type pointer-to function type, or a function declarator. function 1592 declarator return type

According to this definition, the parameters are not part of a function's type. The type checking of the arguments in a function call, against the corresponding declaration, are listed as specific requirements under the function call operator rather than within the discussion on types. However, the following sentence includes parameters as part of the characterization of a function type. function call 997

C++

3.9.2p1 — *functions, which have parameters of given types and return* ***void*** *or references or objects of a given type, 8.3.5;*

The parameters, in C++, need to be part of a function's type because they may be needed for overload resolution. This difference is not significant to developers using C because it does not support overloaded functions.

Other Languages

Functions, as types, are not common in other algorithmic languages. Although nearly every language supports a construct similar to C functions, and may even call them function (or procedure) types, it is not always possible to declare objects to refer to these types (like C supports pointers to functions). Some languages do allow references to function types to be passed as arguments in function calls (this usage invariable requires some form of prototype definition). Then the called function is able to call the function referred to by the corresponding parameter. In functional languages, function types are an integral part of the design of the language type system. A Java method could be viewed as a function type.

A function type is characterized by its return type and the number and types of its parameters. 533

Commentary

function 1522 specifier syntax
The **inline** function specifier is not part of the type.

C++

C++ defines and uses the concept of function *signature* (1.3.10), which represents information amount the number and type of a function's parameters (not its return type). The two occurrences of the word *characterizes* in the C++ Standard are not related to functions.

Usage

Usage information on function return types is given elsewhere (see Table 1005.1) as is information on parameters (see Table 1831.1).

534 A function type is said to be derived from its return type, and if its return type is *T*, the function type is sometimes called "function returning *T*".

function returning T

Commentary

The term *function returning T* is a commonly used term. The term *function taking parameters* is heard, but not as often.

C++

The term *function returning T* appears in the C++ Standard in several places; however, it is never formally defined.

Other Languages

Different languages use a variety of terms to describe this kind of construct.

535 The construction of a function type from a return type is called "function type derivation".

Commentary

This terminology may appear in the standard, but it is very rarely heard in discussions.

C++

There is no such definition in the C++ Standard.

536 35) **CHAR_MIN**, defined in **<limits.h>**, will have one of the values 0 or **SCHAR_MIN**, and this can be used to distinguish the two options.

footnote 35

Commentary

Similarly, CHAR_MAX will have one of two values that could be used to distinguish the two options.

312 CHAR_MAX
326 char
if treated as signed integer

C++

The C++ Standard includes the C90 library by reference. By implication, the preceding is also true in C++.

Example

```
#include <limits.h>

#if CHAR_MIN == 0
/* ... */
#elif CHAR_MIN == SCHAR_MIN
/* ... */
#else
#error Broken implementation
#endif
```

537 Irrespective of the choice made, **char** is a separate type from the other two and is not compatible with either.

char separate type

Commentary

This sentence calls out a special case of the general rule that any two basic types are different. In most cases, **char** not being compatible with its *matching* type is not noticeable (an implicit conversion is performed). However, while objects having different character types may be assigned to each other, a pointer-to **char** and a pointer to any other character type may not.

508 types different
even if same representation

C++

3.9.1p1

Plain **char**, **signed char**, *and* **unsigned char** *are three distinct types.*

Common Implementations

Some implementations have been known to not always honor this requirement, treating **char** and its *matching* character type as if they were the same type.

Coding Guidelines

A common developer expectation is that the type **char** will be treated as either of the types **signed char**, or an **unsigned char**. It is not always appreciated that the types are different. Apart from the occasional surprise, this incorrect assumption does not appear to have any undesirable consequences.

Example

```
1  char p_c,
2       *p_p_c = &p_c;
3  signed char s_c,
4              *p_s_c = &s_c;
5  unsigned char u_c,
6                *p_u_c = &u_c;
7
8  void f(void)
9  {
10 p_c = s_c;
11 p_c = u_c;
12
13 p_p_c = p_s_c;
14 p_p_c = p_u_c;
15 }
```

---

footnote 36

36) Since object types do not include incomplete types, an array of incomplete type cannot be constructed. 538

Commentary

Object types do not include function types either. But they do include pointer-to function types.

C++

3.9p6 *Incompletely-defined object types and the void types are incomplete types (3.9.1).*

object types 475 The C++ Standard makes a distinction between incompletely-defined object types and the **void** type.

3.9p7 *The declared type of an array object might be an array of incomplete class type and therefore incomplete; if the class type is completed later on in the translation unit, the array type becomes complete; the array type at those two points is the same type.*

The following deals with the case where the size of an array may be omitted in a declaration:

8.3.4p3 *When several "array of" specifications are adjacent, a multidimensional array is created; the constant expressions that specify the bounds of the arrays can be omitted only for the first member of the sequence.*

Arrays of incomplete structure and union types are permitted in C++.

```
{
struct st;
typedef struct st_0 A[4]; /* Undefined behavior */
                          // May be well- or ill-formed
typedef struct st_1 B[4]; /* Undefined behavior */
                          // May be well- or ill-formed
struct st_0 {             /* nothing has changed */
              int mem;    // declaration of A becomes well-formed
             };
}                         /* nothing has changed */
                          // declaration of B is now known to be ill-formed
```

Other Languages

Most languages require that the size of the element type of the array be known at the point the array type is declared.

---

539 — A *pointer type* may be derived from a function type, an object type, or an incomplete type, called the *referenced type*.

pointer type
referenced type

Commentary

This defines the terms *pointer type* (a term commonly used by developers) and *referenced type* (a term not commonly used by C developers). Pointers in C have maximal flexibility. They can point at any kind of type (developers commonly use the term *point at*).

C++

C++ includes support for what it calls *reference* types (8.3.2), so it is unlikely to use the term *referenced type* in this context (it occurs twice in the standard). There are requirements in the C++ Standard (5.3.1p1) that apply to pointers to object and function types, but there is no explicit discussion of how they might be created.

Other Languages

Some languages do not include pointer types. They were added to Fortran in its 1991 revision. They are not available in Cobol. Some languages do not allow pointers to refer to function types, even when the language supports some form of function types (e.g., Pascal). Java does not have pointers, it has references.

Coding Guidelines

Use of objects having pointer types is often considered to be the root cause of many faults in programs written in C. Some coding guideline documents used in safety-critical application development prohibit the use of pointers completely, or severely restrict the operations that may be performed on them. Such prohibitions are not only very difficult to enforce in practice, but there is no evidence to suggest that the use of alternative constructs reduces the number of faults.

String literals have type pointer to **char**; an array passed as an argument will be converted to a pointer to its element type, and without the ability to declare parameters having a pointer type, significantly more information has to be passed via file scope objects (pointers are needed to implement the parameter-passing concept of call-by address).

903 string literal
static storage duration

Table 539.1: Occurrence of objects declared using a given pointer type (as a percentage of all objects declared to have a pointer type). Based on the translated form of this book's benchmark programs.

Pointed-to Type	%	Pointed-to Type	%
`struct`	66.5	`struct *`	1.8
`char`	8.0	`int`	1.8
`union`	6.0	`const char`	1.3
other-types	5.5	`char *`	1.2
`void`	3.3	str | str	
`unsigned char`	2.6	`_double` | `_double`	
`unsigned int`	2.2	`_double` | `_double`	

pointer type describes a

A pointer type describes an object whose value provides a reference to an entity of the referenced type. 540

Commentary

The value in a pointer object is a reference. Possible implementations of a reference include an address in storage, or an index into an array that gives the actual address. In C the value of a pointer object is rarely called a *reference*. The most commonly used terminology is *address*, which is what a pointer value is on most implementations. Sometimes the term *pointed-to object* is used.

Other Languages

Other languages use a variety of terms to refer to the value stored in an object having pointer type. Java uses the term *reference* exclusively; it does not use the term *pointer* at all. The implementation details behind a Java reference are completely hidden from the developer.

Common Implementations

pointer 590 segmented architecture

Nearly every implementation known to your author represents a reference using the address of the referenced object only (in some cases the address may not be represented as using a single value). Some implementations use a, so-called, *fat pointer* representation.[65, 1288] These implementations are usually intended for use during program development, where information on out-of-bounds storage accesses is more important than speed of execution. A fat pointer includes information on the pointed-to object such as its base address and the number of bytes in the object.

In the Model Implementation C Checker[681] a function address is implemented as two numbers. One is an index into a table specifying the file containing the translated function definition and the other is an index into a table specifying the offset of the executable code within that file. The IBM AIX compiler[618] also uses a function descriptor, not the address of the generated code.

The Java virtual machine does not include the concept of pointer (or address). It includes the concept of a reference; nothing is said about how such an entity is implemented. A C translator targeted at this host would have to store a JVM reference in an object having pointer type.

Some processors differentiate between different kinds of main storage. Access to different kinds of storage are faster/slower, or accesses to particular storage areas may only be made via particular registers. Translators for such processors usually provide keywords, enabling developers to specify which kinds of storage pointers will be pointing at.

Some implementations use different pointer representations (they usually vary in the number of bytes used), depending on how the pointer is declared. For instance, the keywords **`near`**, **`far`**, and **`huge`** are sometimes provided to allow developers to specify the kind of representation to use.

The HP C/iX translator[1039] supports a short pointer (32-bit) and long pointer (64-bit). A long pointer has two halves, 32 bits denoting a process-id and 32 bits denoting the offset within that process address space. The Unisys A Series implementation[1390] represents pointers as integer values. A pointer to **`char`** is the number of bytes from the start of addressable storage (for that process), not the logical address of the storage location. A pointer to the types **`int`** and **`float`** is the number of words (6 bytes) from the start of storage (the unit of measurement for other types is the storage alignment used for the type).

Zhang and Gupta[1511] developed what they called the *common prefix* transformation, which compresses a 32-bit pointer into 15 bits (this is discussed elsewhere). There has been some research[1311] investigating the use of Gray codes, rather than binary, to represent addresses. Successive values in a Gray code differ from each other in a single bit. This property can have advantages in high-performance, or low-power (electrical) situations when sequencing through a series of storage locations.

1422 pointer compressing members

---

541 A pointer type derived from the referenced type *T* is sometimes called "pointer to *T*".

Commentary

The term *pointer to T* is commonly used by developers, and is almost universally used for all programming languages.

Other Languages

This term is almost universally used for all languages that contain pointer types.

---

542 The construction of a pointer type from a referenced type is called "pointer type derivation".

Commentary

The term *pointer type derivation* is used a lot in the standard to formalize the process of type creation. It is rarely heard outside of the committee and compiler writer discussions.

C++

The C++ Standard does not define this term, although the term *derived-declarator-type-list* is defined (8.3.1p1).

Other Languages

Different languages use different forms of words to describe the type creation process.

---

543 These methods of constructing derived types can be applied recursively.

Commentary

There are two methods of constructing derived types in the visible source; either a typedef name can be used, or the declaration of the type can contain nested declarations. For instance, an array of array of *type T* might be declared as follows:

```
1  typedef int at[10];
2  at obj_x[5];
3
4  int obj_y[10][5];
```

The standard specifies minimum limits on the number of declarators that an implementation is required to support.

279 limit type complexity

Other Languages

Most languages support more than one level of type derivation. Many languages support an alternative method of declaring multidimensional arrays, where **[ ]** are not treated as an operator. Structure types were added in Fortran 90, and only support a single nesting level.

1577 footnote 121

---

544 Arithmetic types and pointer types are collectively called *scalar types*.

scalar types

Commentary

This defines the term *scalar type*. It is commonly used by developers and it is also used in many other programming languages. The majority of operations in C act on objects and values having a scalar type.

C++

3.9p10 *Arithmetic types (3.9.1), enumeration types, pointer types, and pointer to member types (3.9.2), and* `cv-qualified` *versions of these types (3.9.3) are collectively called scalar types.*

While C++ includes type qualifier in the definition of scalar types, this difference in terminology has no impact on the interpretation of constructs common to both languages.

Other Languages

The term *scalar type* is used in many other languages. Another term that is sometimes heard is *simple type*.

Common Implementations

Many processors only contain instructions that can operate on values having a scalar type. Operations on aggregate types are broken down into operations on their constituent scalar components. Many implementations only perform some optimizations at the level of scalar types (components of derived types having a scalar type are considered for optimization, but the larger whole is not). For instance, the level of granularity used to allocate values to registers is often at the level of scalar types.

Coding Guidelines

Pointer types commonly occur in many of the same contexts as arithmetic types. Having guideline recommendations that apply to both is often a useful generalization and reduces the number of special cases. The following is a meta-guideline recommendation.

Rev 544.1 Where possible coding guidelines shall try to address scalar types, rather than just arithmetic types.

---

aggregate type Array and structure types are collectively called *aggregate types*.[37)] 545

Commentary

This defines the term *aggregate type*. This terminology is often incorrectly used by developers. An aggregate type includes array types but does not include union types.

C++

8.5.1p1 *An aggregate is an array or a class (clause 9) with no user-declared constructors (12.1), no private or protected non-static data members (clause 11), no base classes (clause 10), and no virtual functions (10.3).*

Class types in C++ include union types. The C definition of aggregate does not include union types. The difference is not important because everywhere that the C++ Standard uses the term *aggregate* the C Standard specifies aggregate and union types.

The list of exclusions covers constructs that are in C++, but not C. (It does not include static data members, but they do not occur in C and are ignored during initialization in C++.) There is one place in the C++ Standard (3.10p15) where the wording suggests that the C definition of aggregate is intended.

Coding Guidelines

Although the logic behind the term *aggregate type* is straight-forward, a type made up of more than one object (the array type having one element, or the structure type having one member, is considered to be a degenerate case), is a categorization of types that is rarely thought about by developers. In most developer discussions, array and structure types are not thought of as belonging to a common type category. type category 553

The term *aggregate type* is commonly misused. Many developers assume that it includes the union types in its definition; they are not aware that array types are included in the definition. To avoid confusion, this term is probably best avoided in coding guideline documents.

546 An array type of unknown size is an incomplete type.

array unknown size

Commentary

The size is unknown in the sense that the number of elements is not known. The term *incomplete array type* is often used. Objects with no linkage cannot have an incomplete type.

1573 array incomplete type
1361 object type complete by end

Other Languages

Some languages include the concept of an array having an unknown number of elements. This usually applies only to the type of a parameter in which arrays with different numbers of elements are passed. There is often a, language-provided, mechanism for finding the number of elements in the array actually passed as an argument. In other cases it is the developer's responsibility to pass that information as an argument, along with the array itself. In Java all declarations of objects having an array type omit the number of elements. The actual storage is allocated during program execution using the operator **new**.

547 It is completed, for an identifier of that type, by specifying the size in a later declaration (with internal or external linkage).

array type completed by

Commentary

A typedef name that has an incomplete array type cannot be completed. However, an object definition, whose type specifier is the typedef name, can complete this type for its definition. An initializer appearing as part of the object's definition provides a mechanism for a translator to deduce the size of the array type. The size, actually the number of elements, may also be implicitly specified, if there is no subsequent declaration that completes the type, when the end of the translation unit is reached.

In the case of parameters their type is converted to a pointer to the element type.

1683 array of unknown size initialized
1850 object definition implicit
1598 array type adjust to pointer to

C++

> *The declared type of an array object might be an array of unknown size and therefore be incomplete at one point in a translation unit and complete later on;* 3.9p7

Which does not tell us how it got completed. Later on in the paragraph we are given the example:

```
extern int arr[];   // the type of arr is incomplete

int arr[10];        // now the type of arr is complete
```

3.9p7

which suggests that an array can be completed, in a later declaration, by specifying that it has 10 elements. :-)

Other Languages

Fortran supports the declaration of subroutine parameters taking array types, whose size is not known at translation time. Array arguments are passed by reference, so the translator does not need to know their size. Developers usually pass the number of elements as another parameter to the subroutine.

548 A type has *knownconstantsize* if the type is not incomplete and is not a variable length array type.

known constant size

Commentary

The sentence was added by the response to DR #312 and clarifies that *known constant size* is to be interpreted as a technical term involving types and not the kind of expressions that an implementation may chose to treat as being constants.

822 constant syntax

549 A structure or union type of unknown content (as described in 6.7.2.3) is an incomplete type.

structure incomplete type union incomplete type

Commentary

type 1454 contents defined once

Incomplete structure and union types are needed to support self-recursive and mutually recursive declarations involving more than one such structure or union. These are discussed in subclause 6.7.2.3.

Other Languages

A mechanism for supporting mutual recursion in type definitions is invariably provided in languages that support some form of pointer type. A variety of special rules is used by different languages to allow mutually referring data types to be defined.

Example

```
1  struct U {
2            int M1;
3            struct U *next;
4           };
5
6  struct S;  /* Members defined later. */
7
8  struct T {
9            int m1;
10           struct S *s_m;
11          };
12 struct S { /* S now completed. */
13           long m1;
14           struct T *t_m;
15          };
```

The two mutually referential structure types could not be declared without the original, incomplete declaration of S.

---

incomplete type completed by

It is completed, for all declarations of that type, by declaring the same structure or union tag with its defining content later in the same scope. 550

Commentary

A definition of the same tag name in a different scope is a different definition and does not complete the declaration in the outer scope.

C++

3.9p7 *A class type (such as "`class X`") might be incomplete at one point in a translation unit and complete later on;*

An example later in the same paragraph says:

3.9p7

```
class X;                // X is an incomplete type

struct X { int i; };    // now X is a complete type
```

The following specifies when a class type is completed; however, it does not list any scope requirements.

9.2p2 *A class is considered a completely-defined object type (3.9) (or complete type) at the closing `}` of the `class-specifier`.*

In practice the likelihood of C++ differing from C, in scope requirements on the completion of types, is small and no difference is listed here.

Coding Guidelines

1707 statements integrating information between

Having important references to an identifier close together in the visible source code has a number of benefits. In the case of mutually recursive structure and union types, this implies having the declarations and definitions adjacent to each other.

Rev 550.1 The completing definition, of an incomplete structure or union type, shall occur as close to the incomplete declaration as permitted by the rules of syntax and semantics.

Example

```
1  struct INCOMP_TAG;              /* First type declaration. */
2  struct INCOMP_TAG *gp;          /* References first type declaration. */
3  extern void f(struct INCOMP_TAG /* Different scope. */);
4
5  void g(void)
6  {
7  struct INCOMP_TAG {int mem1;} *lp; /* Different type declaration. */
8
9  lp = gp; /* Not compatible pointers. */
10 }
11
12 void h(void)
13 {
14 struct INCOMP_TAG; /* Different type declaration. */
15 struct INCOMP_TAG *lp;
16
17 lp = gp; /* Not compatible pointers. */
18 }
19
20 struct INCOMP_TAG {
21                     int m_1;
22                    };
```

---

551 Array, function, and pointer types are collectively called *derived declarator types*.

derived declarator types

Commentary

This defines the term *derived declarator types*. This term is used a lot in the standard to formalize the process of type creation. It is rarely heard outside of committee and translator writer discussions.

C++

There is no equivalent term defined in the C++ Standard.

Other Languages

Different languages use different terms to describe the type creation process.

Coding Guidelines

This terminology is not commonly used outside of the C Standard and its unfamiliarity, to developers, means there is little to be gained by using it in coding guideline documents.

---

552 A *declarator type derivation* from a type *T* is the construction of a derived declarator type from *T* by the application of an array-type, a function-type, or a pointer-type derivation to *T*.

Commentary

This defines the term *declarator type derivation*. This term does not appear to be used anywhere in the standard, except the index and an incorrect forward reference.

C++

There is no equivalent definition in the C++ Standard, although the description of compound types (3.9.2) provides a superset of this definition.

---

type category

A type is characterized by its *type category*, which is either the outermost derivation of a derived type (as noted above in the construction of derived types), or the type itself if the type consists of no derived types. 553

Commentary

This defines the term *type category*. Other terms sometimes also used by developers, which are not defined in the standard, are *outermost type* and *top level type*. An object is commonly described as an *array-type*, a *pointer-type*, a *structure-type*, and so on. Without reference to its constituents. But the term *type category* is rarely heard in developer discussions.

The following was included in the response to DR #272:

DR #272

Committee Discussion *(for history only)*

The committee wishes to keep the term "type category" for now, removing the term "type category" from the next revision of the standard should be considered at that time.

C++

The term *outermost level* occurs in a few places in the C++ Standard, but the term *type category* is not defined.

Other Languages

The concept denoted by the term *type category* exists in other languages and a variety of terms are used to denote it.

Coding Guidelines

The term *type category* is not commonly used by developers (it only occurs in five other places in the standard). Given that terms such as *outermost type* are not commonly used either, it would appear that there is rarely any need to refer to the concept denoted by these terms. Given that there is no alternative existing common practice there is no reason not to use the technically correct term; should a guidelines document need to refer to this concept.

---

unqualified type

Any type so far mentioned is an *unqualified type*. 554

Commentary

This defines the term *unqualified type*. An unqualified type is commonly referred to, by developers, as just the *type*, omitting the word unqualified. The suffix qualified is only used in discussions involving type qualifiers, to avoid ambiguity.

C++

In C++ it is possible for the term *type* to mean a qualified or an unqualified type (3.9.3).

Coding Guidelines

It is common practice to use the term *type* to mean the unqualified type. Unqualified types are much more commonly used than qualified types. While the usage of the term *type* might be generally accepted by C developers to mean an unqualified type, this usage is not true in C++. Guidelines that are intended to be applied to both C and C++ code will need to be more precise in their use of terminology than if they were aimed at C code only.

Table 554.1: Occurrence of qualified types as a percentage of all (i.e., qualified and unqualified) occurrences of that kind of type (e.g., * denotes any pointer type, **struct** any structure type, and *array of* an array of some type). Based on the translated form of this book's benchmark programs.

Type Combination	%	Type Combination	%
array of **const**	26.7	**const** *	0.4
const integer-type	4.8	**const union**	0.3
const real-type	2.7	**volatile struct**	0.1
* **const**	2.6	**volatile** integer-type	0.1
const struct	2.4	* **volatile**	0.1

555 Each unqualified type has several *qualified versions* of its type,[38] corresponding to the combinations of one, two, or all three of the **const**, **volatile**, and **restrict** qualifiers. qualified type versions of

Commentary

This defines the term *qualified version* of a type. In the case of structure, and union types, qualifiers also qualify their member types. Type qualifiers provide a means for the developer to provide additional information about the properties of an object. In general these properties relate to issues involved with the optimization of C programs.

C90

The **noalias** qualifier was introduced in later drafts of what was to become C90. However, it was controversial and there was insufficient time available to the Committee to resolve the issues involved. The noalias qualifier was removed from the document, prior to final publication. The **restrict** qualifier has the same objectives as **noalias**, but specifies the details in a different way.

Support for the **restrict** qualifier is new in C99.

C++

Each type which is a cv-unqualified complete or incomplete object type or is **void** *(3.9) has three corresponding cv-qualified versions of its type: a* `const-qualified` *version, a* `volatile-qualified` *version, and a* `const-volatile-qualified` *version.* 3.9.3p1

The **restrict** qualifier was added to C99 while the C++ Standard was being finalized. Support for this keyword is not available in C++.

Other Languages

Pascal uses the **packed** keyword to indicate that the storage occupied by a given type should be minimized (packed, so there are no unused holes). Java has 10 different modifiers; not all of them apply directly to types. Some languages contain a keyword that enables an object to be defined as being read-only.

Common Implementations

The standard provides a set of requirements that an implementation must honor for an object with a given qualified type. The extent to which a particular translator makes additional use of the information provided varies.

Table 555.1: Occurrence of type qualifiers on the outermost type of declarations occurring in various contexts (as a percentage of all type qualifiers on the outermost type in these declarations). Based on the translated form of this book's benchmark programs.

Type Qualifier	Local	Parameter	File Scope	**typedef**	Member	Total
const	18.5	4.3	50.8	0.0	1.2	74.8
volatile	1.6	0.1	3.0	0.1	20.4	25.2

qualifiers representation and alignment

The qualified or unqualified versions of a type are distinct types that belong to the same type category and have the same representation and alignment requirements.[39)] 556

Commentary

Qualifiers apply to objects whose declarations include them. They do not play any part in the interpretation of a value provided by a type, but they participate in the type compatibility rules.

Other Languages

This statement can usually be applied to qualifiers defined in other languages.

Common Implementations

Objects declared using a qualified type may have the same representation and alignment requirements, but there are no requirements specifying where they might be allocated in storage. Some implementations chose to allocate differently qualified objects in different areas of storage. For instance, const-qualified objects may be placed in read-only storage; volatile-qualified objects may be mapped to special areas of storage associated with I/O ports.

derived type qualification

A derived type is not qualified by the qualifiers (if any) of the type from which it is derived. 557

Commentary

For instance, a type denoting a const-qualified **char** does not also result in a pointer to it to also being const-qualified, although the pointed-to type retains its **const** qualifier.

A structure type containing a member having a qualifier type does not result in that type also being so qualified. However, an object declared to have such a structure type will share many of the properties associated with objects having the member's qualified type when treated as a whole. For instance, the presence of a member having a const-qualified type, in a structure type, prevents an object declared using it from appearing as the left operand of an assignment operator. However, the fact that one member has a const-qualified type does not affect the qualification of any other members of the same structure type.

Other Languages

This specification usually applies to other languages that support some form of type qualifiers, or modifiers.

Coding Guidelines

Inexperienced developers sometimes have problems distinguishing between constant pointers to types and pointers to constant types. Even the more experienced developer might be a little confused over the following being conforming:

```
1  void f(int * const a[])
2  {
3  a++; /* Type of a is pointer to constant pointer to int. */
4  }
```

Rev 557.1 Array and pointer types that include a qualifier shall be checked to ensure that the type that is so qualified is the one intended by the original author.

Translators will probably issue a diagnostic for those cases in which a **const** qualifier was added where it was not intended (e.g., because of an attempt to modify a value). However, translators are not required to issue a diagnostic for a **const** qualifier that has been omitted (unless there is a type compatibility associated with the assignment, or argument passing). Some static analysis tools[436,438] diagnose declarations where a **const** qualifier could be added to a type without violating any constraints.

Example

In the following declarations x1 is not a const-qualified structure type. However, one of its members is const-qualified. The member x1.m2 can be modified. y1 is a const-qualified structure type. The member y1.m2 cannot be modified.

```
typedef const int CI;

CI *p;   /* The pointed-to type is qualified, not the pointer. */
CI a[3]; /*
          * a is made up of const ints, it is not
          * possible to qualify the array type.
          */

struct S1 {
            const int m1;
            long m2;
           } x1, x2;

const struct S2 {
                  const int m1;
                  long m2;
                 } y1;

void f(void)
{
x1 = x2; /* Constraint violation. */
}
```

What are the types in:

```
typedef int *I;

I const p1; /* A const qualified pointer to int. */
const I p2; /* A const qualified pointer to int. */
```

---

558 A pointer to **void** shall have the same representation and alignment requirements as a pointer to a character type.[39)]

pointer to void same representation and alignment as

Commentary

This is a requirement on the implementation. In its role as a generic container for any pointer value, a pointer to **void** needs to be capable of holding the *hardest* reference to represent. Experience has shown that, in those cases where different representations are used for pointers to different types, this is usually the pointer to character type.

Prior to the publication of C90, pointers to character types were often used to perform the role that pointer to **void** was designed to fill. That is, they were the pointer type used to represent the concept of pointer to any type, a generic pointer type (through suitable casting, which is not required for pointer to **void**). Existing code that uses pointer to character type as the generic pointer type can coexist with newly written code that uses pointer to **void** for this purpose.

523 generic pointer

Other Languages

Most languages that contain pointer types do not specify a pointer type capable of representing any other pointer type. Although pointer to character type is sometimes used by developers for this purpose.

Coding Guidelines

This C requirement is intended to allow existing code to coexist with newly written code using pointer to **void**. Mixing the two pointer types in newly written code serves no useful purpose. The fact that the two

kinds of pointers have the same representation requirements does not imply that they represent a reference to the same object with the same pattern of bits (any more than two pointers of the same type are required to). The guideline recommendation dealing with the use of representation information is applicable here.

representation information using 569.1

Similarly, pointers to qualified or unqualified versions of compatible types shall have the same representation and alignment requirements. 559

pointer to qualified/unqualified types

Commentary

This is a requirement on the implementation.

The representation and alignment of a type is specified as being independent of any qualifiers that might appear on the type. Since the pointed-to type has these properties, it might be expected that pointers to them would also have these properties.

qualifiers 556 representation and alignment

Common Implementations

This requirement on the implementation rules out execution-time checking of pointer usage by using different representations for pointers to qualified and unqualified types.

banked storage

The C model of storage is of a flat (in the sense of not having any structure to it) expanse into which objects can be allocated. Some processors have disjoint storage areas (or *banks*). They are disjoint in that either different pointer representations are required to access the different areas, or because execution of a special instruction causes subsequent accesses to reference a different storage area. The kind of storage referred to by a pointer value, may be part of the encoding of that value, or the processor may have state information that indicates which kind of storage is currently the default to be accessed, or the kind of storage to access may be encoded in the instruction that performs the access.

The IAR PICmicro compiler[612] provides access to more than 10 different kinds of banked storage. Pointers to this storage can be 1, 2, or 3 bytes in size.

Coding Guidelines

The fact that the two kinds of pointers have the same representation requirements does not imply that they represent a reference to the same object with the same pattern of bits (any more than two pointers of the same type are required to). The guideline recommendation dealing with the use of representation information is applicable here.

representation information using 569.1

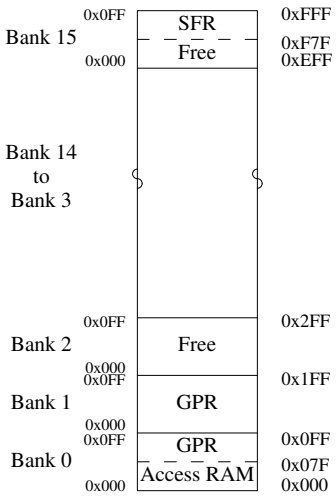

Figure 559.1: Data storage organization for the PIC18CXX2 devices[931] The 4,096 bytes of storage can be treated as a linear array or as 16 banks of 256 bytes (different instructions and performance penalties are involved). Some storage locations hold Special Function Registers (SFR) or General Purpose Registers (GPR). *Free* denotes storage that does not have a preassigned usage and is available for general program use.

560 All pointers to structure types shall have the same representation and alignment requirements as each other.

alignment pointer to structures representation pointer to structures

Commentary

This is a requirement on the implementation. It refers to the pointer type, not the pointed-to type. This specification is redundant in that it can be deduced from other requirements in the standard. A translation unit can define a pointer to an incomplete type, where no information on the pointed-to type is provided within that translation unit. In:

```
#include <stdlib.h>

extern struct tag *glob_p;

int f(void)
{
if (glob_p == NULL)
   return 1;

glob_p = (struct tag *)malloc(8);
return 0;
}
```

a translator knows nothing about the pointed-to type (apart from its tag name, and it would be an unusual implementation that based alignment decisions purely on this information). If pointers to different structure types had different representations and alignments, the implementation would have to delay generating machine code for the function `f` until link-time.

C90

This requirement was not explicitly specified in the C90 Standard.

C++

The C++ Standard follows the C90 Standard in not explicitly stating any such requirement.

Other Languages

Most languages do not get involved in specifying details of pointer representation and alignment.

Coding Guidelines

The fact that the two kinds of pointers have the same representation requirements does not mean that they represent a reference to the same object with the same pattern of bits (any more than two pointers of the same type are required to). The guideline recommendation dealing with the use of representation information is applicable here.

569.1 representation information using

561 All pointers to union types shall have the same representation and alignment requirements as each other.

alignment pointer to unions representation pointer to unions

Commentary

The chain of deductions made for pointers to structure types also apply to pointer-to union types.

560 alignment pointer to structures

C90

This requirement was not explicitly specified in the C90 Standard.

C++

The C++ Standard follows the C90 Standard in not explicitly stating any such requirement.

Other Languages

Most languages do not get involved in specifying details about pointer representation and alignment.

Coding Guidelines

The fact that the two kinds of pointers have the same representation requirements does not mean that they represent a reference to the same object with the same pattern of bits (any more than two pointers of the same type are required to). The guideline recommendation dealing with the use of representation information is applicable here.

representation information using 569.1

---

alignment pointers

Pointers to other types need not have the same representation or alignment requirements. 562

Commentary

Although many host processors use the same representation for all pointer types, this is not universally true, and this permission reflects this fact.

C++

3.9.2p3 *The value representation of pointer types is implementation-defined.*

Other Languages

Most languages do not get involved in specifying details of pointer representation and alignment.

Common Implementations

word addressing 54

Some processors use what is sometimes known as word *addressing*. This hardware characteristic may, or may not, result in some pointer types having different representations.

---

footnote 37

37) Note that aggregate type does not include union type because an object with union type can only contain one member at a time. 563

Commentary

As a phrase, the term *aggregate type* is open to several interpretations. Experience shows that developers sometimes classify union types as being aggregate types. This thinking is based on the observation that structure and union types often contain many different types— an aggregate of types. However, the definition used by the Committee is based on there being an aggregate of objects. Although an object having a union type can have many members, only one of them represents a value at any time (an object having a structure or array type is usually capable of representing several values at the same time).

The phrase *one member at a time* is a reference to the fact that the value of at most one member can be stored in an object having a union type at any time.

union member at most one stored 1426

C++

The C++ Standard does include union types within the definition of aggregate types, 8.5.1p1. So, this rationale was not thought applicable by the C++ Committee.

Other Languages

type category 553

Union types, as a type category, are unique to C (and C++), so this issue does not occur in other languages.

---

footnote 38

38) See 6.7.3 regarding qualified array and function types. 564

---

footnote 39

39) The same representation and alignment requirements are meant to imply interchangeability as arguments to functions, return values from functions, and members of unions. 565

Commentary

footnote 31 509

The text of this footnote is identical to footnote 31; however, the rationale behind it is different. Type qualifiers did not exist prior to C90. Supporting a degree of interchangeability allows developers to gradually introduce type qualifiers into their existing source code without having to modify everything at once. Also source code containing old-style function declarations continues to exist. There is the possibility of pointers to qualified types being passed as arguments to such functions.

Other Languages

Most languages that contain type qualifiers, or modifiers, do not get involved in this level of implementation detail.

Coding Guidelines

Qualified and qualified version of the same type may appear as members of unions. This interchangeability of members almost seems to invite the side-stepping of the qualifier.

---

566 EXAMPLE 1 The type designated as "`float *`" has type "pointer to `float`". Its type category is pointer, not a floating type. The const-qualified version of this type is designated as "`float * const`" whereas the type designated as "`const float *`" is not a qualified type— its type is "pointer to const-qualified `float`" and is a pointer to a qualified type.

---

567 EXAMPLE 2 The type designated as "`struct tag (*[5])(float)`" has type "array of pointer to function returning `struct tag`". The array has length five and the function has a single parameter of type `float`. Its type category is array.

---

568 **Forward references:** compatible type and composite type (6.2.7), declarations (6.7).

6.2.6 Representations of types

6.2.6.1 General

---

569 The representations of all types are unspecified except as stated in this subclause.

types representation

Commentary

These representations are requirements on the implementation. Previous clauses in the C Standard specify cases where some integer types, complex types, qualified types and pointer types must share the same representation. Subclause 5.2.4.2.2 describes one possible representation of floating-point numbers. Other clauses in the standard specify when two or more types have the same representation. However, they say nothing about what the representation might be.

509 footnote 31
506 complex component representation
556 qualifiers representation and alignment
558 pointer to void same representation and alignment as
330 floating types characteristics

C90

This subclause is new in C99, although some of the specifications it contains were also in the C90 Standard.

C++

[Note: 3.9 and the subclauses thereof impose requirements on implementations regarding the representation of types. 3.9p1

These C++ subclauses go into some of the details specified in this C subclause.

Other Languages

Most languages say nothing about the representation of types. The general acceptance of the IEC 60559 Standard means there is sometimes some discussion about using a floating-point representation that conforms to this standard. Java is intended to be processor-independent. To achieve this aim, the representation from a developer's point of view of all arithmetic types are fully specified.

Coding Guidelines

Code that makes use of representation information leaves itself open to several possible additional costs:

- The representation can vary between implementations. The potential for differences in representations between implementations increases the likelihood that there will be unexpected effort required to port programs to new environments.

- The need for readers to consider representation information increase the cognitive effort needed to comprehend code. This increase in required effort can increase the time needed by developers to complete source code related tasks.
- The failure to consider representation information by developers can lead to faults being introduced when existing code is modified.
- The additional complexity introduced by the need to consider representation information increases the probability that the maximum capacity of a reader's cognitive ability will be exceeded (i.e., the code will be too complicated to comprehend). Human response to information overload is often to ignore some of the information, which in turn can lead to an increase in the number of mistakes made.

cognitive effort 0

overconfidence 0

Developers often have a misplaced belief in their ability to use representation information to create more efficient programs (e.g., less time to execute or less machine code generated).

Cg 569.1 A program shall not make use of information on the representation of a type.

Dev 569.1 A program may make use of representation information provided this usage is documented and a rationale given for why it needs to be used.

---

object contiguous sequence of bytes

Except for bit-fields, objects are composed of contiguous sequences of one or more bytes, the number, order, and encoding of which are either explicitly specified or implementation-defined. 570

Commentary

A bit-field can occupy part of one or two bytes (it may occupy more than two bytes, but the third and subsequent bytes will be fully occupied). It can also share a byte with other bit-fields.

The representation of a type must contain sufficient bytes so that it can represent the range of values the standard specifies it must be able to represent. An implementation may choose to use more bytes; for instance, to enable it to represent a greater range of values, or to conform to some processor storage requirement. Requiring that the bytes of an object be contiguous only becomes important when the object is operated on as a sequence of bytes. Such operations are part of existing practice; for instance, using the library function `memcpy` to copy arrays and structures. The number of bytes in an object can be found by using the **`sizeof`** operator.

sizeof result of 1119

In the case of pointers, the response to DR #042 (which involved accesses using `memcpy`, but the response has since been taken to apply to all kinds of access) pointed out that " . . . objects are not "the largest objects into which the arguments can be construed as pointing."", and " . . . a contiguous sequence of elements within an array can be regarded as an object in its own right." and "the non-overlapping halves of array . . . can be regarded as objects in their own rights." In the following example the storage `p_1` and `p_2` can be considered to be pointing at different objects:

```
1  #include <string.h>
2
3  #define N 20
4
5  char a[2*N];
6
7  void f(void)
8  {
9  char *p_1 = a,
10       *p_2 = a+N;
11
12 /* ... */
13 memcpy(p_2, p_1, N);
14 }
```

The ordering of bytes within an object containing more than one of them is not specified, and there is no way for a strictly conforming program can obtain this information. The order that bytes appear in may depend on how they are accessed (e.g., shifting versus access via a pointer).

The terms *little-endian* (byte with lowest address occupies the least significant position) and *big-endian* (byte with lowest address occupies the most significant position) originate from Jonathan Swift's book, *Gulliver's Travels*. Swift invented the terms to describe the egg-eating habits of two groups of people who got so worked up about which way was best that they went to war with each other over the issue. endian

C++

An object of POD[4] type (3.9) shall occupy contiguous bytes of storage. 1.8p5

The acronym POD stands for *Plain Old Data* and is intended as a reference to the simple, C model, or laying out objects. A POD type is any scalar type and some, C compatible, structure and union types.

In general the C++ Standard says nothing about the number, order, or encoding of the bytes making up what C calls an object, although C++ does specify the same requirements as C on the layout of members of a structure or union type that is considered to be a POD.

Other Languages

Java requires integer types to behave as if they were contiguous; how the underlying processor actually represents them is not visible to a program.

Common Implementations

The Motorola DSP563CCC[967] uses two 24-bit storage units to represent floating-point values. The least significant 24 bits is used to represent the exponent (in the most significant 14 bits, the remaining bits being reserved). The significand is represented in the most significant storage unit (in two's complement).

Table 570.1: Byte order (indicated by the value of the digits) used by various processors for some integer and floating types, in different processor address spaces (all address spaces if none is specified).

Vendor	16-bit integer	32-bit integer	64-bit integer	32-bit float	64-bit float
AT&T 3B2		4321 (data space)/ 1234 (program space)			
DEC PDP–11	12	3412		3412 (F format)	78563412 (D format)
DEC VAX	12	1234	12345678	3412 (F format)	78563412 (D format)
NSC32016		1234 (data space)/ 4321 (program space)			

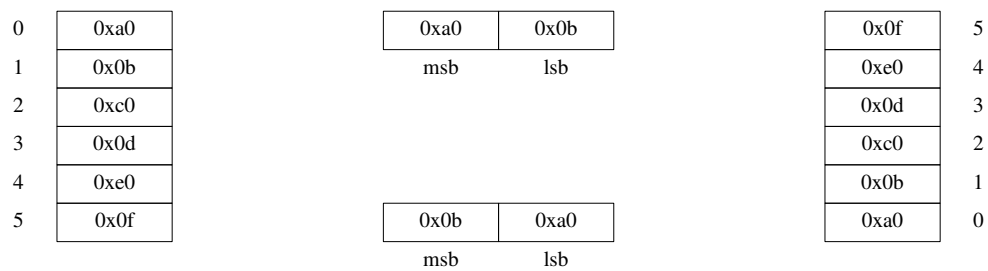

Figure 570.1: Developers who use little-endian often represent increasing storage locations going down the page. Developers who use big-endian often represent increasing storage locations going up the page. The value returned by an access to storage location *0*, using a pointer type that causes 16 bits to be read, will depend on the *endianness* of the processor.

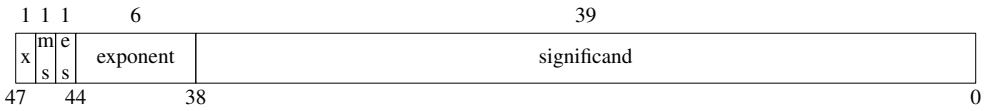

Figure 570.2: The Unisys A Series[1389] uses the same representation for integer and floating-point types. For integer values bit 47 is unused, bit 46 represents the sign of the significand, bits 45 through 39 are zero, and bits 38 through 0 denote the value (a sign and magnitude representation). For floating values bit 47 represents the sign of the exponent and bits 46 through 39 represent the exponent (the representation for double-precision uses an additional word with bits 47 through 39 representing higher order-bits of the exponent and bits 38 through 0 representing the fractional portion of the significand).

Coding Guidelines

Information on the number of bytes in a type is needed by the memory-allocation functions. The **sizeof** operator provides a portable way of obtaining this information. It is common C practice to copy values from one object to another using some form of block copy of bytes between storage locations. Perhaps part of the reason for this is lack of awareness, by developers, that objects having a structure type can be assigned, or in the case of objects having an array type, because there is no appropriate assignment operator available for this type category.

sizeof 1118 constraints

There are no portable constructs that provide information on the order or encoding of the bytes in an object. The only way to obtain this information is to use constructs whose behavior is implementation-defined. For these cases the guideline recommendation on using representation information is applicable.

representation information using 569.1

---

unsigned char pure binary

Values stored in unsigned bit-fields and objects of type **unsigned char** shall be represented using a pure binary notation.[40)] 571

Commentary

This is a requirement on the implementation. It prevents an implementation from using any of the bits in one of these types for other purposes. For instance, an implementation cannot define the type **unsigned char** to be 9 bits, the most significant bit being a parity bit and the other bits being the value bits; all 9 bits would have to participate in the representation of the type (or the byte size reduced to 8 bits).

This requirement implies that using the type **unsigned char** to access the bytes in an object guarantees that all of the bits in that object will be accessed (read or written). There is no such requirement for any other types. For instance, the type **int** may contain bits in its object representation that do not participate in the value representation of that object. Taking the address of an object and casting it to pointer-to **unsigned char** makes all of the bits in its object representation accessible. This requirement is needed to implement the library function `memcpy`, among others.

C90

This requirement was not explicitly specified in the C90 Standard.

C++

3.9.1p1 *For unsigned character types, all possible bit patterns of the value representation represent numbers. These requirements do not hold for other types.*

The C++ Standard does not include unsigned bit-fields in the above requirement, as C does. However, it is likely that implementations will follow the C requirement.

Other Languages

Most languages do not get involved in specifying this level of detail.

Coding Guidelines

representation information using 569.1

The lack of such a guarantee for the other types only becomes visible when programs get involved with details of the representation. The guideline on not using representation information is applicable here.

572 Values stored in non-bit-field objects of any other object type consist of *n* × **CHAR_BIT** bits, where *n* is the size of an object of that type, in bytes.

Commentary

This means that non-bit-field objects cannot share the sequence of bytes they occupy with any other object (members of union types share the same storage, but only one value can be stored in such a type at any time).

C90

This level of detail was not specified in the C90 Standard (and neither were any of the other details in this paragraph).

C++

The object representation of an object of type T is the sequence of N ***unsigned char*** *objects taken up by the object of type T, where N equals* `sizeof(T)`. 3.9p4

That describes the object representation. But what about the value representation?

The value representation of an object is the set of bits that hold the value of type T. For POD types, the value representation is a set of bits in the object representation that determines a value, which is one discrete element of an implementation-defined set of values.[37)] 3.9p4

This does not tie things down as tightly as the C wording. In fact later on we have:

For character types, all bits of the object representation participate in the value representation. For unsigned character types, all possible bit patterns of the value representation represent numbers. These requirements do not hold for other types. 3.9.1p1

QED.

Other Languages

Most languages do not get involved in specifying this level of detail.

Coding Guidelines

Developers sometimes calculate the range of values that a type, in a particular implementation, can represent based on the number of bits in its object representation (which for most commonly used processors will deliver the correct answer). Such calculations are the result of developers focusing too narrowly on the details in front of them. There are object-like macros in the **<limits.h>** header that provide this information.

```
#include <limits.h>

unsigned short lots_of_assumptions(void)
{
return (1 << (sizeof(short)*CHAR_BIT)) - 1;
}
```

The following is a special case of the guideline recommendation dealing with the use of representation information (just in case developers regard this as a special case). 569.1 representation information using

Rev 572.1 The possible range of values that an integer type can represent shall not be calculated from the number of bits in its object representation.

value copied using unsigned char

The value may be copied into an object of type **unsigned char [***n***]** (e.g., by **memcpy**); 573

Commentary

Using the type **unsigned char** guarantees that all of the bits in the original object representation will be copied because there cannot be any unused bits in that type. While code may be written to copy the value into an array of any type, the standard only guarantees the behavior for this case, and when the element type is the same as the object being copied. Once the value has been copied into an object having type array of **unsigned char** copying them back to an object of the original type will restore the original pattern of bits, and hence the original value. The type pointer to **unsigned char** is a commonly used interface mechanism that offers a generic way of copying one region of storage to another region of storage. Although the library functions provide this functionality, there is existing code that does such copies as loops within the code itself rather than via calls to library functions.

C90

This observation was first made by the response to DR #069.

Other Languages

Many languages do not support the equivalent of the memory copying and related library functions. Neither do they define the behavior of casting pointers to different types, which enables developers to provide such functionality. So this discussion does not apply to them.

Common Implementations

All implementations known to your author use the same number of bits in the representation of the types **unsigned char** and **signed char** and there are no trap representations in the object representation of the type **signed char**. In such implementations values may be copied using an array of any character type.

Coding Guidelines

Copying objects a byte at a time is making use of representation information. However, this usage is sufficiently common in existing source to be regarded as a cultural norm.

Dev 569.1 An object may be copied by treating its contents as a sequence of objects having type **unsigned char**.

object representation

the resulting set of bytes is called the *object representation* of the value. 574

Commentary

value representation 595

This defines the term *object representation* (it was first used by the response to DR #069). An object representation is the complete sequence of bits making up any object. It differs from the value representation in that it may contain additional bits (which do not form part of the value). An object representation may be thought of in terms of being a sequence of bits, while the value representation is the interpretation of the contents of storage according to a type.

Other Languages

The term *object* usually has a very different meaning in object-oriented languages. In other languages, this term, if used, is often not defined in this way.

Coding Guidelines

The term *object representation* was introduced in C99 and is not used by developers in this context. Many developers have some familiarity with object-oriented languages. It is likely that they will assume this term has a very different meaning from its actual C99 definition. It is probably a good idea not to use the term *object representation* in guidelines unless plenty of explanatory information is also provided on the terminology.

575 Values stored in bit-fields consist of *m* bits, where *m* is the size specified for the bit-field.

bit-field value is m bits

Commentary

This is a requirement on the implementation. Bit-fields cannot contain any padding bits. A previous requirement specified the representation for bit-fields having an unsigned type. The integer constant given in the declaration of the bit-field member corresponds to the value of *m*. There is a maximum value that *m* can take.

571 unsigned char pure binary

1393 bit-field maximum width

C++

> *The* `constant-expression` *may be larger than the number of bits in the object representation (3.9) of the bit-field's type; in such cases the extra bits are used as padding bits and do not participate in the value representation (3.9) of the bit-field.*

9.6p1

This specifies the object representation of bit-fields. The C++ Standard does not say anything about the representation of values stored in bit-fields.

C++ allows bit-fields to contain padding bits. When porting software to a C++ translator, where the type **`int`** has a smaller width (e.g., 16 bits), there is the possibility that some of the bits will be treated as padding bits on the new host. In:

```
1  struct T {
2             unsigned int m1:18;
3            };
```

the member `m1` will have 18 value bits when the type **`unsigned int`** has a precision of 32, but only 16 value bits when **`unsigned int`** has a precision of 16.

Other Languages

A few languages (e.g., Ada, CHILL, and PL/1) provide functionality for enabling developers to specify the number of bits of storage to use in representing objects having integer types. Languages in the Pascal family support the specification of types that are subranges of the integer type. Some implementations chose to pack members of records having such types into the smallest number of bits, effectively having the same outcome as a C bit-field definition. But this implementation detail is hidden from the developer and an implementation is at liberty to use exactly the same amount of storage for all integer types.

576 The object representation is the set of *m* bits the bit-field comprises in the addressable storage unit holding it.

Commentary

This defines the object representation for bit-fields. It differs from the object representation for other types in that it is based on addressable storage units rather than bytes. This is because the storage occupied by a bit-field might only partially fill two bytes and share that storage with other bit-fields.

53 byte addressable unit

577 Two values (other than NaNs) with the same object representation compare equal, but values that compare equal may have different object representations.

Commentary

To be exact, two object representations whose values are interpreted using the same type can compare equal (using an equality operator) and have different object representations (two object representations can only be compared by treating them as an array of **`unsigned char`** objects and can be compared by using, for instance, the library function `memcmp`). This difference can occur if there are padding bits in the object representation that differ. Thus, although the values compare equal, the object representations are different.

1212 equality operators syntax

Two object representations can have the same bit pattern, but compare unequal when interpreted using two different types (e.g., integer and floating types).

There are also cases that do not involve padding bits in the object representation, two values comparing equal, but the object representations being different. This can occur when there is more than one representation for the same value; for instance, plus and minus zero in signed magnitude notation, or when the values are different but compare equal (i.e., plus and minus floating-point zero).

x == y 604
x not same as y

NaN 339

NaN always compares unequal to anything, including NaN.

C++

3.9p3 *For any POD type T, if two pointers to T point to distinct T objects `obj1` and `obj2`, if the value of `obj1` is copied into `obj2`, using the `memcpy` library function, `obj2` shall subsequently hold the same value as `obj1`.*

This handles the first case above. The C++ Standard says nothing about the second value compare case.

Coding Guidelines

This statement highlights the dangers of dealing with object representations. They can contain padding bits whose value may not be explicitly controlled by developers.

Example

```
1  #include <string.h>
2
3  extern int glob_1,
4             glob_2;
5
6  int f(void)
7  {
8  if (memcmp(&glob_1, &glob_2, sizeof(glob_1)) == 0)
9     {
10    if (glob_1 == glob_2)
11       return 1;
12    else
13       return 2;
14    }
15 return 3;
16 }
```

Certain object representations need not represent a value of the object type. 578

Commentary

On some processors, pointers have a limit on the maximum amount of memory they can access; for instance, 24 bits of a possible 32-bit pointer representation can refer to an object.

The IEC 60559 Standard specifies that certain bit patterns do not represent floating-point numbers. However, these bit patterns are still values within the standard. They represent such quantities as the infinities and NaNs. These are all values of the object type.

floating types 338
can represent

C90

This observation was not explicitly made in the C90 Standard.

C++

3.9p4

The value representation of an object is the set of bits that hold the value of type T. For POD types, the value representation is a set of bits in the object representation that determines a value, which is one discrete element of an implementation-defined set of values.[37)]

37) The intent is that the memory model of C++ is compatible with that of ISO/IEC 9899 Programming Languages C.

Footnote 37

By implication this is saying what C says. It also explicitly specifies that these representation issues are implementation-defined.

Other Languages

Most languages do not get involved in specifying this level of detail.

Common Implementations

This situation is sometimes seen for pointer types. A processor may place restrictions on what storage locations can be addressed (perhaps because the program does not have access rights to them, or because there is no physical storage at those locations). The representation of the floating-point significand on the Motorola DSP563CCC[967] reserves the bit patterns `0x000001` through `0x3fffff` and `0xc00000` through `0xffffff`.

Coding Guidelines

Although such object representations may exist, creating a value having such a representation invariably relies on undefined or implementation-defined behavior:

- An object that has not been initialized can contain an object representation that is not a value in the object type.
- For pointer and floating-point types, there are implementations where some object representations do not represent a value of the object type. Creating such a representation invariably requires modifying the object through types other than the underlying pointer or floating-point type.

---

579 If the stored value of an object has such a representation and is read by an lvalue expression that does not have character type, the behavior is undefined.

trap representation reading is undefined behavior

Commentary

The pattern of bits held in an object has no meaning until they are interpreted as having a particular type. A pattern of bits that does not correspond to a value of the type used for the read access may be treated by the host processor in special ways— for instance, raising an exception. This statement points out this fact.

The exception for character types is to support the practice of copying objects using a pointer-to character type. This would not work if accessing one or more values, having a character type, represented undefined behavior.

C90

The C90 Standard specified that reading an uninitialized object was undefined behavior. But, it did not specify undefined behaviors for any other representations.

C++

The C++ Standard does not explicitly specify any such behavior.

Other Languages

Most languages specified some form of undefined or implementation-defined behavior for a read access to an uninitialized object. But they are usually silent on other kinds of *non-values*.

Common Implementations

There are so few processors that have a sequence of bits in the value representation that does not represent a value, it is not possible to determine any common behaviors.

pointer 454 cause undefined behavior
pointer 590 segmented architecture

Some processors check that the value of address operands is within the bounds of addressable storage. This kind of checking is common in processors that represent addresses using a *segment+offset* representation. In this case the segment number is often checked to ensure that it denotes a segment that can be accessed by the current process.

Coding Guidelines

object 461 initial value indeterminate representation 569.1 information using

A guideline recommending that such values not be read is acting after the fact, they should not have been created in the first place. These issues are dealt with under uninitialized objects and making use of representation information.

If such a representation is produced by a side effect that modifies all or any part of the object by an lvalue expression that does not have character type, the behavior is undefined.[41)] 580

Commentary

The representation could be produced by doing one of the following:

- Assigning it from another object of the same type; in which case the behavior is undefined because of the previous sentence.
- Treating all or part of the object as a type different from its declared type; in which case the behavior is also undefined.

effective type 948

- manipulating the values of bits directly using a sequence of operations on operands. While creating the value may not be undefined behavior, storing it into the appropriate type could be.

If a pointer to character type is used to copy all of the bits in an object to another object, the transfer will be performed a byte at a time. A trap representation might be produced after some bytes have been copied, but not all of them. An exception to the general case is thus needed for character types.

C90

The C90 Standard did not explicitly specify this behavior.

C++

The C++ Standard does not explicitly discuss this issue.

Other Languages

Other languages do not usually give special status to values copied using character types.

Common Implementations

Few implementations do anything other than treat whatever bit pattern they are presented with as a value. In other cases processors raise some kind of exception, or set some status bits.

Coding Guidelines

object 960 value accessed if type

These side effects are dealt with in more detail elsewhere.

---

trap representation

Such a representation is called a *trap representation*. 581

Commentary

This defines the term *trap representation*. The standard does not require that use of this representation cause a processor to generate trap (the original source for this terminology). As specified in the previous two sentences, the behavior is undefined. The term *trap representation* is not often used by developers because there are few implementations that contain such a representation. The Committee's response to DR #222 said, in part: "A TC should remove the notion of objects of struct or union type having a trap representation . . . ".

C90

This term was not defined in the C90 Standard.

C++

Trap representations in C++ only apply to floating-point types.

Common Implementations

Support for a trap representations outside of pointer and floating-point types is very rarely seen. A few processors use tagged memory; for instance, the Tera computer system[24] has four access bits for each 64-bit object, two of these bits are available for the translator implementor to use. Possible uses include stack limit checking and runtime type exception signaling. (If a location's trap bit is set and the corresponding trap-disable bit in the pointer is clear, a trap will occur.)

The IEC 60559 Standard specifies support for signaling NaNs. While these trigger the invalid exception when accessed, they are not trap representations (although their use may be intended to act as a trap for when certain kinds of situations occur during program execution).

Note. Some processors are said to *trap* for reasons other than accessing a trap representation. For instance, use of an invalid instruction is often defined, by processor specifications, to cause a trap.

---

582 40) A positional representation for integers that uses the binary digits 0 and 1, in which the values represented by successive bits are additive, begin with 1, and are multiplied by successive integral powers of 2, except perhaps the bit with the highest position.

footnote 40

Commentary

The bit with the highest position might be used as a sign bit.

C90

Integer type representation issues were discussed in DR #069.

Other Languages

Most languages rely on the definitions given for this representation provided by other standards and don't repeat them in modified form.

---

583 (Adapted from the *American National Dictionary for Information Processing Systems*.)

Commentary

The ISO definition is in ISO 2382–1.

25 ISO 2382

---

584 A byte contains **CHAR_BIT** bits, and the values of type **unsigned char** range from 0 to $2^{\mathbf{CHAR\_BIT}} - 1$.

unsigned char value range

Commentary

This duplicates requirements given elsewhere for CHAR_BIT and UCHAR_MAX.

307 CHAR_BIT macro
328 UCHAR_MAX value

C++

The C++ Standard includes the C library by reference, so a definition of CHAR_BIT will be available in C++.

> *Unsigned integers, declared* ***unsigned****, shall obey the laws of arithmetic modulo* 2^n *where* n *is the number of bits in the value representation of that particular size of integer.*[41)]

3.9.1p4

From which it can be deduced that the C requirement holds true in C++.

---

585 41) Thus, an automatic variable can be initialized to a trap representation without causing undefined behavior, but the value of the variable cannot be used until a proper value is stored in it.

footnote 41

Commentary

Such initialization could be performed, for instance, by the implementation on function entry. However, an implementation does not have access to any special instructions that could not also be used in the translation of the rest of a C program. It would need to make use of the exception granted for character types. An implementation could also choose to not explicitly initialize such a variable (the most common situation), using the pattern of bits it happens to contain. Whether this pattern of bits is a trap representation is something that an implementation does not need to be concerned about.

object 461 initial value indeterminate

C90

The C90 Standard did not discuss trap representation and this possibility was not discussed.

C++

The C++ Standard does not make this observation about possible implementation behavior.

Other Languages

This technique, for helping developers find uninitialized variables, has been used by implementations of various languages.

Common Implementations

The technique of giving uninitialized objects a representation that caused some form of unexpected behavior, if they are read without first being given an explicit value in the code, has long been used by implementations. It predates the design of the C language.

---

value stored in structure
value stored in union

When a value is stored in an object of structure or union type, including in a member object, the bytes of the object representation that correspond to any padding bytes take unspecified values.[42)] 586

Commentary

footnote 601 42

As the footnote points out, there are two possible ways of copying structure or union objects. Depending on the method used any padding bits may, or may not, also be copied.

Scalar types may include padding bits in their representation, structure types may have padding between members, and both structure and union types may have padding after the last member.

structure 1424 unnamed padding
structure 1428 trailing padding
footnote 1042 DR283

The response to DR #283 clarified the situation with regard to wording that appeared in C90 but not C99.

C90

The sentences:

> *With one exception, if a member of a union object is accessed after a value has been stored in a different member of the object, the behavior is implementation-defined 41).*

> *41) The "byte orders" for scalar types are invisible to isolated programs that do not indulge in type punning (for example, by assigning to one member of a union and inspecting the storage by accessing another member that is an appropriately sized array of character type), but must be accounted for when conforming to externally-imposed storage layouts.*

appeared in C90, but does not appear in C99.

If a member of a union object is accessed after a value has been stored in a different member of the object, the behavior is implementation-defined in C90 and unspecified in C99.

C++

This specification was added in C99 and is not explicitly specified in the C++ Standard.

Other Languages

The values of padding bytes, or even the very existence of such bytes, is not usually discussed in other languages.

Common Implementations

Many implementations simply copy all of the bytes making up an object having structure or union type; it is the simplest option. Whether the copy occurs a byte at a time or in multiple bytes (it is usually much more efficient to copy as many bytes as possible in a single instruction) is an implementation detail that is hidden from the developer. For padding bytes to play a part in the choice of algorithm used to make the copy there would have to be a significant percentage of the number of bytes needing to be copied.

In the case of an object having union type a translator may, or may not be able to deduce which member was last assigned to. In the former case it can copy the member assigned to, while in the latter case it has to assume that the largest member is the one that has to be copied. Whether padding bytes are copied can depend on the context in which the copy occurs.

Cyclone C[668] supports tagged union types, which contain information that identifies the current member.

Coding Guidelines

A program cannot rely on the padding bits of an object having structure or union type remaining unchanged when one of its members is modified, or the entire object is assigned a new value. Similarly, a program cannot assume that because one structure object was assigned to another structure object, a call to `memcmp` will return zero.

Copying a structure object using the assignment operator is still not widely used by developers, even though support for both structure assignment, parameter passing, and functions returning a structure has been available since the C90 Standard. Many developers continue to use the `memcpy` library function to copy objects having structure type. In this case any padding bytes will also be copied and the two objects will compare equal after the copy operation.

The issue of copying and assigning structure objects is discussed elsewhere. 601 footnote 42

Example

```
#include <string.h>

struct T {
          double m_1;
          short m_2;
         } x, y;

_Bool f(void)
{
x = y;
return memcmp(&x, &y, sizeof(x)) == 0;
}

void g(void)
{
union {
       char a[5];
       char b[2];
      } u;

u.a[4] = 7;
/*
 * The following assignment to the member b effectively turns
 * most of the elements of member a into padding bytes.
 */
u.b[1] = 2;
/*
 * After the following assignment it is not guaranteed
 * that u.a[4] has the value 7.
 */
```

```
31  u.a[0] = 3;
32  }
```

~~The values of padding bytes shall not affect whether the value of such an object is a trap representation.~~ The value of a structure or union object is never a trap representation, even though the value of a member of a structure or union object may be a trap representation. 587

Commentary

This is a requirement on the implementation. If it is possible for such a type to have a trap representation, it is the implementation's responsibility to ensure that the padding bytes never take on values that generate such a representation.

The wording was changed by the response to DR #222.

C90

This requirement is new in C99.

~~C++~~

This wording was added in C99 and is not explicitly specified in the ~~C++~~ Standard.

Common Implementations

Trap representations are not usually associated with non-scalar types.

~~Those bits of a structure or union object that are in the same byte as a bit-field member, but are not part of that member, shall similarly not affect whether the value of such an object is a trap representation.~~ 588

Commentary

This sentence was deleted by the response to DR #222.

As an example, consider an implementation where a particular pattern of bits within a 32-bit storage unit constitutes a trap representation. If a member of a structure type is declared to have a width of 28 bits and the translator assigns storage for it within the 32-bit storage unit without allocating any member to the remaining 4 bits, then it is the implementation's responsibility to ensure that either:

- These padding bits never take on values that generate a trap representation. This could enable the translator to generate machine code that loaded the value held in the 32-bit storage unit in a single instruction, followed by instructions to scrap off the unwanted 4 bits.
- For accesses to the bit-field, generate machine code that never loads the 32-bit storage unit directly, but uses a sequence of loads of narrower quantities (16 or 8 bits). These narrower quantities are joined together to create the value of the 28-bit wide bit-field. This ensures that, although the 32-bit storage unit may hold a trap representation it is never accessed as such.

Common Implementations

While a few processors[968] contain instructions that can load a specific number of bits from storage, it is likely that the underlying hardware operations will access the complete byte or word to extract the required bits. The number of processors that support bit-field access is low. Your author does not know of any processor supporting such instructions and a trap representation.

union member when written to

When a value is stored in a member of an object of union type, the bytes of the object representation that do not correspond to that member but do correspond to other members take unspecified values~~, but the value of the union object shall not thereby become a trap representation~~. 589

Commentary

This is a requirement on the implementation. If trap representations are supported, then any padding bytes must never take on values that would cause the value of the union object to become a trap representation.

Any bytes in a union type's object representation that are not part of the representation of any of the members are padding bytes. A consequence of these bytes taking unspecified values is that accessing the value of other members is undefined behavior. (The standard does not require the value representation of any scalar type to completely overlap the value representation of another scalar type; their object representations may contain padding bytes at various offsets such that a complete overlap cannot occur.)

1428 structure trailing padding

The wording was changed by the response to DR #222.

Common Implementations

For non-bit-field members, most implementations store operation into a member object does not affect the values held in other bytes of a union object. For bit-field members, an implementation may chose to write a value into all of the bytes occupied by the storage unit containing the bit-field. (This is an optimization that simplifies the machine code generated for a read access; no masking operation is needed to zero bits that are not part of the value representation if store operations set them to zero.)

Trap representations, when they are supported, are invariably associated with scalar types only.

---

590 Where an operator is applied to a value that has more than one object representation, which object representation is used shall not affect the value of the result.[43)]

Commentary

This is a requirement on the implementation. Operators operate on the value representation, not the object representation. Padding bits, which are one way a value can have more than one object representation, do not affect operations on the value representation. It is also possible for there to be more than value representation denoting the same value.

602 footnote 43

C90

This requirement was not explicitly specified in the C90 Standard.

C++

This requirement was added in C99 and is not explicitly specified in the C++ Standard (although the last sentence of 3.9p4 might be interpreted to imply this behavior).

Other Languages

Most languages do not get involved in specifying this level of representation detail.

Common Implementations

While processors that have a linear address space create few complications for vendors of translators, there are a number of reasons why hardware vendors might want to divide up a processor's address space into discrete *segments* (as always the driving forces are cost and performance). The most well-known segmented architecture is the Intel x86 processor family (whose early family members' 64 K segment size was considered generous for the first few years of their life). Segmented architectures did not die with the introduction of the Pentium. Some vendors of 32-bit processors have introduced 2^{32} segment sizes as a way of transitioning existing code to 64-bit address spaces. At the other end of the scale, low-cost embedded processors may have a flat address space, but support pointers capable of accessing only part of it (instructions involving such short-range pointers invariably occupy less storage and are often faster than other pointers).

pointer segmented architecture

The following discussion is based on techniques adopted by vendors of translators targeting the Intel 80286 member of the Intel x86 family and supporting pointers that handle various forms of segmented addressing. Some, or all, of these issues are likely to be applicable to other processor architectures. There are several ways instructions can specify an address in storage on the Intel 80286, including the following:

- *Specifying a 16-bit offset value.* This offset value is added to the value held in a segment register (the choice of segment register, one of four, is implicit in the instruction) to form an address in storage.

This form is the simplest and fastest, but addressable storage was limited to a single 64 K segment. The value of a pointer object is the 16-bit offset (i.e., it is a 16-bit pointer).

- *Specifying a 16-bit pointer value and the segment register to use in forming the final address in storage.* This form does not have the 64 K restriction, but incurs the cost of having to generate code to load the chosen segment register with an appropriate value. The value of a pointer object has two parts — the 16-bit offset and the 16-bit value loaded into the segment register (i.e., it is a 32-bit pointer).

Pointers using the 16-bit representation are sometimes referred to as *near* pointers (after the keyword that is usually used in their declaration— e.g., `char near *p`); while pointers using the 32-bit representation are sometimes referred to as *far* pointers (after the keyword that is usually used in their declaration— e.g., `char far *p`).

Additional complications are caused by the fact that the two 16-bit components do not specify the value of a 32-bit address but the value in the 20-bit address space supported by the Intel 80286. The address is formed by left shifting the segment value by four and adding the offset to it (e.g., `(seg << 4) + offset`). This means that two different pairs of 16-bit values can specify the same address (e.g., the hexadecimal pairs *ABCD:0000* and *ABCC:0010* both specify the address *0xABCD0*). Additional complications arise because of vendors' desire to optimize the machine code generated for operations involving pointers. For instance, the machine code needed to compare or subtract two pointer values will depend on whether the operands are both near pointers (only need to deal with the offset on the basis that the segment register values will be the same) or some other combination (where both components need to be considered).

Using a normalized form for the representation of far pointers, where the bits from the two components don't overlap (e.g., arranging that the offset is always less than 0x10), allows equality and relational tests to be performed without having to add the two values together. However, the results obtained from pointer arithmetic have to be converted to a normalized form.

Developers writing programs that need to simultaneously contain more than 64 K of object data had to be very careful how they mixed any operations that involved the two kinds of pointers (the above discussion has been simplified and most implementations supported more than two kinds of pointers).

null pointer 750
conversion yields
null pointer

Some of the issues involved in the representation of the null pointer constant on a segmented architecture are discussed elsewhere.

---

object representation more than one

Where a value is stored in an object using a type that has more than one object representation for that value, it is unspecified which representation is used, but a trap representation shall not be generated. 591

Commentary

This is a requirement on the implementation. It ensures that a subsequent read operation can always access the value of the object without worrying that a previous store had stored a trap representation into it. There are ways of causing an object to hold a trap representation, but they all involve making use of undefined behavior. The standard is silent on the case where there is more than one possible value representation for the stored value.

C90

The C90 Standard was silent on the topic of multiple representations of object types.

C++

This requirement is not explicitly specified in the C++ Standard.

Common Implementations

pointer 590
segmented
architecture

The following discusses the case where there is more than one value representation for the same value. On segmented architectures, an implementation may define some canonical representation for pointer types (this has the advantage of simplifying some operations— e.g., pointer compare). All values are converted to this form when they are stored into a pointer object. An implementation may not exhibit the expected behavior if it reads a pointer value that does not use this canonical representation (which might be created by manipulating the object representation of an object having a pointer type).

592 **Forward references:** declarations (6.7), expressions (6.5), lvalues, arrays, and function designators (6.3.2.1).

6.2.6.2 Integer types

593 For unsigned integer types other than **unsigned char**, the bits of the object representation shall be divided into two groups: value bits and padding bits (there need not be any of the latter).

unsigned integer types object representation

Commentary

Padding bits can be used for several reasons:

- A value representation may be stored in a larger object representation. This can occur if a processor only has a single load and store instruction, which always operate on a fixed number of bits.
- The host processor uses additional bits to indicate properties of the object representation; for instance, parity of the stored value, or tagged data, where the tag specifies type stored at that location.
- Representations are shared between different types (either to reduce processor transistor count, or for backward compatibility with existing code); for instance, integer types and floating-point types, or integer types and pointer types.

C90

Explicit calling out of a division of the bits in the representation of an unsigned integer representation is new in C99.

C++

Like C90 the grouping of bits into value and padding bits is not explicitly specified in the C++ Standard (3.9p2, also requires that the type **unsigned char** not have any padding bits).

Other Languages

Most languages do not get involved in specifying this level of representation detail.

Common Implementations

On some Cray processors the type **short** has 32 bits of precision but is held in 64 bits worth of storage.

54 word addressing

The Unisys A Series unsigned integer type contains a padding bit that is treated as a sign bit in the signed integer representation (see Figure 570.2).

Coding Guidelines

569.1 representation information using

Programs whose behavior depends on the value of padding bits make use of representation information. The fact that modern processors rarely contain padding bits in their integer types does not mean that future processors will continue this trend. The main developer assumption that fails in the presence of padding bits is that there are `CHAR_BIT*sizeof(integer_type)` bits in the value representation. The only reliable way of finding out the number of bits in the value representation is to look at the `MIN_*` and `MAX_*` macros defined in the header **<limit.h>**.

300 numerical limits

594 If there are N value bits, each bit shall represent a different power of 2 between 1 and 2^{N-1}, so that objects of that type shall be capable of representing values from 0 to $2^{N}-1$ using a pure binary representation;

Commentary

This is a requirement on the implementation. Representations ruled out by this requirement include BCD for integer types (some processors, including the Intel x86 processor family, contain instructions for operating on this representation) and Gray codes (consecutive decimal values are represented by binary values that differ in the state of a single bit; there is no requirement that ones start in the least significant bit and percolate up, so there are many possible bit sequences that are Gray codes).

Table 594.1: Pattern of bits used to represent decimal numbers using various coding schemes.

Decimal	Binary	Gray code	111 biased	2–out-of–5
0	0000	0000	0111	00011
1	0001	0001	1000	00101
2	0010	0011	1001	00110
3	0011	0010	1010	01001
4	0100	0110	1011	01010
5	0101	0111	1100	01100
6	0110	0101	1101	10001
7	0111	0100	1110	10010
8	1000	1100	1111	10100
9	1001	1101		11000
10	1010	1111		
11	1011	1110		
12	1100	1010		
13	1101	1011		
14	1110	1001		
15	1111	1000		

shift-expression syntax 1181

This requirement means there has to be a sequential ordering of the bits used in the value representation. A sequential ordering of bits means that the shift operators cause a uniform pattern of bit movement. For instance, the following two functions are equivalent:

```
#include <limits.h>

/*
 * This code assumes that sizeof(int) == 2
 */

unsigned int obj_htons(unsigned int h)
{
/*
 * Relies on type unsigned char copying all bits.
 */
unsigned char *hp = (unsigned char *)&h;
unsigned int n;
unsigned char *np = (unsigned char *)&n;

np[0] = hp[1];
np[1] = hp[0];
return n;
}

unsigned int val_htons(unsigned int h)
{
#define MASK ((1U << CHAR_BIT) - 1)
return ((h & MASK) << CHAR_BIT) | ((h >> CHAR_BIT) & MASK);
}
```

value bits signed/unsigned 600

Requirements on the value bits of signed integer types are phrased in terms of the value of the corresponding bits in the corresponding unsigned integer type. There is no requirement that other non-integer scalar types be represented using a binary notation.

C90

These properties of unsigned integer types were not explicitly specified in the C90 Standard.

Other Languages

Even those languages that contain an unsigned integer type do not specify this level of detail.

Coding Guidelines

When targeting hosts with relatively low-performance processors, there are advantages to making use of the mathematical properties of a pure binary representation— for instance, using the shift operator to replace multiplies and divides of positive values by powers of two; or using the sequence add, shift and add for multiplication by 10. A number of arguments against this usage are often heard:

- Performing these kinds of optimizations based on representation details at the source code level creates a dependency on that representation. However, the standard specifies what the representation must be.
- It is claimed that an optimizing translator would perform the mapping to shift and add instructions, and that developers should leave this kind of optimization to the translator. However, not all optimizers live up to their name.
- Using such constructs makes the code more difficult to comprehend. Is an expression that uses a shift operator, for instance, harder to comprehend than one that uses a multiply or divide? It is really a question of familiarity. Developers who frequently encounter this usage learn to quickly recognize it and comprehend its purpose. This is not true for developers that rarely encounter this usage.

The general issue is one of developer overconfidence and comprehension. Overconfidence, or perhaps tunnel vision, by the original developer in believing that an optimization performed at any point in the source will impact the efficiency of the program. Subsequent readers are likely to require greater cognitive resources to comprehend the use of sequences of bit manipulation operations that are intended to mimic the effects of an arithmetic operator. These issues are discussed in more detail in the respective operator sentences.

One issue, which is rarely considered, is the impact of bit manipulation on optimizers and static analysis tools. These do not usually analyze bit manipulation operations in terms of their arithmetic effect. They tend to treat these operations as creating a sequence of bits of unknown value. As such, these operations reduce the information that optimizers and static analysis tools are able to deduce from the source.

---

595 this shall be known as the value representation.

value representation

Commentary

This defines the term *value representation* (it was first used in the response to DR #069). Given that, for most implementations the value representation and the object representation are bit-for-bit identical, it seems unlikely that this term will become commonly used by developers.

---

596 The values of any padding bits are unspecified.[44)]

unsigned integer padding bit values

622 integer padding bit values

Commentary

This is a special case of a more general one specified elsewhere. A strictly conforming program cannot access the value of these bits. Given that programs are not intended to access the values of these padding bits, there is no obvious reason for specifying the value as being implementation-defined. Such a specification would have required implementations to document their behavior in this area, which is likely to vary between objects in different contexts and be generally very difficult to specify for all cases.

C90

Padding bits were not discussed in the C90 Standard, although they existed in some C90 implementations.

C++

This specification of behavior was added in C99 and is not explicitly specified in the C++ Standard.

Common Implementations

Some hosts have one or more parity bits associated with each storage byte. The purpose is to provide confidence that storage has not been corrupted (to at least the additional degree of probability provided by the number of parity bits used) or even corrected hardware errors (if enough parity bits are available). These parity bits are normally handled by the storage hardware and are not visible at the software level. (It is likely that the processor knows nothing about how the bytes in storage are handled.)

representation information using 569.1

Coding Guidelines

The guideline recommendation dealing with the use of representation information applies to access to padding bits.

---

signed integer types object representation unsigned 593 integer types object representation IEC 60559 29

For signed integer types, the bits of the object representation shall be divided into three groups: value bits, padding bits, and the sign bit. 597

Commentary

The difference in the representation, from unsigned integer types, is that there is a sign bit. An alternative representation of signed numbers, not using a sign bit, is to use biased notation. This method of representation is used for the exponent in the IEC 60559 floating-point standard.

Other Languages

All known computer languages can represent signed integer types, so their implementations have some means of representing the sign. But language specifications do not usually go into this level of detail.

Common Implementations

This division of the object representation into three groups makes it a superset of the representations used by all known processors (many do not have padding bits). The Harris/6 computer represented the type **long** using two consecutive **int** types. This meant that the sign bit of one of the ints had to be ignored; it was treated as a padding bit. The value representation of the type **int** is 24 bits wide, and **long** had a value representation of 47 bits with one padding bit. The Unisys A Series uses a representation for its signed integer types that contain all three groups (see Figure 570.2). Also, the sign bit is not part of the value representation of its unsigned integer types.

There need not be any padding bits; 598

Commentary

The standard places no upper limit on the number of padding bits that may exist in an integer representation.

Common Implementations

Most implementations have no padding bits.

---

sign one bit

there shall be exactly one sign bit. 599

Commentary

sign bit 610 representation

Having specified that there is a sign bit, the standard needs to say something about it. The encoding of the sign bit limits the number of possible integer representations to three (when a binary representation is used).

C90

This requirement was not explicitly specified in the C90 Standard.

C++

3.9.1p7 *[Example: this International Standard permits 2's complement, 1's complement and signed magnitude representations for integral types.]*

These three representations all have exactly one sign bit.

Other Languages

Cobol provides several different arithmetic types. One of these types requires a representation based on using the Ascii character set values for the digits and the sign. This sign representation not only occupies more than one bit, but where it occurs in the object representation can vary. (It can occupy a single byte that leads or trails the digits, or it can be encoded as part of the value representation of the leading or trailing digit.)

600 Each bit that is a value bit shall have the same value as the same bit in the object representation of the corresponding unsigned type (if there are *M* value bits in the signed type and *N* in the unsigned type, then $M \leq N$).

value bits signed/unsigned

Commentary

This is a requirement on the implementation. The value bits in the signed integer representation must represent the same power of two as the corresponding bit in the unsigned representation. From this we can deduce that, provided there are no padding bits in the object representation of the unsigned type, the sign bit is the most significant bit.

The relational condition on the number of bits in each value representation is specified in terms of ranges of values elsewhere.

495 positive signed integer type subrange of equivalent unsigned type

C90

This requirement is new in C99.

C++

> *The range of nonnegative values of a signed integer type is a subrange of the corresponding unsigned integer type, and the value representation of each corresponding signed/unsigned type shall be the same.* 3.9.1p3

If the value representation is the same, the value bits will match up. What about the requirement on the number of bits?

> *. . . each of which occupies the same amount of storage and has the same alignment requirements (3.9) as the corresponding signed integer type[40]; that is, each signed integer type has the same object representation as its corresponding unsigned integer type.* 3.9.1p3

Combining these requirements with the representations listed in 3.9.1p7, we can deduce that C++ has the same restrictions on the relative number of value bits in signed and unsigned types.

Other Languages

Most languages do not contain both signed and unsigned types. Those languages that do, do not get involved in this level of detail.

Common Implementations

In most implementations there is one more bit in the value representation of an unsigned type than in its corresponding signed type (the sign bit). The Unisys A Series (see Figure 570.2) is the only processor known to your author where the number of value bits in both the signed and unsigned types are the same.

601 42)Thus, for example, structure assignment ~~may be implemented element-at-a-time or via **memcpy**.~~ need not copy any padding bits.

footnote 42

Commentary

The wording was changed by the response to DR #222, which also contained the following Committee discussion:

> *It was observed that the point of the original footnote was primarily to illustrate one reason why padding bits might not be copied: because member-by-member assignment might be performed. But member-by-member assignment would imply that struct assignment could produce undefined behavior if a member of the struct had a value that was a trap representation. Instead of adding further text explaining that member values that were trap representations were not permitted to render assignment of a containing struct or union object undefined (e.g., if member-by-member copying were used), it was decided that the footnote should simply clarify the issue of padding bits directly.* DR #222

C90

The C90 Standard did not explicitly specify that padding bits need not be copied.

C++

Footnote 36 *36) By using, for example, the library functions (17.4.1.2) `memcpy` or `memmove`.*

The C++ Standard does not discuss details of structure object assignment for those constructs that are supported by C. However, it does discuss this issue (12.8p8) for copy constructors, a C++ construct.

Example

```
1  #include <stdio.h>
2
3  struct T_1 {
4              int mem_1;
5              unsigned : 4;
6              int mem_2: 2;
7              double mem_3;
8             };
9  struct T_2 {
10             int mem_1;
11             unsigned int mem_name: 4;
12             int mem_2: 2;
13             double mem_3;
14            };
15 union T_3 {
16            struct T_1 su; /* First named member is initialized. */
17            struct T_2 sn; /* Both structure types have a common initial sequence. */
18           } gu;
19 struct T_1 s;
20
21 int main(void)
22 {
23 union T_3 lu;
24
25 lu.su = s;
26
27 if (lu.sn.mem_name != 0)
28    print("Whether this string is output is unspecified\n");
29 if (gu.sn.mem_name != 0)
30    print("Whether this string is output is unspecified\n");
31 }
```

footnote 43 43) It is possible for objects **x** and **y** with the same effective type **T** to have the same value when they are accessed as objects of type **T**, but to have different values in other contexts. 602

Commentary

For this situation to occur, the two objects must contain different bit patterns. But, how can two objects containing different sequences of bits ever be considered to contain the same value?

effective type 948

- When there are padding bits in the object representation. They are padding bits in the sense of not being part of the value representation of the object's effective type. When the object is treated as, for instance, an array of **`unsigned char`**, the padding bits are included in its value.

- When two different sequences of bits are interpreted using some type to have the same value; for instance, plus and minus zero in signed magnitude or IEC 60559 floating-point. Also, in some implementations, two different sequences of bits can represent the same address in storage.

604 x == y
x not same as
590 pointer
segmented
architecture

C90

This observation was not pointed out in the C90 Standard.

C++

The C++ Standard does not make a general observation on this issue. However, it does suggest that such behavior might occur as a result of the **reinterpret_cast** operator (5.2.10p3).

Other Languages

Most languages do not get involved in specifying this level of detail.

Common Implementations

Very few implementations have padding bits in the object representation of arithmetic types. Most implementations use two's complement notation for integer types. Each value has a unique *value representation* in this notation.

In the past some processors have used 32 bits in the object representation of pointer types, but used fewer bits in their value representation. As the price of memory chips dropped and customers demanded support for greater amounts of storage capacity, vendors upgraded their processors to use the full 32 bits of representation. Processors using 64 bits in their pointer type object representation are now available, but it is expected that it will be some years before memory chip prices reach the point where this capability will be fully utilized. At the time of this writing some processors only use 48 bits effectively making the remaining 16 bits padding.

On segmented architectures, there is often more than one sequence of bits (pointer value representations) capable of denoting the same address.

590 pointer
segmented
architecture

Coding Guidelines

This footnote highlights the dangers of developers becoming involved in the representation details of objects.

569 types
representation

Example

```
1  _Bool negative_zero_may_have_more_than_one_representation(int valu)
2  {
3  if (valu == 0)
4     if (value & 1) /* Representation used affects the result here. */
5        return 1;
6  return 0;
7  }
```

---

603 In particular, if == is defined for type **T**, then **x == y** does not imply that **memcmp(&x, &y, sizeof (T)) == 0**.

Commentary

The equality operators are not defined for operands having structure or union types, so padding bytes are not an issue here. It is also true that

1213 equality
operators
constraints

- `x != y` does not imply `memcmp(&x, &y, sizeof(T)) != 0` (this case occurs if both `x` and `y` have the same NaN value);
- `(x-y) == 0` does not imply `x == y` (it need not apply for nonzero values of `x` and `y` if an implementation does not support subnormals);
- on a segmented architecture, there may be more than one representation of the null pointer constant; this is discussed elsewhere.

1164 subtraction
result of
338 subnormal
numbers

590 pointer
segmented
architecture

Other Languages

Very few languages define a function that is the equivalent of `memcmp`, so this is rarely an issue. However, some implementations of these languages provide an equivalent function, although such implementations do not usually go into the implications of its use.

Coding Guidelines

representation information using 569.1

Calling `memcmp` is making use of representation information, even though developers do not see it in that light. The guideline recommendation dealing with the use of representation information is applicable. Given that C does not contain support for objects having structure or union types as operands of the equality operators, use of `memcmp` has some attractions. Used in conjunction with the **`sizeof`** operator, it does not need modification when new members are added to the types. However, padding bytes do need to be taken into account.

---

x == y
x not same as y

Furthermore, **`x == y`** does not necessarily imply that **`x`** and **`y`** have the same value; 604

Commentary

equality operators true or false 1219

The values `-0.0` and `+0.0` are different values (dividing by these values results in -∞ and -∞, respectively), but they compare equal. If x and y have different integer types, there are several different cases where they can compare equal and have different values; for instance (assuming the type **`int`** is 16 bits and the type **`long`** is 32 bits), the values `-1` and `0xffff` compare equal.

pointers compare equal 1233

For pointer types, equality is defined in terms of them pointing to the same object.

Other Languages

The values that create this behavior in C are caused by the underlying representations used by the host processor. As such, the cases are applicable to all languages supporting the same C representations that are translated for execution on that processor.

equality operators syntax 1212

Some languages provide more than one mechanism for comparing for equality. This issue is discussed elsewhere.

Coding Guidelines

equality operators not floating-point operands 1214.1

Modern processors have a single representation for integer zero. If the guideline recommendation dealing with comparing objects having floating-point types for equality is followed, there will not be any issues for those types.

Example

```
1  #include <stdio.h>
2
3  extern double x, y;
4
5  void f(void)
6  {
7  if (x == y)
8     if ((1.0 / x) != (1.0 / y))
9        printf("x and y are differently signed zeros\n");
10 }
11
12 void g(void)
13 {
14 unsigned int x = 0xffff;
15 signed int y = -1;
16 unsigned long z = 0xffff;
17
18 if (x == y)
19    if ((x == z) == (y == z))
20       printf("int and long probably have the same representation\n");
21    else
```

```
22          printf("int and long probably have a different representation\n");
23      }
```

605 other operations on values of type `T` may distinguish between them.

Commentary

In the case of integer types represented using signed magnitude or one's complement notation, there are two representations for zero, −0 and +0. Arithmetic operations always deliver the same result. In the case of bitwise operations, their behavior on signed operands is undefined, so the issue of two representations is moot.

946 bitwise operations signed types

There are also two representations of zero, `-0.0` and `+0.0`, in IEC 60559. A great deal of thought lay behind the decision to have a signed zero and the results of arithmetic operations on them (in some cases the result depends on the sign, while in others it does not). For instance, dividing by −0 returns -∞ and dividing by +0 returns +∞ (they may produce the same results using other floating-point models), but adding a nonzero value always delivers the same result. The `copysign` library function will also return different results.

338 floating types can represent
342 signed of non-numeric values

Coding Guidelines

This situation usually arises when there is more than one representation of zero. This occurs for integer types represented in one's complement and signed magnitude format, or the floating-point representation in IEC 60559. The number of defined operations that can be performed using pointer types is sufficiently limited that multiple representations are not an issue.

In the case of IEC 60559 the decision to have signed zeros was intended to be an aid to the developer writing numerical software. If unexpected behavior occurs in this case, the cause is likely to be developer misunderstanding of the mathematics involved, which is outside the scope of these coding guidelines.

606 44) Some combinations of padding bits might generate trap representations, for example, if one padding bit is a parity bit.

footnote 44

Commentary

The trap representations that occur because of parity errors are usually caused by hardware rather than software faults, while parity bits are not limited to those supported by hardware. It is rare for an implementation to choose to use one or more bits for this purpose.

This footnote is identical to footnote 45.

628 footnote 45

C90

This footnote is new in C99.

C++

This wording was added in C99 and is not explicitly specified in the C++ Standard. Trap representations in C++ only apply to floating-point types.

Common Implementations

Processors that contain a trap representation for integer types (apart from parity bits, which are not usually visible at the program level) are rare. At least one processor includes a parity bit in its floating-point representation.

335 WE DSP32

Coding Guidelines

Any program that accesses a subpart of an object to manipulate padding bits is making use of representation information and is covered by a guideline recommendation.

569.1 representation information using

607 Regardless, no arithmetic operation on valid values can generate a trap representation other than as part of an exceptional condition such as an overflow, and this cannot occur with unsigned types.

arithmetic operation exceptional condition

Commentary

divide by zero 1150

This statement excludes arithmetic operations, not bitwise operations. While divide by zero (or the remainder operation) often raises an exception, the standard specifies the result of such an operation as being undefined.

C++

This discussion on trap representations was added in C99 and is not explicitly specified in the C++ Standard.

Common Implementations

While various processor status flags might be set as a result of an arithmetic operation, they are not part of the representation of a value.

All other combinations of padding bits are alternative object representations of the value specified by the value bits. 608

Commentary

The object representation includes all bits in the storage allocated to the object, while the value representation may be a subset of these bits. The standard treats the combination of the value bits and the different values of the padding bits as alternative object representations.

C++

This discussion of padding bits was added in C99 and is not explicitly specified in the C++ Standard.

If the sign bit is zero, it shall not affect the resulting value. 609

Commentary

This is a requirement on the implementation. It reflects existing processor integer representation practice.

C90

This requirement was not explicitly specified in the C90 Standard.

C++

3.9.1p7 *[Example: this International Standard permits 2's complement, 1's complement and signed magnitude representations for integral types.]*

In these three representations a sign bit of zero does not affect the resulting value.

Other Languages

Other languages do not usually go into the representation details of their supported integer types. However, implementations of these languages will target the same hosts as C implementations. Unless a nonbinary representation is used to represent integer types, these implementations will follow the C model.

---

sign bit representation

If the sign bit is one, the value shall be modified in one of the following ways: 610

Commentary

This is a requirement on the implementation. These three ways correspond to the three representations of binary notation in common (well one of them is) usage.

C90

This requirement was not explicitly specified in the C90 Standard.

---

sign and magnitude

— the corresponding value with sign bit 0 is negated (*sign and magnitude*); 611

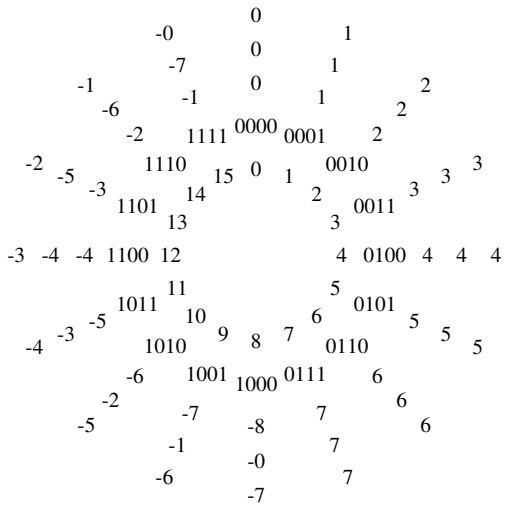

Figure 610.1: Decimal values obtained by interpreting a sequence of bits in various ways. From the inside out: unsigned, binary, two's complement, sign and magnitude, and one's complement.

Commentary

Sign and magnitude is a symmetric representation (i.e., the minimum representable value is the negated form of the maximum representable value). Every value, including zero, has the same representation for its magnitude (rather like putting +/– on the front of an integer constant). This representation is used for the significand in the IEC 60559 Standard.

317 int minimum value

C++

Support for sign and magnitude is called out in 3.9.1p7, but the representational issues are not discussed.

Common Implementations

Integer types, excluding the character types, on the Unisys A Series[1389] use sign and magnitude representation.

---

612 — the sign bit has the value -(2^N) (*two's complement*); two's complement

Commentary

When this value (i.e., the sign bit) is added to the value of the numeric quantity, the result is the bit pattern held in storage. The set of possible representable values are asymmetric about zero and there is one representation of zero.

C++

Support for two's complement is called out in 3.9.1p7, but the representational issues are not discussed.

Common Implementations

This is by far the most common representation in use today (and for the last 30 years). Even the translator for the Unisys A Series, whose underlying representation is sign and magnitude, provides an option to emulate two's complement.[1390]

---

613 — the sign bit has the value $-(2^N - 1)$ (*one's complement*). one's complement

Commentary

From the developers point of view, one's complement differs from two's complement in that the set of possible representable values are symmetric about zero and there are two representations of zero.

C++

Support for one's complement is called out in 3.9.1p7, but the representational issues are not discussed.

Common Implementations

The CDC 6600, 7600, and Cyber 200 are the only known (to your author) commercially sold processors (no longer available) using one's complement representation that supported a C translator.[852]

Which of these applies is implementation-defined, as is whether the value with sign bit 1 and all value bits zero (for the first two), or with sign bit and all value bits 1 (for one's complement), is a trap representation or a normal value. 614

Commentary

Implementations with such trap representations are thought to have existed in the past. Your author was unable to locate any documents describing such processors.

C90

The choice of representation for signed integer types was not specified as implementation-defined in C90 (although annex G.3.5 claims otherwise). The C90 Standard said nothing about possible trap representations.

C++

The following suggests that the behavior is unspecified.

3.9.1p7 *The representations of integral types shall define values by use of a pure binary numeration system[44]. [Example: this International Standard permits 2's complement, 1's complement and signed magnitude representations for integral types.]*

Trap representations in C++ only apply to floating-point types.

Other Languages

Most languages do not get involved in specifying this level of detail.

Common Implementations

The Unisys A Series[1390] uses two's complement for character types and a sign and magnitude representation for the other integer types.

Coding Guidelines

The use of two's complement, by commercially available processors, is almost universal. Is there any worthwhile benefit in writing programs to execute correctly using all three representations?

Calculating the cost/benefit requires estimating the probability of having to port to a non-two's complement processor and the costs of writing code that has the same behavior for all integer representations likely to be used. There is only one commercially available processor (known to your author) that does not use two's complement, the Unisys A Series.[1389] The probability of having to port code to this platform can only be calculated by individual development groups. Because of the likelihood that the overwhelming volume of existing code contains some representation dependencies, there is every incentive for hardware vendors to continue to use two's complement in new processors.

There are two ways a program can depend on details of the representation— by explicitly manipulating the bits of the value representation using bitwise operators, and by generating values that are not guaranteed to be representable in all implementations of an integer type. Manipulating bits rather than numeric values is generally recommended against for reasons other than portability to other representations.

types 569 representation

Is simply specifying use of a two's complement representation sufficient? The minimum integer limits specified by the C Standard are symmetrical. However, all two's complement implementations (known to your author) are not symmetrical. They support one more negative value than positive value. Writing programs that only make use of a symmetrical set of positive and negative values could involve considerable cost. In this situation a program is not manipulating representations details, but having to deal with the

integer types 303 sizes

consequences of a particular representation. Given the rarity of two of the possible integer representations being encountered, and overwhelming support for an asymmetric implementation of two's complement notation, the following is suggested:

- One's complement or sign and magnitude issues should only be dealt with when writing for such implementations.
- The asymmetric nature of existing two's complement implementations should be accepted and no attempts made to handle the *extra* negative value any differently than the other values.

---

615 In the case of sign and magnitude and one's complement, if this representation is a normal value it is called a *negative zero*. negative zero

Commentary

This defines the term *negative zero*. The term *zero* is commonly used to imply the zero value with the sign bit also set to zero. The term *positive zero* is sometimes used to help distinguish this case when discussing both representations of zero.

C90

The C90 Standard supported hosts that included a representation for negative zero, however, the term *negative zero* was not explicitly defined.

C++

The term *negative zero* does not appear in the C++ Standard.

Other Languages

This terminology is also used in Cobol, where negative zero is always supported irrespective of the underlying host representation of binary integers.

---

616 If the implementation supports negative zeros, they shall be generated only by: negative zero only generated by

Commentary

This is a requirement on the implementation. In the case of arithmetic operations, unless one of the operands has a value of negative zero, the operation does not deliver a negative zero result. The principle of *least surprise* (sometimes known as the *Principle of Least Astonishment*) could be said to be the driving principle here.

This requirement only applies to integer types and the list excludes all operators whose result is not derived by manipulating the operands (e.g., relational operators, comparison operators, or logical operators, which are all defined to return a value of 0 or 1). For these operators, an implementation cannot choose to use a negative zero value.

Negative zero can also be created as the result of a conversion operation. 686 floating-point converted to integer

C90

The properties of negative zeros were not explicitly discussed in the C90 Standard.

C++

This requirement was added in C99; negative zeros are not explicitly discussed in the C++ Standard.

Other Languages

Cobol also supports a negative zero under some conditions.

Example

```
1  _Bool is_negative_zero(int valu)
2  {
3  if (valu == 0)
4     if (value & ~0)
5        return 1;
6  return 0;
7  }
```

---

bitwise operators
negative zero

— the &, |, ^, ~, <<, and >> operators with arguments that produce such a value; 617

Commentary

The bitwise operators operate directly on the individual bits of the value representation of integer types. If negative zero is supported by an implementation, there is the possibility that any of them could generate the bit pattern representing this value (starting from a bit pattern that does not represent negative zero). The use of bitwise operators on values having a signed integer type and exhibit implementation-defined and undefined behaviors (Also the standard does not guarantee that a negative zero value can be stored into an object without a change to its representation.)

negative zero 615
bitwise operations 946
signed types
negative zero 620
storing

Other Languages

Cobol does not include these operators.

Common Implementations

The Unisys A Series[1390] uses signed magnitude representation. If the operands have unsigned types, the sign bit is not affected by these bitwise operators. If the operands have signed types, the sign bit does take part in bitwise operations.

Example

The following will produce a negative zero on an implementation that uses a sign and magnitude representation; for implementations that use other representations the behavior is undefined.

```
1  int unsigned_zero(void)
2  {
3  return (-1) & (-2);
4  }
```

— the +, -, *, /, and % operators where one argument is a negative zero and the result is zero; 618

Commentary

The + and - operators exist in unary and binary form. The phrase *where one argument* could be taken to imply two operands (i.e., only the binary operator are intended). In the case of unary minus this requirement means that -0 does not represent negative zero. In fact only negating a negative zero can return a result of negative zero.

negative zero 615

— compound assignment operators based on the above cases. 619

Commentary

This is specified to ensure that all the cases are covered. Compound assignment is defined in terms of its equivalent binary operator.

compound assignment 1312
semantics

Other Languages

Cobol does not contain compound assignment operators.

Common Implementations

Compound assignment is commonly implemented using the associated operator followed by an assignment. Although processors having instructions capable of operating directly on the contents of storage are no longer common (e.g., the Motorola 680x0 family[968]), implementations are not required to operate directly on the contents of storage for this permission to apply.

---

620 It is unspecified whether these cases actually generate a negative zero or a normal zero, and whether a negative zero becomes a normal zero when stored in an object.

negative zero storing

Commentary

It is unspecified because developers may not have any control over what happens and the combinations of circumstances may be too disparate for an implementation to document. For instance, in one case a value may be operated on in a register before being written to storage (so any conversion that may be carried out by the store will not have happened), while in another case the same value may be operated on directly in its storage location. It is possible that a store operation, treating the contents of a register as signed, may convert the value to another kind of zero.

C90

This unspecified behavior was not called out in the C90 Standard, which did not discuss negative integer zeros.

C++

Negative zero is not discussed in the C++ Standard.

Other Languages

Cobol specifies when a negative zero is generated. For the object types involved, there is never any question of a negative zero being converted to any other value when it is written to storage.

Common Implementations

The Unisys A Series[1390] uses a sign and magnitude representation and does not copy the sign bit when storing a value having an **`unsigned int`** type.

Coding Guidelines

The surprising effects of negative zeros is something that will need to be brought to developers' attention if a processor with this characteristic is ever encountered. However, implementations that support more than one integer representation of zero are very rare. For this reason no recommendations are made.

---

621 If the implementation does not support negative zeros, the behavior of the `&`, `|`, `^`, `~`, `<<`, and `>>` operators with arguments that would produce such a value is undefined.

Commentary

On processors that use a sign and magnitude representation the behavior of the code `(-1) & (-2)` will either be acceptable to an implementation or result in undefined behavior.

611 sign and magnitude
617 bitwise operators
negative zero

C90

This undefined behavior was not explicitly specified in the C90 Standard.

C++

This specification was added in C99 and is not explicitly specified in the C++ Standard.

---

622 The values of any padding bits are unspecified.[45)]

integer padding bit values

unsigned integer padding bit values 596

Commentary

This duplicates a sentence given earlier. The earlier sentence could be read to apply to unsigned integer types only. This sentence applies to all integer types.

---

object representation same padding signed/unsigned

A valid (non-trap) object representation of a signed integer type where the sign bit is zero is a valid object representation of the corresponding unsigned type, and shall represent the same value. 623

Commentary

This is a requirement on the implementation. Two corresponding integer types must use the same number of bytes in their object representation. The value bits of a signed integer type are required to be a subset of the corresponding unsigned type and these value bits are at the same relative bit positions. If a signed integer object contains a positive value it can be copied, using `memcpy`, into an object having the corresponding unsigned integer type and the two value representations will compare equal. The signed integer type contains a sign bit, which may be a value bit in the corresponding unsigned integer type (in two's complement implementations), or it may not (in some sign and magnitude implementation— e.g., the Unisys A Series[1390]).

value bits 600 signed/unsigned positive 495 signed integer type subrange of equivalent unsigned type footnote 509 31 alignment 39

It is possible for the unsigned type to have more than one additional value bit. An earlier sentence deals with the value representation.

The interchangeability discussed in footnote 31 does not mention pointers to corresponding signed/unsigned integer types. The preceding requirement, along with the alignment requirements, is sufficient to deduce that pointers to corresponding signed/unsigned integer types can be used to access positive values held in the pointed-to objects.

C90

positive 495 signed integer type subrange of equivalent unsigned type

There was no such requirement on the object representation in C90, although this did contain the C99 requirement on the value representation.

C++

3.9.1p3 *. . . ; that is, each signed integer type has the same object representation as its corresponding unsigned integer type. The range of nonnegative values of a signed integer type is a subrange of the corresponding unsigned integer type, and the value representation of each corresponding signed/unsigned type shall be the same.*

Example

This requirement guarantees that:

```
1  #include <stdio.h>
2  #include <string.h>
3
4  signed short ss;
5  unsigned short us;
6
7  void f(void)
8  {
9  memcpy(&us, &ss, sizeof(ss));
10
11 if ((long)us == (long)ss)
12    printf("Value of ss is positive or (sizeof(short) == sizeof(long))\n");
13 }
```

is defined if the value of `ss` is positive.

For any integer type, the object representation where all the bits are zero shall be a representation of the value zero in that type. 624

Commentary

This sentence was added by the response to DR #263.

DR #263

Problem

Consider the code:

```
int v [10];
memset (v, 0, sizeof v);
```

Most programmers would expect this code to set all the elements of `v` *to zero. However, the code is actually undefined: it is possible for* `int` *to have a representation in which all-bits-zero is a trap representation (for example, if there is an odd-parity bit in the value).*

C90

The C90 Standard did not specify this requirement.

---

625 The *precision* of an integer type is the number of bits it uses to represent values, excluding any sign and padding bits.

precision
integer type

Commentary

This defines the term *precision* (when applied to integer types). This term is also used in the definition of the I/O conversion specifiers. The term *precision* has a common usage meaning in the sense of the accuracy of a measurement. It is also used in the context of floating types. Values or objects having a floating type are commonly referred to as being single- or double-precision.

335 precision
floating-point

C90

The definition of this term is new in C99.

C++

The term *precision* was added in C99 and is only defined in C++ for floating-point types.

Other Languages

The term *precision* is used in several different languages to mean a variety of different things.

Coding Guidelines

The term *width* is often used by developers when discussing the number of bits used to represent integer types. Use of the term *precision*, in an integer type context is limited to only a handful of locations in the C Standard. There are no obvious advantages to training developers to use this term in the context of integer types.

626 width
integer type

---

626 The *width* of an integer type is the same but including any sign bit;

width
integer type

Commentary

This defines the term *width* (when applied to integer types), $width = precision + one\_if\_there\_is\_a\_sign\_bit$. If the width of type A is less than the width of type B, then type A is said to be *narrower* than type B.

narrower type
1306 narrower
example

C90

The definition of this term is new in C99.

C++

The term *width* was added in C99 and is not defined in the C++ Standard.

Other Languages

The term *width* is used in several different languages to mean a variety of different things.

Coding Guidelines

Many terms are commonly used by developers to describe the number of bits in an integer type, including the term *number of bits*. Because there is no commonly used term, guideline documents will need to fully define the terms used. The term *width* has the advantage of being defined by the C Standard and fitting with the usage of the term *narrow*.

---

thus for unsigned integer types the two values are the same, while for signed integer types the width is one greater than the precision. 627

Commentary

rank 662 standard integer types

The standard does not require the precision of integer types having the same rank (i.e., a signed integer type and its equivalent unsigned form) to be the same. However, in practice they are the same in the majority of implementations.

---

footnote 45

45) Some combinations of padding bits might generate trap representations, for example, if one padding bit is a parity bit. 628

Commentary

footnote 606 44

This footnote duplicates footnote 44.

Regardless, no arithmetic operation on valid values can generate a trap representation other than as part of an exceptional condition such as an overflow. 629

Commentary

footnote 606 44

This footnote duplicates footnote 44.

All other combinations of padding bits are alternative object representations of the value specified by the value bits. 630

Commentary

footnote 606 44

This footnote duplicates footnote 44.

6.2.7 Compatible type and composite type

Commentary

This clause primarily deals with type compatibility across translation units. Few developers are aware of the concept of *composite type*. It is needed to handle the cases where there is more than one declaration of the same identifier in the same scope and name space.

Coding Guidelines

Translators are not required to perform type compatibility checks across translation units, and it is very rare to find one that does. Some static analysis tools perform various kinds of cross translation unit type checking.[681] Without automated tool support, these checks are unlikely to be carried out. The approach of these coding guideline is to recommend practices that remove the need to perform these checks, e.g., having a single, textually, point of declaration for identifiers.

identifier 422.1 declared in one file

---

compatible type if same type

Two types have *compatible type* if their types are the same. 631

Commentary

This defines the term *compatible type*. It is possible for two types to be compatible when their types are not the same type. When are two types the same? Other sentences in the standard specify when two types are the same.

qualified type 1494 to be compatible
pointer types 1562 to be compatible
array type 1585 to be compatible

C++

The C++ Standard does not define the term *compatible type*. It either uses the term *same type* or *different type*. The terms *layout-compatible* and *reference-compatible* are defined by the C++ Standard. The specification of layout-compatible structure (9.2p14) and layout compatible union (9.2p15) is based on the same set of rules as the C cross translation unit compatibility rules. The purpose of layout compatibility deals with linking objects written in other languages; C is explicitly called out as one such language.

Other Languages

All languages that have more than one type specify rules for how objects and values of different types may occur together as operands of operators. Languages in the Pascal family have a much stricter concept of type compatibility than C. It is possible for two types to be incompatible because their type names are different, even if their underlying representation is identical. Languages like Basic, Perl, and PL/1 take a much more laid-back approach, trying to provide conversions between almost any pair of types.

650 footnote 46

Coding Guidelines

Developers who have seen the advantages of a stricter definition of compatible type might be tempted to try to create guidelines that implement such a system; for instance, requiring name equivalence for types in C. However, an increase in strictness of the type system can only, practically, be enforced using automatic tool support. Developer training will also be required. Experience suggests that it takes months, if not a year or more, for some developers to be able to design and make use of good type categories. In:

type compatibility general guideline

```
1   typedef int frequency;
2   typedef int dpi;
3
4   extern frequency color_red;
5
6   dpi printer_resolution(char *printer_name)
7   {
8   /* ... */
9   return color_red;
10  }
```

the type of the expression returned by `printer_resolution` is compatible with the return type.

The same source rewritten in Ada would result in a diagnostic being issued; the type of the return expression is not compatible with the declared return type of the function. Yes, the developer-defined types, `frequency` and `dpi`, do have the same underlying basic type, but it makes no sense to return a frequency from this function. The expected return type is `dpi`.

It is believed that type checking of this kind, coupled with source code that makes extensive use of the appropriate type definitions, reduces the cost of software development (because in many cases unintended or ill-formed constructs are flagged, and can be corrected at translation time). However, there have been no studies investigating the cost effectiveness of strong typing.

---

632 Additional rules for determining whether two types are compatible are described in 6.7.2 for type specifiers, in 6.7.3 for type qualifiers, and in 6.7.5 for declarators.[46)]

compatible type additional rules

Commentary

Another way of expressing the idea behind these rules is that compatible types always have the same representation and alignment requirements. The following are the five sets of type compatibility rules:

1. Same type.
2. Structure/union/enumerated types across translation units (the following C sentences).
3. Type specifier rules.
4. Type qualifier rules.

631 compatible type if
1378 type specifier syntax
1476 type qualifier syntax

declarator syntax 1547

5. Declarator rules.

compatible separate translation units

Moreover, two structure, union, or enumerated types declared in separate translation units are compatible if their tags and members satisfy the following requirements: 633

Commentary

These requirements apply if the structure or union type was declared via a typedef or through any other means. Because there can be more than one declaration of a type in the same translation unit, these requirements really apply to the composite type in each translation unit.

compos-ite type 642

In the following list of requirements, those that only apply to structures, unions, enumerations, or a combination thereof are explicitly called out as such. There is no requirement that prevents a structure type from being compatible with an appropriate union type; at the time of writing this issue is the subject of an outstanding DR (251). Two types are compatible if they obey both of the following requirements:

- *Tag compatibility.*
  1. If both types have tags, both shall be the same.
  2. If one, or neither, type has a tag, there is no requirement to be obeyed.
- *Member compatibility.* Here the requirement is that for every member in both types there is a corresponding member in the other type that has the following properties:
  1. The corresponding members have a compatible type.
  2. The corresponding members either have the same name or are unnamed.
  3. For structure types, the corresponding members are defined in the same order in their respective definitions.
  4. For structure and union types, the corresponding members shall either both be bit-fields having the same width, or neither shall be bit-fields.
  5. For enumerated types, the corresponding members (the enumeration constants) have the same value.

C90

Moreover, two structure, union, or enumerated types declared in separate translation units are compatible if they have the same number of members, the same member names, and compatible member types;

There were no requirements specified for tag names in C90. Since virtually no implementation performs this check, it is unlikely that any programs will fail to link when using a C99 implementation.

C++

The following paragraph applies when both translation units are written in C++.

3.2p5 *There can be more than one definition of a class type (clause 9), enumeration type (7.2), inline function with external linkage (7.1.2), class template (clause 14), non-static function template (14.5.5), static data member of a class template (14.5.1.3), member function template (14.5.1.1), or template specialization for which some template parameters are not specified (14.7, 14.5.4) in a program provided that each definition appears in a different translation unit, and provided the definitions satisfy the following requirements.*

There is a specific set of rules for dealing with the case of one or more translation units being written in another language and others being written in C++:

> *Linkage (3.5) between C++ and non-C++ code fragments can be achieved using a* `linkage-specification`*:* 7.5p2
>
> . . .
>
> *[Note: . . . The semantics of a language linkage other than C++ or C are implementation-defined.]*

which appears to suggest that it is possible to make use of defined behavior when building a program image from components translated using both C++ and C translators.

The C++ Standard also requires that:

> *The* `class-key` *or* **`enum`** *keyword present in the* `elaborated-type-specifier` *shall agree in kind with the declaration to which the name in the* `elaborated-type-specifier` *refers.* 7.1.5.3p3

Other Languages

In many languages that support separate compilation, the implementation is required to store information on the types of identifiers defined in one unit that may be used in other units. This information is then read by a translator when already-translated units are referenced. Such a separate compilation model means that there is only ever one declaration of a type. (there is the configuration-management issue caused by changes to an externally visible type needing to be percolated through to any units that reference it through retranslation.)

Common Implementations

It is very rare for an implementation to perform cross translation unit checking of structure, union, or enumerated types. Most linkers (translation phase 8) simply match-up identifiers from different translation units, that have the same spelling. The extra checks performed by C++ implementations usually only apply to identifiers having function type (they are needed to support function overloading).

139 translation phase 8

Coding Guidelines

Having the same identifier declared in more than one source file opens the door to a modification of a declaration in one source file not being mirrored by equivalent changes in other source files. If there is only one source file containing the declaration, a developer header file, this problem disappears.

type definition only one
422.1 identifier declared in one file

Dev 422.1 The declaration of an incomplete structure or union type may occur in a header file, provided any subsequent completion of its type occurs in only one of the source files making up a complete program.

Example

file_1.c

```
1 union u { int m1 : 3; int : 8; int : 8; };
```

file_2.c

```
1 union u { int m1 : 3; int : 8;          }; /* Not compatible with declaration in file_1.c */
```

---

634 If one is declared with a tag, the other shall be declared with the same tag.

tag declared with same

Commentary

The same tag, as in the spelling of the tags, shall be identical (subject to translator limits on the length of internal identifiers). Nothing is said about members here because one or more of the types may be incomplete.

C90

This requirement is not specified in the C90 Standard.
Structures declared using different tags are now considered to be different types.

xfile.c

```
#include <stdio.h>

extern int WG14_N685(struct tag1 *, struct tag1 *);

struct tag1 {
            int m1,
                m2;
            } st1;

void f(void)
{
if (WG14_N685(&st1, &st1))
   {
   printf("optimized\n");
   }
else
   {
   printf("unoptimized\n");
   }
}
```

yfile.c

```
struct tag2 {
            int m1,
                m2;
            };
struct tag3 {
            int m1,
                m2;
            };

int WG14_N685(struct tag2 *pst1,
              struct tag3 *pst2)
{
pst1->m1 = 2;
pst2->m1 = 0;   /* alias? */

return pst1->m1;
}
```

An optimizing translator might produce **optimized** as the output of the program, while the same translator with optimization turned off might produce **unoptimized** as the output. This is because translation unit `y.c` defines `func` with two parameters each as pointers to different structures, and translation unit `x.c` calls `WG14_N685func` but passes the address of the same structure for each argument.

Other Languages

Very few other languages make use of the concept of tags.

Coding Guidelines

While the spelling of tag names might be thought not to alter the behavior of a program, the preceding example shows how a translator might rely on the information provided by tag names to make optimization decisions. While translators that take such information into account are rare, at the time of this writing, the commercial pressure to increase the quality of generated machine code means that such translators are likely

to become more common. The guideline recommendation dealing with a single point of declarations is applicable here.

422.1 identifier declared in one file

Another condition is where two unrelated structure or union types, in different translation units, use the same tag name. Identifiers in the tag name space have internal linkage and the usage may occur in a strictly conforming program. However, the issue is not language conformance but likelihood of developer confusion. The guideline recommendation dealing with reusing identifier names is applicable here.

792.3 identifier reusing names

Example

file_1.c

```
1  extern struct S {
2                  int m1;
3                  } x;
```

file_2.c

```
1  extern struct S {
2                  int m1;
3                  } x;
```

file_3.c

```
1  extern struct T {
2                  int m1;
3                  } x;
```

The declarations of x in `file_1.c` and `file_2.c` are compatible. The declaration in `file_3.c` is not compatible.

---

635 If both are complete types, then the following additional requirements apply:

Commentary

The only thing that can be said about the case where one type is complete and the other is incomplete is that their tag names match. There is no danger of mismatch of member names, types, or relative ordering with a structure if the type is incomplete. If both are complete, there is more information available to be compared.

Except in one case, a pointer to an incomplete structure type, a type used in the declaration of an object or function must be completed by the end of the translation unit that contains it.

---

636 there shall be a one-to-one correspondence between their members such that each pair of corresponding members are declared with compatible types, and such that if one member of a corresponding pair is declared with a name, the other member is declared with the same name.

Commentary

For structure types, this requirement ensures that the same storage location is always interpreted in the same way when accessed through a specific member. It is also needed to ensure that the offsets of the storage allocated for successive members is identical for both types. For union types, this requirement ensures that the same named member is always interpreted in the same way when accessed.

What does *corresponding member* mean if there are no names to match against? The ordering rule is discussed elsewhere.

637 members corresponding

The standard does not give any explicit rule for breaking the recursion that can occur when checking member types for compatibility. For instance:

file_3.c

```
1  extern struct  S4 {
2                    struct S4 *mem;
3                    } glob;
```

file_4.c
```
1  extern struct  S4 {
2                     struct S4 *mem;
3                     } glob;
```

enumeration constant type 864

Enumeration constants always have an implied type of **int**.

The reply to DR #013 explains that the Committee feels the only reasonable solution is for the recursion to stop and the two types to be compatible.

C90

. . . if they have the same number of members, the same member names, and compatible member types;

The C90 Standard is lax in that it does not specify any correspondence for members defined in different structure types, their names and associated types.

C++

3.2p5 *— each definition of D shall consist of the same sequence of tokens; and*

— in each definition of D, corresponding names, looked up according to 3.4, shall refer to an entity defined within the definition of D, or shall refer to the same entity, after overload resolution (13.3) and after matching of partial template specialization (14.8.3), except that a name can refer to a ***const*** *object with internal or no linkage if the object has the same integral or enumeration type in all definitions of D, and the object is initialized with a constant expression (5.19), and the value (but not the address) of the object is used, and the object has the same value in all definitions of D; and*

The C Standard specifies an effect, compatible types. The C++ Standard specifies an algorithm, the same sequence of tokens (not preprocessing tokens), which has several effects. The following source files are strictly conforming C, but undefined behavior in C++.

file_1.c
```
1  extern struct {
2                short s_mem1;
3                } glob;
```

file_2.c
```
1  extern struct {
2                short int s_mem1;
3                } glob;
```

9.2p14 *Two POD-struct (clause 9) types are layout-compatible if they have the same number of members, and corresponding members (in order) have layout-compatible types (3.9).*

9.2p15 *Two POD-union (clause 9) types are layout-compatible if they have the same number of members, and corresponding members (in any order) have layout-compatible types (3.9).*

Layout compatibility plays a role in interfacing C++ programs to other languages and involves types only. The names of members plays no part.

Other Languages

Those languages that have a more sophisticated model of separate compilation usually ensure that textually, the same sequence of tokens is seen by all separately translated source files.

Coding Guidelines

Using different names for corresponding members is unlikely to change the generated machine code. However, it could certainly be the cause of a great deal of developer confusion. The guideline recommendation specifying a single point of declaration is applicable here.

422.1 identifier declared in one file

Example

In the two files below the two declarations of x1 are compatible, but neither x2 or x3 are compatible across translation units.

file_1.c

```
1  extern struct S1 {
2                   int m1;
3                   } x1;
4  extern struct S2 {
5                   int m1;
6                   } x2;
7  extern struct S3 {
8                   int m1;
9                   } x3;
```

file_2.c

```
1  extern struct S1 {
2                   int m1;
3                   } x1;
4  extern struct S2 {
5                   long m1;
6                   } x2;
7  extern struct S3 {
8                   int m_1;
9                   } x3;
```

637 For two structures, corresponding members shall be declared in the same order.

members corresponding

Commentary

On first reading this sentence appears to be back to front; shouldn't the order decide what the corresponding members are? In fact, the wording is a constructive definition of the term *corresponding*. The standard defines a set of requirements that must be met, not an algorithm for what to do. It is the developer's responsibility to ensure that the requirements are met. In the case of unnamed bit-fields, this ordering requirement means there is only one way of creating a correspondence that meets them.

These requirements ensure that members of the same structure type have the same offsets within different definitions (in different translation units) of that structure type. There is no corresponding requirement on union types because all members start at the same address offset. The order in which union members are declared makes no difference to their member storage layout.

1207 pointer to union members compare equal
1354 storage layout

Enumeration constants may also be declared in different orders within their respective enumerated type definitions.

C90

. . . for two structures, the members shall be in the same order;

The C90 Standard is lax in that it does not specify how a correspondence is formed between members defined in different structure definitions. The following two source files could have been part of a strictly conforming program in C90. In C99 the behavior is undefined and, if the output depends on `glob`, the program will not be strictly conforming.

file_1.c

```
extern struct {
              short s_mem1;
              int i_mem2;
              } glob;
```

file_2.c

```
extern struct {
              int i_mem2;
              short s_mem1;
              } glob;
```

While the C90 Standard did not require an ordering of corresponding member names, developer expectations do. A diagnostic, issued by a C99 translator, for a declaration of the same object as a structure type with differing member orders, is likely to be welcomed by developers.

Coding Guidelines

identifier declared in one file 422.1

The guideline recommendation specifying a single point of declaration is applicable here. For each structure type, its member names are in their own unique name space. There is never an issue of other structure types, containing members using the same set of names, influencing other types.

Example

In the following example none of the members are not declared in the same order; however, it only matters in the case of structures.

file_1.c

```
extern struct S1 {
                  int m1;
                  char m2;
                  } x;
extern union U1 {
                 int m1;
                 char m2;
                 } y;

extern enum {E1, E2} z;
```

file_2.c

```
extern struct S2 {
                  char m2;
                  int m1;
                  } x;
extern union U1 {
                 char m2;
                 int m1;
                 } y;

extern enum {E2=1, E1=0} z;
```

638 For two structures or unions, corresponding bit-fields shall have the same widths.

Commentary

The common initial sequence requirement ensures that the decision on where to allocate bit-fields within a storage unit is deterministic. If corresponding bit-fields have the same width they will be placed in the same location, relative to other members, in both structure types. In the case of union types a bit-field can occur in any position within the lowest address storage unit. Requiring that the members have the same width ensures that implementations assign them the same bit offsets within the storage unit.

1038 common initial sequence

Common Implementations

Implementations assign locations within storage units to bit-fields based on their width (and type if non-**int** bit-fields are supported as an extension). These factors are dealt with by these type compatibility requirements.

1395 bit-field shall have type

Coding Guidelines

The guideline recommendation specifying a single point of declaration is applicable here.

422.1 identifier declared in one file

639 For two enumerations, corresponding members shall have the same values.

Commentary

The only requirement is on the value, not on how that value was specified in the source. For instance, it could have been obtained through a direct assignment of any number of constant expressions (all returning the same value), or implicitly calculated to be one greater than the previous enumeration constant value.

C90

> *. . . for two enumerations, the members shall have the same values.*

The C90 Standard is lax in not explicitly specifying that the members with the same names have the same values.

C++

> *— each definition of D shall consist of the same sequence of tokens; and* 3.2p5

The C++ requirement is stricter than C. In the following two translation units, the object `e_glob` are not considered compatible in C++:

file_1.c
```
1 extern enum {A = 1, B = 2} e_glob;
```

file_2.c
```
1 extern enum {B= 2, A = 1} e_glob;
```

Common Implementations

The debugging information written out to the object file in some implementations uses an implied enumeration constant ordering (i.e., that given in the definition). This can cause some inconsistencies in the display of enumeration constants, but debuggers are outside the scope of the standard.

Coding Guidelines

The guideline recommendation specifying a single point of declaration is applicable here.

422.1 identifier declared in one file

Example

In the following two files members having the same name appear in the same order, but their values are different.

file_1.c
```
extern enum {E1, E2} z;
```

file_2.c
```
extern enum {E1 = 99, E2} z;
```

---

same object have compatible types
same function have compatible types

All declarations that refer to the same object or function shall have compatible type; 640

Commentary

This *shall* is not in a constraint, making it undefined behavior if different declarations of the same object are not compatible types. There can be more than one declaration referring to the same object or function if

- they occur in different translation units, in which case they will have external linkage;
- they occur in the same translation unit with internal linkage, or external linkage.

no linkage 424
identifier declaration is unique

It is not possible to have multiple declarations of identifiers that have no linkage. The case:

file_1.c
```
extern int i;
```

file_2.c
```
extern enum {e1, e2} i;
```

(assuming that this enumerated type is compatible with the type **int**) is something of an oddity.

C++

3.2p5 — *each definition of D shall consist of the same sequence of tokens; and*

— *in each definition of D, corresponding names, looked up according to 3.4, shall refer to an entity defined within the definition of D, or shall refer to the same entity, after overload resolution (13.3) and after matching of partial template specialization (14.8.3), except that a name can refer to a* ***const*** *object with internal or no linkage if the object has the same integral or enumeration type in all definitions of D, and the object is initialized with a constant expression (5.19), and the value (but not the address) of the object is used, and the object has the same value in all definitions of D; and*

3.5p10 *After all adjustments of types (during which typedefs (7.1.3) are replaced by their definitions), the types specified by all declarations referring to a given object or function shall be identical, except that declarations for an array object can specify array types that differ by the presence or absence of a major array bound (8.3.4).*

The C++ Standard is much stricter in requiring that the types be identical. The **int**/**enum** example given above would not be considered compatible in C++. If translated and linked with each other the following source files are strictly conforming C, but undefined behavior in C++.

file_1.c
```
extern short es;
```

file_2.c
```
extern short int es = 2;
```

Other Languages

Languages that have a type system usually require that declarations of the same object or function, in separately translated source files, have compatible (however that term is defined) types.

Common Implementations

It is very rare for an implementation to do cross translation unit type compatibility checking of object and function declarations. C++ implementations use some form of name mangling to resolve overloaded functions (based on the parameter types). Linkers supporting C++ usually contain some cross translation unit checks on function types. If C source code is translated by a C++ translator running in a C compatibility mode, many of these link-time checks often continue to be made.

Coding Guidelines

The guideline recommendation specifying a single point of declaration is applicable here. Within existing code, old-style function declarations often still appear in headers. Such usage does provide a single declaration. However, these declarations do not provide all of the type information that it is possible to made available. For economic reasons developers may choose to leave these existing declarations unchanged.

422.1 identifier declared in one file

Example

Most implementations will translate and create a program image of the following two files without issuing any diagnostic:

file_1.c

```
extern int f;

int main(void)
{
f++;
return 0;
}
```

file_2.c

```
extern int f(void)
{
return 0;
}
```

641 otherwise, the behavior is undefined.

Commentary

The most common behavior is to create a program image without issuing a diagnostic. The execution-time behavior of such a program image is very unpredictable.

C++

A violation of this rule on type identity does not require a diagnostic. 3.5p10

The C++ Standard bows to the practical difficulties associated with requiring implementations to issue a diagnostic for this violation.

Other Languages

Some languages require that a diagnostic be issued for this situation. Others say nothing about how their translators should behave in this situation.

Common Implementations

The linkers in most implementations simply resolve names without getting involved in what those names refer to. In many implementations storage for all static duration objects is aligned on a common boundary (e.g., a two- or eight-byte boundary). This can mean, for scalar types, that there is sufficient storage available, whatever different types the same object is declared with. (Linkers usually obtain information on the number of bytes in an object from the object-file containing its definition, ignoring any such information that might be provided in the object-files containing declarations of it.) The effect of this link-time storage organization strategy is that having the same object declared with different scalar types, in different translation units, may not result in any unexpected behaviors (other objects being modified as a side-effect of assigning to the object) occurring.

---

composite type

A *composite type* can be constructed from two types that are compatible; 642

Commentary

This C paragraph defines the term *composite type*; which are rarely talked about outside of C Standards-related discussions. Composite types arise because C allows multiple declarations, in some circumstances, of the same object or function. Two declarations of the same identifier only need be compatible; neither are they required to be token-for-token identical. In practice composite types are applied to types occurring in the same translation unit. There is no construction of composite types across translation units.

C++

One of the two types involved in creating composite types in C is not supported in C++ (function types that don't include prototypes) and the C++ specification for the other type (arrays) is completely different from C.

array 644 composite type
conditional 1282 operator pointer to qualified types

Because C++ supports operator overloading type qualification of pointed-to types is a more pervasive issue than in C (where it only has to be handled for the conditional operator). The C++ Standard defines the concept of a *composite pointer type* (5.9p2). This specifies how a result type is constructed from pointers to qualified types, and the null pointer constant and other pointer types.

Other Languages

In most languages two types can only be compatible if they are token-for-token identical, so the need for a composite type does not usually occur.

Coding Guidelines

identifier 422.1 declared in one file

If the guideline recommendation specifying a single point of declarations is followed, a composite type will only need to be created in one case— in the translation unit that defines an object, or function, having external linkage.

Example

Assume the type **int** is the type that all enumerated types are compatible with:

```
1  enum ET {r, w, b};
2
3  extern enum ET obj;
4  extern int obj;
```

Possible composite type are the enumeration, ET, or the basic type **int**.

---

it is a type that is compatible with both of the two types and satisfies the following conditions: 643

Commentary

A composite type is formed by taking all the available information from both type declarations to create a type that maximizes what is known. The specification in the standard lists the properties of the composite type in relation to the two types from which it is created. It is not a set of rules to follow in constructing such a type. The possible composite types meeting the specification is not always unique.

644 — If one type is an array of known constant size, the composite type is an array of that size;

array composite type

Commentary

For them to be compatible, the other array would have to be an incomplete array type. In this case encountering a declaration of known constant size also completes the type.

548 known constant size

C90

If one type is an array of known size, the composite type is an array of that size;

Support for arrays declared using a nonconstant size is new in C99.

C++

An incomplete array type can be completed. But the completed type is not called the composite type, and is regarded as a different type:

. . . ; the array types at those two points ("array of unknown bound of T" and "array of N T") are different types. 3.9p7

The C++ Standard recognizes the practice of an object being declared with both complete and incomplete array types with the following exception:

After all adjustments of types (during which typedefs (7.1.3) are replaced by their definitions), the types specified by all declarations referring to a given object or function shall be identical, except that declarations for an array object can specify array types that differ by the presence or absence of a major array bound (8.3.4). 3.5p10

645 otherwise, if one type is a variable length array, the composite type is that type.

Commentary

This situation can only occur if the array type appears in function prototype scope. In this scope a VLA type is treated as if the size was replaced by *. The case of one of the array types having a constant size is covered by the previous rule; the remaining possibilities are another VLA type or an incomplete array type. In both cases a VLA type will be compatible with them, providing their element types are compatible.

1581 VLA size treated as *
1585 array type to be compatible

C90

Support for VLA types is new in C99.

C++

Variable length array types are new in C99. The C++ library defined container classes (23), but this is a very different implementation concept.

Example

The composite type of:

```
1  extern int i(int m, int p4[m]);
2  extern int i(int n, int p4[n]);
```

is:

```
1  extern int i(int m, int p4[*]); /* Parameter names are irrelevant. */
```

function composite type

— If only one type is a function type with a parameter type list (a function prototype), the composite type is a function prototype with the parameter type list. 646

Commentary

The other type could be an old-style function declaration. If the other type is also a function prototype, the compatibility requirements mean that additional information can only be provided if the parameters have a pointer-to function type (which is an old-style function declaration). This issue is discussed in more detail elsewhere.

parameter 1616 qualifier in composite type

C++

All C++ functions must be declared using prototypes. A program that contains a function declaration that does not include parameter information is assumed to take no parameters.

```
1  extern void f();
2
3  void g(void)
4  {
5  f(); // Refers to a function returning int and having no parameters
6       /* Non-prototype function referenced */
7  }
8
9  void f(int p) /* Composite type formed, call in g linked to here */
10                // A different function from int f()
11                // Call in g does not refer to this function
12 { /* ... */ }
```

Other Languages

Most languages either require that the types of parameters be given or that the types not be given. C is unusual in allowing both kinds of function declarations. Both C++ and Java require that the parameter types always be given.

— If both types are function types with parameter type lists, the type of each parameter in the composite parameter type list is the composite type of the corresponding parameters. 647

Commentary

This is a recursive definition. If a parameter has pointer-to function type, then a composite type will be constructed for its parameters, and so on. Wording elsewhere in the standard specifies that the composite type of parameters is the unqualified version of their types.

parameter 1616 qualifier in composite type

C++

C++ allows functions to be overloaded based on their parameter types. An implementation must not form a composite type, even when the types might be viewed by a C programmer as having the same effect:

```
1  /*
2   * A common, sloppy, coding practice.  Don't declare
3   * the prototype to take enums, just use int.
4   */
5  extern void f(int);
6
7  enum ET {E1, E2, E3};
8
9  void f(enum ET p) /* composite type formed, call in g linked to here */
10                   // A different function from void f(int)
11                   // Call in g does not refer here
12 { /* ... */ }
13
14 void g(void)
```

```
{
f(E1); // Refers to a function void (int)
       /* Refers to definition of f above */
}
```

Example

It is thus possible to slowly build up a picture of what the final function prototype is:

```
void f();
void f(int p1[], const int p2, float *          p3);
void f(int p1[2],      int p2, float *          p3);
/*
 * Composite type is: void f(int p1[2], int p2, float *p3);
 */
void f(int p1[], const int p2, float * volatile p3);
/*
 * Composite type is unchanged.
 */
```

---

648 These rules apply recursively to the types from which the two types are derived.

Commentary

The possible types, not already covered before, to which these rules can be applied are array, structure, union, and pointer. Although it is not possible to declare an array of incomplete type, an array of pointer-to functions would create a recursive declaration that would need to be processed by these rules.

C++

The C++ Standard has no such rules to apply recursively.

Other Languages

Languages that support nesting of derived types usually apply any applicable rules recursively.

---

649 For an identifier with internal or external linkage declared in a scope in which a prior declaration of that identifier is visible,[47)] if the prior declaration specifies internal or external linkage, the type of the identifier at the later declaration becomes the composite type.

prior declaration visible

Commentary

Any change to an object's type, to a composite type, will not affect the way that accesses to it are handled. Any operation that accesses an object after its first declaration, but before a second declaration, will behave the same way after any subsequent declaration is encountered.

It is possible for references to an identifier, having a function type, to be different after a subsequent declaration. This occurs if the type of a parameter is not compatible with its promoted type (the issue of the composite type of function types is also discussed elsewhere). For instance:

675 integer promotions
1616 parameter qualifier in composite type

```
extern void f();

void g_1(void)
{
f('w');
}

extern void f(char);

void g_2(void)
{
f('x');
}
```

function definition ends with ellipsis 1011

the first call to `f` uses the information provided by the first, old-style, declaration of `f`. At the point of this first call, the behavior is undefined (assuming the function definition is defined using a prototype). At the point of the second call to `f`, in `g_2`, the composite type matches the definition and the behavior is defined.

C90

The wording in the C90 Standard:

> *For an identifier with external or internal linkage declared in the same scope as another declaration for that identifier, the type of the identifier becomes the composite type.*

was changed to its current form by the response to DR #011, question 1.

C++

3.5p9 *Two names that are the same (clause 3) and that are declared in different scopes shall denote the same object, reference, function, type, enumerator, template or namespace if*

— both names have external linkage or else both names have internal linkage and are declared in the same translation unit; and

— both names refer to members of the same namespace or to members, not by inheritance, of the same class; and

— when both names denote functions, the function types are identical for purposes of overloading; and

This paragraph applies to names declared in different scopes; for instance, file scope and block scope externals.

13p1 *When two or more different declarations are specified for a single name in the same scope, that name is said to be overloaded. By extension, two declarations in the same scope that declare the same name but with different types are called overloaded declarations. Only function declarations can be overloaded; object and type declarations cannot be overloaded.*

The following C++ requirement is much stricter than C. The types must be the same, which removes the need to create a composite type.

3.5p10 *After all adjustments of types (during which typedefs (7.1.3) are replaced by their definitions), the types specified by all declarations referring to a given object or function shall be identical, except that declarations for an array object can specify array types that differ by the presence or absence of a major array bound (8.3.4). A violation of this rule on type identity does not require a diagnostic.*

The only composite type in C++ are composite pointer types (5.9p2). These are only used in relational operators (5.9p2), equality operators (5.10p2, where the term common type is used), and the conditional operator (5.16p6). C++ composite pointer types apply to the null pointer and possibly qualified pointers to **`void`**.

If declarations of the same function do not have the same type, the C++ link-time behavior will be undefined. Each function declaration involving different adjusted types will be regarded as referring to a different function.

```
1  extern void f(const int);
2  extern void f(int);        /* Conforming C, composite type formed */
3                             // A second (and different) overloaded declaration
```

Example

The following illustrates various possibilities involving the creation of composite types (the behavior is undefined because the types are not compatible with each other).

```
1   extern int a[];
2
3   void f(void)
4   {
5   extern int a[3]; /* Composite type applies inside this block only. */
6   }
7
8   void g(void)
9   {
10  extern int a[4]; /*
11                    * Compatible with file scope a[],
12                    * composite type applies to this block.
13                    */
14  }
15
16  void h(void)
17  {
18  float a;
19     {
20     extern int a[5]; /* No prior declaration visible. */
21     }
22  }
23
24  extern int a[5]; /* Composite type is int a[5]. */
```

650 46) Two types need not be identical to be compatible.

footnote 46

Commentary

Neither do two types have to consist of the same sequence of tokens to be the same types. It is possible for different sequences of tokens to represent the same type. The standard does not specify what it means for two types to be identical.

1380 type specifiers sets of

C++

The term *compatible* is used in the C++ Standard for *layout-compatible* and *reference-compatible*. Layout compatibility is aimed at cross-language sharing of data structures and involves types only. The names of structure and union members, or tags, need not be identical. C++ reference types are not available in C.

Other Languages

Languages take different approaches to the concept of compatibility. Pascal and many languages influenced by it use name equivalence (every type is unique and denoted by its name). Other languages, for instance CHILL, support *structural equivalence* (two types are the same if the underlying representation is the same, no matter how the declarations appear in the text). In fact CHILL specifies a number of different kinds of equivalence, which are used in different contexts.

structural equivalence

```
1   /*
2    * Some languages specify that the first two definitions of X are not
3    * compatible, because the structure of their declarations is different.
4    * Languages that do not expose the internal representation of a type
5    * could regard the last definition of X as being compatible with the
6    * previous two.  There are matching members and their types are the same.
7    */
8   struct X {
9             int a,
```

```
                b;
          };
struct X {
           int a;
           int b;
          };
struct X {
           int b;
           int a;
          };

/*
 * From the structural point of view the following
 * declarations are all different.
 */
extern unsigned int ui_1;
extern unsigned ui_2;
extern int unsigned ui_3;
```

Some languages (e.g., Ada, Java, and Pascal) base type equivalence on names, hence this form is called *name equivalence*. The extent to which name equivalence is enforced for arithmetic types varies between languages. Some languages are strict, while others have a more relaxed approach (Ada offers the ability to specify which approach to use in the type declaration).

```
typedef unsigned int UINT_1;
typedef unsigned int UINT_2;

/*
 * Some languages would specify that the following objects were not
 * compatible because they were declared with types that had different
 * names (an anonymous one in the last case).  Others would be more
 * relaxed, because the underlying types were the same.
 */
extern UINT_1 ui_1;
extern UINT_2 ui_2;
extern unsigned int ui_3;

/*
 * All languages based on name equivalence would treat the following
 * as different types that were not compatible with each other.
 */
typedef struct {
                int x, y;
               } coordinate;
typedef struct {
                int x, y;
               } position;
typedef int APPLES;
typedef int ORANGES;
```

Coding Guidelines

type compatibility 631
general guideline

Most coding guideline documents recommend a stricter interpretation of *identical* types than that made by the C Standard.

---

footnote 47

47) As specified in 6.2.1, the later declaration might hide the prior declaration. 651

Commentary

outer scope 413
identifier hidden

To be exact a different declaration, in a scope between that of the file scope declaration and the current declaration, might hide the later declaration.

652 EXAMPLE Given the following two file scope declarations:

```
int f(int (*)(), double (*)[3]);
int f(int (*)(char *), double (*)[]);
```

The resulting composite type for the function is:

```
int f(int (*)(char *), double (*)[3]);
```

C++

The C++ language supports the overloading of functions. They are overloaded by having more than one declaration of a function with the same name and return type, but different parameter types. In C++ the two declarations in the example refer to different versions of the function `f`.

6.3 Conversions

653 Several operators convert operand values from one type to another automatically.

operand convert automatically

Commentary

The purpose of these implicit conversions is to reduce the number of type permutations that C operators have to deal with. Forcing developers to use explicit casts was considered unacceptable. There is also the practical issue that most processors only contain instructions that can operate on a small number of scalar types.

Other Languages

There are two main lines of thinking about binary operators whose operands have different types. One is to severely restrict the possible combination of types that are permitted, requiring the developer to explicitly insert casts to cause the types to match. The other (more developer-friendly, or the irresponsible approach, depending on your point of view) is to have the language define implicit conversions, allowing a wide range of differing types to be operated on together.

Common Implementations

Conversion of operand values on some processors can be a time-consuming operation. This is one area where the as-if rule can be applied to make savings— for instance, if the processor has instructions that support operations on mixed types.

Coding Guidelines

Experience suggests that implicit conversions are a common cause of developer miscomprehension and faults in code. Some guideline documents only consider the problems caused by these implicit conversions and simply recommend that all conversions be explicit. The extent to which these explicit conversions increase the cost of program comprehension and are themselves a source of faults is not considered.

The first issue that needs to be addressed is why the operands have different types in the first place. Why weren't they declared with the same type? C developers are often overly concerned with using what they consider to be the *right* integer type. This usually involves attempting to use the type with the smallest representable range needed for the job. Using a single integer type would remove many implicit conversions, and is the recommended practice.

480.1 object int type only

How should those cases where the operands do have different types be handled? Unfortunately, there is no published research on the effects, on developer source code comprehension performance, of having all conversions either implicit or explicit in the source. Without such experimental data, it is not possible to make an effective case for any guideline recommendation.

The potential costs of using explicit conversions include:

- Ensuring that the types used in conversions continue to be the correct ones when code is modified. For instance, the expression `(unsigned int)x+y` may have been correct when the source was originally written, but changes to the declaration of `y` may need to be reflected in changes to the type used to

typedef name syntax 1629

cast x. Typedef names offer a partial solution to the dependence between the declaration of an object and its uses in that they provide a mechanism for dealing with changes in x's type. However, handling changes to both y's and y's types is more complex.

- An explicit conversion has to be explicitly read and comprehended, potentially increasing a reader's cognitive load for that expression. Depending on the reason for reading the expression, information on conversions taking place may represent a level of detail below what is required (readers are then paying a cost for no benefit). For instance, in the expression `(unsigned int)x+y` knowing that `x` and `y` are referenced together may be the only information of interest to a reader. The fact that they are added together may be the next level of detail of interest. The exact sequence of operations carried out in the evaluation of the expression being the final level of detail of interest.

The potential costs of relying on implicit conversions include:

- Modifications to the source may change the implicit conversions performed, resulting in a change of program behavior. While this situation is familiar to developers, it can also occur when explicit conversions are used. The implicit conversion case is more well known because most source relies on them rather than explicit conversions. It is not known whether the use of explicit conversions would result in a decrease or increase in faults whose root cause was conversion-related.
- In those cases where readers need to comprehend the exact behavior of an expression's evaluation, effort will need to be invested in deducing what conversions are performed. In the case of explicit conversions, it is generally assumed that the conversions specified are correct and it is often also assumed that they are the only ones that occur. No effort has to be expended in recalling operand types from (human) memory, or searching the source to obtain this information.

There is no experimental evidence showing that use of explicit conversions leads to fewer faults. Those cases where a potential benefit from using an explicit conversion might be found, include:

- Where it is necessary to comprehend the details of the evaluation of an expression, the cognitive effort needed to deduce the conversions performed will be reduced. It is generally assumed that the result of explicit conversions will not themselves be the subject of any implicitly conversions, and that the result type will be that of the explicit conversion.
- Experience has shown that developer beliefs about what implicit conversions will occur are not always the same as what the standard specifies. For instance, a common misconception is that no implicit conversion takes places if the operands have exactly the same type. Your author has heard several explanations for why a conversion is unnecessary, but has never recorded these (so no analysis is possible). A good example is the following:

```
1  unsigned char c1, c2, c3;
2
3  if (c1 + c2 > c3)
```

integer promotions 675

A developer who believes that no conversions take place will be under the impression that `c1+c2` will always return a result that is within the range supported by the type **`unsigned char`**. In fact, the integer promotions are applied to all the operands and the result of `c1+c2` can exceed the range supported by the type **`unsigned char`** (assuming the type **`int`** has a greater precision than the type **`unsigned char`**, which is by far the most common situation).

The following is one potential benefit of using implicit conversions:

- In those cases where exact details on the evaluation of an expression is not required, a reader of the source will not have to invest cognitive effort in reading and comprehending any explicit conversion operations.

The faults associated with mixing signed and unsigned operands are often perceived as being the most common conversion faults. Whether this perception is caused by the often-dramatic nature of these faults, or reflects actual occurrences, is not known.

Usage

Usage information on the cast operator is given elsewhere (see Table 1134.1).

Table 653.1: Occurrence of implicit conversions (as a percentage of all implicit conversions; an _ prefix indicates a literal operand). Based on the translated form of this book's benchmark programs.

Converted to	Converted from	%	Converted to	Converted from	%
`( unsigned char )`	`_int`	33.0	`( int )`	`unsigned short`	1.9
`( unsigned short )`	`_int`	17.7	`( unsigned long )`	`_int`	1.8
(other-types)	other-types	11.3	`( unsigned int )`	`int`	1.7
`( short )`	`_int`	7.6	`( short )`	`int`	1.7
`( unsigned int )`	`_int`	5.1	`( enum )`	`_int`	1.3
(ptr-to)	ptr-to	4.7	`( unsigned long )`	`int`	1.2
`( char )`	`_int`	3.6	`( int )`	`char`	1.2
(ptr-to)	_ptr-to	2.9	`( int )`	`enum`	1.0
`( int )`	`unsigned char`	2.3			

654 This subclause specifies the result required from such an *implicit conversion*, as well as those that result from a cast operation (an *explicit conversion*).

implicit conversion
explicit conversion

Commentary

This defines the terms *implicit conversion* and *explicit conversion*. The commonly used developer term for *implicit conversion* is *implicit cast* (a term that is not defined by the standard).

C++

The C++ Standard defines a set of implicit and explicit conversions. Declarations contained in library headers also contain constructs that can cause implicit conversions (through the declaration of constructors) and support additional explicit conversions— for instance, the complex class.

The C++ language differs from C in that the set of implicit conversions is not fixed. It is also possible for user-defined declarations to create additional implicit and explicit conversions.

Other Languages

Most languages have some form of implicit conversions. Strongly typed languages tend to minimize the number of implicit conversions. Other languages (e.g., APL, Basic, Perl, and PL/1) go out of their way to provide every possible form of implicit conversion. PL/1 became famous for the extent to which it would go to convert operands that had mismatched types. Some languages use the term *coercion*, not conversion. A value is said to be coerced from one type to another.

Coding Guidelines

Although translators do not treat implicit conversions any different from explicit conversions, developers and static analysis tools often treat them differently. The appearance of an explicit construct is given greater weight than its nonappearance (although an operation might still be performed). It is often assumed that an explicit conversion indicates that its consequences are fully known to the person who wrote it, and that subsequent readers will also comprehend its consequences (an implicit conversion is not usually afforded such a status). The possibility that subsequent modifications to the source may have changed the intended behavior of the explicit conversion, or that the developer may not have only had a limited grasp of the effects of the conversion (but just happened to work for an organization that enforces a *no implicit conversion* guideline), is not usually considered.

The issues involved in conversions between integer types is discussed elsewhere. The following example highlights some of the issues:

486 signed integer
corresponding unsigned integer

```
#if MACHINE_Z
typedef unsigned int X;
typedef signed int Y;
#else
typedef signed int X;
typedef unsigned int Y;
#endif

unsigned int ui;
signed int si;
X xi;
Y yi;

void f(void)
{
/*
 * It is not apparent from the source that the type of any object might change.
 */
unsigned int uloc;
signed int sloc;

uloc = ui + si;    uloc = ui + (unsigned int)si;
sloc = ui + si;    sloc = (signed int)(ui + si);
}

void g(void)
{
/*
 * The visible source shows that it is possible for the type of an object to change.
 */
X xloc;
Y yloc;

/*
 * The following sequence of casts might not be equivalent to those used in f.
 */
xloc = xi + yi;    xloc = xi + (X)yi;
yloc = xi + yi;    yloc = (Y)(xi + yi);
}
```

In the function `f`, the two assignments to `uloc` give different impressions. The one without an explicit cast of `si` raises the issue of its value always being positive. The presence of an explicit cast in the second cast gives the impression that the author of the code intended the conversion to take place and that there is no need to make further checks. In the second pair of assignments the result is being converted back to a signed quantity. The explicit cast in the second assignment gives the impression that the original author of the code intended the conversion to take place and that there is no need to make further checks.

In the function `g`, the issues are less clear-cut. The underlying types of the operands are not immediately obvious. The fact that typedef names have been used suggests some intent to hide implementation details. Is the replacement of a subset of the implicit conversions by explicit casts applicable in this situation? Having the definition of the typedef names conditional on the setting of a macro name only serves to reduce the possibility of being able to claim any kind of developer intent. Having a typedef name whose definition is conditional also creates problems for tool users. Such tools tend to work by tracing a single path of translation through the source code. In the function `g`, they are likely to give diagnostics applicable to one set of the `X` and `Y` definitions. Such diagnostics are likely to be different if the conditional inclusion results in a different pair of definitions for these typedef names.

Conversions between integer and floating types are special for several reasons:

- Although both represent numerical quantities, in the floating-point case literals visible in the source code need not be exact representations of the value used during program execution.

- The internal representations are usually significantly different.
- One of the representations is capable of representing very large and very small quantities (it has an exponent and fractional part),

These differences, and the resulting behavior, are sufficient to want to draw attention to the fact that a conversion is taking place. The issues involved are discussed in more detail elsewhere.

686 floating-point converted to integer
688 integer conversion to floating

Example

```
1  extern short es_1, es_2, es_3;
2
3  void f(void)
4  {
5  es_1 = es_2 + es_3;
6  es_1 = (short)((int)es_2 + (int)es_3);
7  es_1 = (short)(es_2 + es_3);
8  }
```

---

655 The list in 6.3.1.8 summarizes the conversions performed by most ordinary operators;

Commentary

All operators might be said to be *ordinary* and these conversions apply to most of them (e.g., the shift operators are one example of where they are not applied).

702 operators cause conversions
1183 shift operator integer promotions

C++

Clause 4 ‘Standard conversions’ and 5p9 define the conversions in the C++ Standard.

---

656 it is supplemented as required by the discussion of each operator in 6.5.

Commentary

Clause 6.5 deals with expressions and describes each operator in detail.

940 expressions

C++

There are fewer such supplements in the C++ Standard, partly due to the fact that C++ requires types to be the same and does not use the concept of compatible type.

C++ supports user-defined overloading of operators. Such overloading could change the behavior defined in the C++ Standard, however these definitions cannot appear in purely C source code.

---

657 Conversion of an operand value to a compatible type causes no change to the value or the representation.

compatible type conversion

Commentary

This might almost be viewed as a definition of compatible type. However, there are some conversions that cause no change to the value, or the representation, and yet are not compatible types; for instance, converting a value of type **int** to type **long** when both types have the same value representation.

C++

No such wording applied to the same types appears in the C++ Standard. Neither of the two uses of the C++ term *compatible* (layout-compatible, reference-compatible) discuss conversions.

Other Languages

More strongly typed languages, such as Pascal and Ada, allow types to be created that have the same representation as a particular integer type, but are not compatible with it. In such languages, conversions are about changes of type rather than changes of representation (which is usually only defined for a few special cases, such as between integer and floating-point).

Common Implementations

While an obvious optimization for a conversion of an operand value to a compatible type is to not generate any machine code, some translators have been known to generate code to perform this conversion. The generation of this conversion code is often a characteristic of translators implemented on a small budget.

Coding Guidelines

Conversion of an operand value to a compatible type can occur for a variety of reasons:

- The type of the operand has changed since the code was originally written— the conversion has become redundant.
- The type specified in the explicit conversion is a typedef name. The definition of this typedef name might vary depending on the host being targeted. For some hosts it happens to be compatible with the type of the operand value; in other cases it is not.
- The cast operation, or its operand is a parameter in a function-like macro definition. In some cases the arguments specified may result in the expanded body containing a conversion of a value having a compatible type.

macro function-like 1933

In only the first of these cases might there be a benefit in removing the explicit conversion. The issue of redundant code is discussed elsewhere.

redundant code 190

Forward references: cast operators (6.5.4). 658

6.3.1 Arithmetic operands

6.3.1.1 Boolean, characters, and integers

---

conversion rank

Every integer type has an *integer conversion rank* defined as follows: 659

Commentary

This defines the term *integer conversion rank*. Although this is a new term, there already appears to be a common usage of the shorter term *rank*. C90 contained a small number of integer types. Their relative properties were enumerated by naming each type with its associated properties. With the introduction of two new integer types and the possibility of implementation-defined integer types, documenting the specification in this manner is no longer practical.

The importance of the rank of a type is its value relative to the rank of other types. The standard places no requirements on the absolute numerical value of any rank. The standard does not define any mechanism for a developer to control the rank assigned to any extended types. That is not to say that implementations cannot support such functionality, provided the requirements of this clause are met.

There is no rank defined for bit-fields.

C90

The concept of integer conversion rank is new in C99.

C++

The C++ Standard follows the style of documenting the requirements used in the C90 Standard. The conversions are called out explicitly rather than by rank (which was introduced in C99). C++ supports operator overloading, where the conversion rules are those of a function call. However, this functionality is not available in C.

Other Languages

Most languages have a single integer type, which means there are no other integer types to define a relationship against. Languages that support an unsigned type describe the specific relationship between the signed and unsigned integer type.

Common Implementations

Whether implementations use the new concept of rank or simply extend the existing way things are done internally is an engineering decision, which is invisible to the user of a translator product — the developer.

Coding Guidelines

Although integer conversion rank is a new term it has the capacity to greatly simplify discussions about the integer types. Previously, general discussions on integer types either needed to differentiate them based on some representation characteristic, such as their size or width, or by enumerating the types and their associated attributes one by one.

---

660 — No two signed integer types shall have the same rank, even if they have the same representation.

Commentary

This mirrors the concept that two types are different, even if they have the same representation.

508 types different even if same representation

---

661 — The rank of a signed integer type shall be greater than the rank of any signed integer type with less precision.

rank signed integer vs less precision

Commentary

The standard could equally well have defined things the other way around, with the rank being less than. On the basis that the precision of integral types continues to grow, over time, it seems more intuitive to also have the ranks grow. So the largest rank is as open-ended as the largest number of bits in an integral type. Given the requirement that follows this one, for the time being, this requirement, only really applies to extended integer types.

C++

The relative, promotion, ordering of signed integer types defined by the language is called out explicitly in clause 5p9.

---

662 — The rank of **`long long int`** shall be greater than the rank of **`long int`**, which shall be greater than the rank of **`int`**, which shall be greater than the rank of **`short int`**, which shall be greater than the rank of **`signed char`**.

rank standard integer types

Commentary

This establishes a pecking order among the signed integer types defined by the standard.

C++

Clause 5p9 lists the pattern of the usual arithmetic conversions. This follows the relative orderings of rank given here (except that the types **`short int`** and **`signed char`** are not mentioned; nor would they be since the integral promotions would already have been applied to operands having these types).

---

663 — The rank of any unsigned integer type shall equal the rank of the corresponding signed integer type, if any.

rank corresponding signed/unsigned

Commentary

The only unsigned integer type that does not have a corresponding signed integer type is **`_Bool`**.

487 standard unsigned integer

Rank is not sufficient to handle all conversion cases. Information on the sign of the integer type is also needed.

488 extended unsigned integer

---

664 — The rank of any standard integer type shall be greater than the rank of any extended integer type with the same width.

rank standard integer relative to extended

Commentary

This is a requirement on the implementation. It gives preference to converting to the standard defined type rather than any extended integer type that shares the same representation.

Why would a vendor provide an extended type that is the same width as one of the standard integer types? The translator vendor may support a variety of different platforms and want to offer a common set of typedefs, across all supported platforms, in the **<stdint.h>** header. This could have the effect, on some platforms, of an extended integer type having the same width as one of the standard integer types. A vendor may also provide more than one representation of integer types. For instance, by providing support for extended integer types whose bytes have the opposite endianness to that of the standard integer types.

endian 570

C++

The C++ Standard specifies no requirements on how an implementation might extend the available integer types.

---

char rank

— The rank of **char** shall equal the rank of **signed char** and **unsigned char**. 665

Commentary

This statement is needed because the type **char** is distinct from that of the types **signed char** and **unsigned char**.

char 537 separate type

_Bool rank

— The rank of **_Bool** shall be less than the rank of all other standard integer types. 666

Commentary

This does not imply that the object representation of the type **_Bool** contains a smaller number of bits than any other integer type (although its value representation must).

unsigned 593 integer types object representation

C++

3.9.1p6 *As described below, **bool** values behave as integral types.*

4.5p4 *An rvalue of type **bool** can be converted to an rvalue of type **int**, with **false** becoming zero and **true** becoming one.*

The C++ Standard places no requirement on the relative size of the type **bool** with respect to the other integer types. An implementation may choose to hold the two possible values in a single byte, or it may hold those values in an object that has the same width as type **long**.

Other Languages

Boolean types, if supported, are usually viewed as the smallest type, irrespective of the amount of storage used to represent them.

---

rank enumerated type

— The rank of any enumerated type shall equal the rank of the compatible integer type (see 6.7.2.2). 667

Commentary

The compatible integer type can vary between different enumerated types. An enumeration constant has type **int**. There is no requirement preventing the rank of an enumerated type from being less than, or greater than, the rank of **int**.

enumeration 1447 type compatible with enumerators 1441 type int

Other Languages

Most languages that contain enumerated types treat them as being distinct from the integer types and an explicit cast is required to obtain their numeric value. So the C issues associated with rank do not occur.

---

rank extended integer relative to extended

— The rank of any extended signed integer type relative to another extended signed integer type with the same precision is implementation-defined, but still subject to the other rules for determining the integer conversion rank. 668

Commentary

The reasons why an implementation might provide two extended signed integer types of the same precision is the same as the reasons why it might provide such a type having the same precision as a standard integer type. Existing practice provides a ranking for the standard integer types (some or all of which may have the same precision).

664 rank standard integer relative to extended
662 rank standard integer types

C++

The C++ Standard does not specify any properties that must be given to user-defined classes that provide some form of extended integer type.

Coding Guidelines

The same issues apply here as applied to the extended integer types in relation to the standard integer types.

664 rank standard integer relative to extended

---

669 — For all integer types **T1**, **T2**, and **T3**, if **T1** has greater rank than **T2** and **T2** has greater rank than **T3**, then **T1** has greater rank than **T3**.

rank transitive

Commentary

The rank property is transitive.

---

670 The following may be used in an expression wherever an **int** or **unsigned int** may be used:

expression wherever an int may be used

Commentary

An **int** can be thought of as the smallest functional unit of type for arithmetic operations (the types with greater rank being regarded as larger units). This observation is a consequence of the integer promotions. Any integer type can be used in an expression wherever an **int** or **unsigned int** may be used (this may involve them being implicitly converted). However, operands having one of the types specified in the following sentences will often return the same result if they also have the type **int** or **unsigned int**.

675 integer promotions

C90

The C90 Standard listed the types, while the C99 Standard bases the specification on the concept of rank.

*A **char**, a **short int**, or an **int** bit-field, or their signed or unsigned varieties, or an enumeration type, may be used in an expression wherever an **int** or **unsigned int** may be used.*

C++

C++ supports the overloading of operators; for instance, a developer-defined definition can be given to the binary **+** operator, when applied to operands having type **short**. Given this functionality, this C sentence cannot be said to universally apply to programs written in C++. It is not listed as a difference because it requires use of C++ functionality for it to be applicable. The implicit conversion sequences are specified in clause 13.3.3.1. When there are no overloaded operators visible (or to be exact no overloaded operators taking arithmetic operands, and no user-defined conversion involving arithmetic types), the behavior is the same as C.

Other Languages

Most other languages do not define integer types that have less precision than type **int**, so they do not contain an equivalent statement. The type **char** is usually a separate type and an explicit conversion is needed if an operand of this type is required in an **int** context.

Coding Guidelines

If the guideline recommendation specifying use of a single integer type is followed, this permission will never be used.

480.1 object int type only
675 integer promotions

Example

In the following:

```
1  #include <limits.h>
2
3  typedef unsigned int T;
4  T x;
5
6  int f(void)
7  {
8  if (sizeof(x) == 2)
9     return (x << CHAR_BIT) << CHAR_BIT;
10 else
11    return sizeof(x);
12 }
```

the first **return** statement will always return zero when the rank of type T is less than or equal to the rank of **int**. There is no guarantee that the second **return** statement will always deliver the same value for different types.

— An object or expression with an integer type whose integer conversion rank is less than or equal to the rank of **int** and **unsigned int**. 671

Commentary

rank 663
corresponding signed/unsigned integer promotions 675

The rank of **int** and **unsigned int** is the same. The integer promotions will be applied to these objects.

The wording was changed by the response to DR #230 and allows objects having enumeration type (whose rank may equal the rank of **int** and **unsigned int**) to appear in these contexts (as did C90).

C++

4.5p1 *An rvalue of type* ***char****,* ***signed char****,* ***unsigned char****,* ***short int****, or* ***unsigned short int*** *can be converted to an rvalue of type* ***int*** *if* ***int*** *can represent all the values of the source type; otherwise, the source rvalue can be converted to an rvalue of type* ***unsigned int****.*

4.5p2 *An rvalue of type* ***wchar_t*** *(3.9.1) or an enumeration type (7.2) can be converted to an rvalue of the first of the following types that can represent all the values of its underlying type:* ***int****,* ***unsigned int****,* ***long****, or* ***unsigned long****.*

4.5p4 *An rvalue of type* ***bool*** *can be converted to an rvalue of type* ***int****, with* ***false*** *becoming zero and* ***true*** *becoming one.*

The key phrase here is *can be*, which does not imply that they *shall be*. However, the situations where these conversions might not apply (e.g., operator overloading) do not involve constructs that are available in C. For binary operators the *can be* conversions quoted above become *shall be* requirements on the implementation (thus operands with rank less than the rank of **int** are supported in this context):

5p9 *Many binary operators that expect operands of arithmetic or enumeration type cause conversions and yield result types in a similar way. The purpose is to yield a common type, which is also the type of the result. This pattern is called the usual arithmetic conversions, which are defined as follows:*

— *Otherwise, the integral promotions (4.5) shall be performed on both operands.*[54)]

54) As a consequence, operands of type ***bool****,* ***wchar_t****, or an enumerated type are converted to some integral type.* Footnote 54

The C++ Standard does not appear to contain explicit wording giving this permission for other occurrences of operands (e.g., to unary operators). However, it does not contain wording prohibiting the usage (the wording for the unary operators invariably requires the operand to have an arithmetic or scalar type).

Other Languages

The few languages that do support more than one integer type specify their own rules for when different types can occur in an expression at the same time.

---

672 — A bit-field of type **_Bool**, **int**, **signed int**, or **unsigned int**. bit-field in expression

Commentary

A bit-field is a method of specifying the number of bits to use in the representation of an integer type. The type used in a bit-field declaration specifies the set of possible values that might be available, while the constant value selects the subset (which can include all values) that can be represented by the member. Because the integer promotion rules are based on range of representable values, not underlying signedness of the type, it is possible for a member declared as a bit-field using an unsigned type to be promoted to the type **signed int**. 1393 bit-field maximum width

C90

Support for bit-fields of type **_Bool** is new in C99.

C++

An rvalue for an integral bit-field (9.6) can be converted to an rvalue of type ***int*** *if* ***int*** *can represent all the values of the bit-field; otherwise, it can be converted to* ***unsigned int*** *if* ***unsigned int*** *can represent all the values of the bit-field. If the bit-field is larger yet, no integral promotion applies to it. If the bit-field has an enumerated type, it is treated as any other value of that type for promotion purposes.* 4.5p3

C does not support the definition of bit-fields that are larger than type **int**, or bit-fields having an enumerated type.

Other Languages

Languages, such as Pascal and Ada, provide developers with the ability to specify the minimum and maximum values that need to be represented in an integer type (a bit-field specifies the number of bits in the representation, not the range of values). These languages contain rules that specify how objects defined to have these subrange types can be used anywhere that an object having integer type can appear.

Common Implementations

Obtaining the value of a member that is a bit-field usually involves several instructions. The storage unit holding the bit-field has to be loaded, invariably into a register. Those bits not associated with the bit-field being read then need to be removed. This can involve using a bitwise-and instruction to zero out bits and right shift the bit sequence. For signed bit-fields, it may then be necessary to sign extend the bit sequence. Storing a value into an object having a bit-field type can be even more complex. The new value has to be converted to a bit sequence that fits in the allocate storage, without changing the values of any adjacent objects.

Some CISC processors[968] have instructions designed to access bit-fields. Such relatively complex instructions went out of fashion when RISC design philosophy first took off, but they have started to make a come back.[6,631] Li and Gupta[850] found that adding instructions to the ARM processor that operated (add, subtract, compare, move, and bitwise operations) on subwords reduced the cycle count of various multimedia benchmarks by between 0.39% and 8.67% (code size reductions were between 1.27% and 21.05%).

int can represent values converted to int

If an **int** can represent all values of the original type, the value is converted to an **int**; 673

Commentary

Type conversions occur at translation time, when actual values are usually unknown. The standard requires the translator to assume that the value of the expression can be any one of the representable values supported by its type. While flow analysis could reduce the range of possible values, the standard does not require such analysis to be performed. (If it is performed, a translator cannot use it to change the external behavior of a program; that is, optimizations may be performed but the semantics specified by the standard is followed.)

Other Languages

Most languages have a single signed integer type, so there is rarely a smaller integer type that needs implicit conversion.

Coding Guidelines

typedef assumption of no integer promotions

Some developers incorrectly assume that objects declared using typedef names do not take part in the integer promotions. Incorrect assumptions by a developer are very difficult to deduce from an analysis of the source code. In some cases the misconception will be harmless, the actual program behavior being identical to the misconstrued behavior. In other cases the behavior is different. Guideline recommendations are not a substitute for proper developer training.

Example

```
1  typedef short SHORT;
2
3  extern SHORT es_1,
4              es_2;
5
6  void f(void)
7  {
8  unsigned int ui = 3;    /* Value representable in a signed int.     */
9
10 if (es_1 == (es_2 + 1)) /* Operands converted to int.               */
11    ;
12 if (ui > es_1)          /* Right operand converted to unsigned int. */
13    ;
14 }
```

int cannot represent values converted to unsigned int

otherwise, it is converted to an **unsigned int**. 674

Commentary

This can occur for the types **unsigned short**, or **unsigned char**, if either of them has the same representation as an **unsigned int**. Depending on the type chosen to be compatible with an enumeration type, it is possible for an object that has an enumerated type to be promoted to the type **unsigned int**.

Common Implementations

On 16-bit processors the types **short** and **int** usually have the same representation, so **unsigned short** promotes to **unsigned int**. On 32-bit processors the type **short** usually has less precision than **int**, so the type **unsigned short** promotes to **int**. There are a few implementations, mostly on DSP-based processors, where the character types have the same width as the type **int**.[967]

Coding Guidelines

Existing source code ported, from an environment in which the type **int** has greater width than **short**, to an environment where they both have the same width may have its behavior changed. If the following is executed on a host where the width of type **int** is greater than the width of **short**:

```
1  #include <stdio.h>
2
3  extern unsigned short us;
4  extern signed int si; /* Can hold negative values. */
5
6  void f(void)
7  {
8  if (us > si)
9     printf("Pass\n");
10 else
11    printf("Fail\n");
12 }
```

the object us will be promoted to the type **int**. There will not be any change of values. On a host where the types **int** and **short** have the same width, an **unsigned short** will be promoted to **unsigned int**. This will lead to si being promoted to **unsigned int** (the usual arithmetic conversions) and a potential change in its value. (If it has a small negative value, it will convert to a large positive value.) The relational comparison will then return a different result than in the previous promotion case.

Cg 674.1

An object having an unsigned integer type shall not be implicitly converted to **unsigned int** through the application of the integer promotions.

The consequence of this guideline recommendation is that such conversions need to be made explicit, using a cast to an integer type whose rank is greater than or equal to **int**.

---

675 These are called the *integer promotions*.[48)]

integer promotions

Commentary

This defines the term *integer promotions*. Integer promotions occur when an object having a rank less than **int** appears in certain contexts. This behavior differs from arithmetic conversions where the type of a different object is involved. Integer promotions are affected by the relative widths of types (compared to the width of **int**). If the type **int** has greater width than **short** then, in general (the presence of extended integer types whose rank is also less than **int** can complicate the situation), all types of less rank will convert to **int**. If **short** has the same precision as **int**, an **unsigned short** will invariably promote to an **unsigned int**.

690 footnote 48

It is possible to design implementations where the integer conversions don't follow a simple pattern, such as the following:

```
signed short 16 bits including sign     unsigned short 24 bits
signed int   24 bits including sign     unsigned int   32 bits
```

Your author does not know of any implementation that uses this kind of unusual combination of bits for its integer type representation.

C90

These are called the integral promotions.[27)]

C++

The C++ Standard uses the C90 Standard terminology (and also points out, 3.9.1p7, "A synonym for integral type is *integer type*.").

Other Languages

The *unary numeric promotions* and *binary numeric promotions* in Java have the same effect.

Common Implementations

Many processors have load instructions that convert values having narrower types to a wider type. For instance, loading a byte into a register and either sign extending (**signed char**), or zero filling (**unsigned char**) the value to occupy 32 bits (promotion to **int**). On processors having instructions that operate on values having a type narrower than **int** more efficiently than type **int**, optimizers can make use of the as-if rule to improve efficiency. For instance, in some cases an analysis of the behavior of a program may find that operand values and the result value is always representable in the their unpromoted type. Implementations need only to act as if the object had been converted to the type **int**, or **unsigned int**.

Coding Guidelines

object 480.1 int type only

operand 653 convert automatically

If the guideline recommendation specifying use of a single integer type is followed there would never be any integer promotions. The issue of implicit conversions versus explicit conversions might be a possible cause of a deviation from this recommendation and is discussed elsewhere.

Example

```
1  signed short    s1,  s2,  s3;
2  unsigned short us1, us2, us3;
3
4  void f(void)
5  {
6  s1 = s2 + s3;  /*
7                  * The result of + may be undefined.
8                  * The conversion for the = may be undefined.
9                  */
10                /* s1 = (short)((int)s2 + (int)s3);           */
11 s1 = us2 + s3; /* The conversion for the = may be undefined. */
12                /*
13                 * The result of the binary + is always defined (unless
14                 * the type int is only one bit wider than a short; no
15                 * known implementations have this property).
16                 *
17                 * Either both shorts promote to a wider type:
18                 *
19                 *       s1 = (short)((int)us2 + (int)s3);
20                 *
21                 * or they both promote to an unsigned type of the same width:
22                 *
23                 *       s1 = (short)((unsigned int)us2 + (unsigned int)s3);
24                 */
25  s1 = us2 + us3; /* The conversion for the = may be undefined. */
26 us1 = us2 + us3; /* Always defined */
27 us1 = us2 +  s3; /* Always defined */
28 us1 =  s2 +  s3; /* The result of + may undefined.             */
29 }
```

Table 675.1: Occurrence of integer promotions (as a percentage of all operands appearing in all expressions). Based on the translated form of this book's benchmark programs.

Original Type	%	Original Type	%
unsigned char	2.3	**char**	1.2
unsigned short	1.9	**short**	0.5

All other types are unchanged by the integer promotions.

Commentary

The integer promotions are only applied to values whose integer type has a rank less than that of the **int** type.

C++

This is not explicitly specified in the C++ Standard. However, clause 4.5, Integral promotions, discusses no other types, so the statement is also true in C++

---

677 The integer promotions preserve value including sign. value preserving

Commentary

These rules are sometimes known as *value preserving promotions*. They were chosen by the Committee because they result in the least number of surprises to developers when applied to operands. The promoted value would remain unchanged whichever of the two rules used by implementations were used. However, in many cases this promoted value appears as an operand of a binary operator. If *unsigned preserving promotions* were used (see Common implementations below), the value of the operand could have its sign changed (e.g., if the operands had types **unsigned char** and **signed char**, both their final operand type would have been **unsigned int**), potentially leading to a change of that value (if it was negative). The *unsigned preserving promotions* (sometimes called rules rather than promotions) are sometimes also known as *sign preserving rules* because the form of the sign is preserved.

Most developers think in terms of values, not signedness. A rule that attempts to preserve sign can cause a change of value, something that is likely to be unexpected. Value preserving rules can also produce results that are unexpected, but these occur much less often.

Rationale

The *unsigned preserving* rules greatly increase the number of situations where **unsigned int** confronts **signed int** to yield a questionably signed result, whereas the *value preserving* rules minimize such confrontations. Thus, the value preserving rules were considered to be safer for the novice, or unwary, programmer. After much discussion, the C89 Committee decided in favor of value preserving rules, despite the fact that the UNIX C compilers had evolved in the direction of unsigned preserving.

Other Languages

This is only an issue for languages that contain more than one signed integer type and an unsigned integer type.

Common Implementations

The base document specified unsigned preserving rules. If the type being promoted was either **unsigned char** or **unsigned short**, it was converted to an **unsigned int**. The corresponding signed types were promoted to **signed int**. Some implementations provide an option to change their default behavior to follow unsigned preserving rules.[600, 1314, 1340] [1] base document

Coding Guidelines

Existing, very old, source code may rely on using the unsigned preserving rules. It can only do this if the translator is also running in such a mode, either because that is the only one available or because the translator is running in a compatibility mode to save on the porting (to the ISO rules) cost. Making developers aware of any of the issues involved in operating in a nonstandard C environment is outside the scope of these coding guidelines.

Example

```
1  extern unsigned char uc;
2
3  void f(void)
```

```
4   {
5   int si = -1;
6   /*
7    * Value preserving rules promote uc to an int -> comparison succeeds.
8    *
9    * Signed preserving rules promote uc to an unsigned int, usual arithmetic
10   * conversions then convert si to unsigned int -> comparison fails.
11   */
12  if (uc > si)
13     ;
14  }
```

---

char plain treated as

As discussed earlier, whether a "plain" **char** is treated as signed is implementation-defined. 678

Commentary

char 516 range, representation and behavior

The implementation-defined treatment of "plain" char will only affect the result of the integer promotions if any of the character types can represent the same range of values as an object of type **int** or **unsigned int**.

Forward references: enumeration specifiers (6.7.2.2), structure and union specifiers (6.7.2.1). 679

6.3.1.2 Boolean type

_Bool converted to

When any scalar value is converted to **_Bool**, the result is 0 if the value compares equal to 0; 680

Commentary

Converting a scalar value to type **_Bool** is effectively the same as a comparison against 0; that is, `(_Bool)x` is effectively the same as `(x != 0)` except in the latter case the type of the result is **int**.

Conversion to **_Bool** is different from other conversions, appearing in a strictly conforming program, in that it is not commutative— `(T1)(_Bool)x` need not equal `(_Bool)(T1)x`. For instance:

```
(int)(_Bool)0.5 ⇒ 1
(_Bool)(int)0.5 ⇒ 0
```

Reordering the conversions in a conforming program could also return different results:

```
(signed)(unsigned)-1 ⇒ implementation-defined
(unsigned)(signed)-1 ⇒ UINT_MAX
```

C90

Support for the type **_Bool** is new in C99.

C++

4.12p1 *An rvalue of arithmetic, enumeration, pointer, or pointer to member type can be converted to an rvalue of type* ***bool****. A zero value, null pointer value, or null member pointer value is converted to* ***false****;*

The value of **false** is not defined by the C++ Standard (unlike **true**, it is unlikely to be represented using any value other than zero). But in contexts where the integer conversions are applied:

4.7p4 *. . . the value* ***false*** *is converted to zero . . .*

Other Languages

Many languages that include a boolean type specify that it can hold the values true and false, without specifying any representation for those values. Java only allows boolean types to be converted to boolean types. It does not support the conversion of any other type to boolean.

Coding Guidelines

The issue of treating boolean values as having a well-defined role independent of any numeric value is discussed elsewhere; for instance, treating conversions of values to the type **_Bool** as representing a change of role, not as representing the values 0 and 1. The issue of whether casting a value to the type **_Bool**, rather than comparing it against zero, represents an idiom that will be recognizable to C developers is discussed elsewhere.

476 boolean role

476 boolean role

---

681 otherwise, the result is 1.

Commentary

In some contexts C treats any nonzero value as representing true — for instance, controlling expressions (which are also defined in terms of a comparison against zero). A conversion to **_Bool** reduces all nonzero values to the value 1.

1744 if statement operand compare against 0

C++

> *. . . ; any other value is converted to* ***true****.* 4.12p1

The value of **true** is not defined by the C++ Standard (implementations may choose to represent it internally using any nonzero value). But in contexts where the integer conversions are applied:

> *. . . the value* ***true*** *is converted to one.* 4.7p4

6.3.1.3 Signed and unsigned integers

---

682 When a value with integer type is converted to another integer type other than **_Bool**, if the value can be represented by the new type, it is unchanged.

Commentary

While it would very surprising to developers if the value was changed, the standard needs to be complete and specify the behavior of all conversions. For integer types this means that the value has to be within the range specified by the corresponding numerical limits macros.

300 numerical limits

The type of a bit-field is more than just the integer type used in its declaration. The width is also considered to be part of its type. This means that assignment, for instance, to a bit-field object may result in the value being assigned having its value changed.

1407 bit-field interpreted as

```
1   void DR_120(void)
2   {
3   struct {
4            unsigned int mem : 1;
5           } x;
6   /*
7    * The value 3 can be represented in an unsigned int,
8    * but is changed by the assignment in this case.
9    */
10  x.mem = 3;
11  }
```

C90

Support for the type **_Bool** is new in C99, and the C90 Standard did not need to include it as an exception.

Other Languages

This general statement holds true for conversions in other languages.

Common Implementations

The value being in range is not usually relevant because most implementations do not perform any range checks on the value being converted. When converting to a type of lesser rank, the common implementation behavior is to ignore any bit values that are not significant in the destination type. (The sequence of bits in the value representation of the original type is truncated to the number of bits in the value representation of the destination type.) If the representation of a value does not have any bits set in these ignored bits, the converted value will be the same as the original value. In the case of conversions to value representations containing more bits, implementations simply sign-extend for signed values and zero-fill for unsigned values.

Coding Guidelines

One way of reducing the possibility that converted values are not representable in the converted type is to reduce the number of conversions. This is one of the rationales behind the general guideline on using a single integer type.

object 480.1 int type only

---

unsigned integer conversion to

Otherwise, if the new type is unsigned, the value is converted by repeatedly adding or subtracting one more than the maximum value that can be represented in the new type until the value is in the range of the new type.[49)] 683

Commentary

This behavior is what all known implementations do for operations on values having unsigned types. The standard is enshrining existing processor implementation practices in the language. As footnote 49 points out, this adding and subtracting is done on the abstract mathematical value, not on a value with a given C type. There is no need to think in terms of values wrapping (although this is a common way developers think about the process).

footnote 691 49

C90

Otherwise: if the unsigned integer has greater size, the signed integer is first promoted to the signed integer corresponding to the unsigned integer; the value is converted to unsigned by adding to it one greater than the largest number that can be represented in the unsigned integer type.[28)]

When a value with integral type is demoted to an unsigned integer with smaller size, the result is the nonnegative remainder on division by the number one greater than the largest unsigned number that can be represented in the type with smaller size.

The C99 wording is a simpler way of specifying the C90 behavior.

Common Implementations

For unsigned values and signed values represented using two's complement, the above algorithm can be implemented by simply chopping off the significant bits that are not available in the representation of the new type.

Coding Guidelines

The behavior for this conversion may be fully specified by the standard. The question is whether a conversion should be occurring in the first place.

unsigned 496 computation modulo reduced

---

integer value not represented in signed integer

Otherwise, the new type is signed and the value cannot be represented in it; 684

Commentary

To be exact, the standard defines no algorithm for reducing the value to make it representable (because there is no universal agreement between different processors on what to do in this case).

Other Languages

The problem of what to do with a value that, when converted to a signed integer type, cannot be represented is universal to all languages supporting more than one signed integer type, or support an unsigned integer type (the overflow that can occur during an arithmetic operation is a different case).

Coding Guidelines

A guideline recommendation that the converted value always be representable might be thought to be equivalent to one requiring that a program not contain defects. However, while the standard may not specify an algorithm for this conversion, there is a commonly seen implementation behavior. Developers sometimes intentionally make use of this common behavior and the applicable guideline is the one dealing with the use of representation information.

569.1 representation information using

---

685 either the result is implementation-defined or an implementation-defined signal is raised.

signed integer conversion implementation-defined

Commentary

There is no universally agreed-on behavior (mathematical or processor) for the conversion of out-of-range signed values, so the C Standard's Committee could not simply define this behavior as being what happens in practice. The definition of implementation-defined behavior does not permit an implementation to raise a signal; hence, the additional permission to raise a signal is specified here.

42 implementation-defined behavior

C90

The specification in the C90 Standard did not explicitly specify that a signal might be raised. This is because the C90 definition of implementation-defined behavior did not rule out the possibility of an implementation raising a signal. The C99 wording does not permit this possibility, hence the additional permission given here.

C++

. . . ; otherwise, the value is implementation-defined. 4.7p3

The C++ Standard follows the wording in C90 and does not explicitly permit a signal from being raised in this context because this behavior is considered to be within the permissible range of implementation-defined behaviors.

Other Languages

Languages vary in how they classify the behavior of a value not being representable in the destination type. Java specifies that all the unavailable significant bits (in the destination type) are discarded. Ada requires that an exception be raised. Other languages tend to fall between these two extremes.

Common Implementations

The quest for performance and simplicity means that few translators generate machine code to check for nonrepresentable conversions. The usual behavior is for the appropriate number of least significant bits from the original value to be treated as the converted value. The most significant bit of this new value is treated as a sign bit, which is sign-extended to fill the available space if the value is being held in a register. If the conversion occurs immediately before a store (i.e., a right-hand side value is converted before being assigned into the left hand side object), there is often no conversion; the appropriate number of value bits are simply written into storage.

Some older processors[284] have the ability to raise a signal if a conversion operation on an integer value is not representable. On such processors an implementation can choose to use this instruction or alternatively use a sequence of instructions having the same effect, that do not raise a signal.

6.3.1.4 Real floating and integer

floating-point converted to integer

When a finite value of real floating type is converted to an integer type other than **_Bool**, the fractional part is discarded (i.e., the value is truncated toward zero). 686

Commentary

NaNs are not finite values and neither are they infinities.

IEEE-754 6.3 *The Sign Bit. . . . and the sign of the result of the round floating-point number to integer operation is the sign of the operand. These rules shall apply even when operands or results are zero or infinite.*

negative zero 616 only generated by

When a floating-point value in the range (-1.0, -0.0) is converted to an integer type, the result is required to be a positive zero.

C90

Support for the type **_Bool** is new in C99.

Other Languages

This behavior is common to most languages.

Common Implementations

FLT_ROUNDS 352

Many processors include instructions that perform truncation when converting values of floating type to an integer type. On some processors the rounding mode, which is usually set to round-to-nearest, has to be changed to round-to-zero for this conversion, and then changed back after the operation. This is an execution-time overhead. Some implementations give developers the choice of faster execution provided they are willing to accept round-to-nearest behavior. In some applications the difference in behavior is significantly less than the error in the calculation, so it is acceptable.

Coding Guidelines

integer constant expression 1328

An expression consisting of a cast of a floating constant to an integer type is an integer constant expression. Such a constant can be evaluated at translation time. However, there is no requirement that the translation-time evaluation produce exactly the same results as the execution-time evaluation. Neither is there a requirement that the translation-time handling of floating-point constants be identical. In the following example it is possible that a call to `printf` will occur.

```
1  #include <stdio.h>
2
3  void f(void)
4  {
5  float fval = 123456789.0;
6  long lval = (long)123456789.0;
7
8  if (lval != (long)fval)
9     printf("(long)123456789.0 == %ld and %ld\n", lval, (long)fval);
10 }
```

There is a common, incorrect, developer assumption that floating constants whose fractional part is zero are always represented exactly by implementations (i.e., many developers have a mental model that such constants are really integers with the characters `.0` appended to them). While it is technically possible to convert many such constants exactly, experience shows that a surprising number of translators fail to achieve the required degree of accuracy (e.g., the floating constant 6.0 might be translated to the same internal representation as the floating constant 5.999999 and subsequently converted to the integer constant 5).

Rev 686.1 A program shall not depend on the value of a floating constant being converted to an integer constant having the same value.

A developer who has made the effort of typing a floating constant is probably expecting it to be used as a floating type. Based on this assumption a floating constant that is implicitly converted to an integer type is unexpected behavior. Such an implicit conversion can occur if the floating constant is the right operand of an assignment or the argument in a function call. Not only is the implicit conversion likely to be unexpected by the original author, but subsequent changes to the code that cause a function-like macro to be invoked, rather than a function call, to result in a significant change in behavior.

In the following example, a floating constant passed to `CALC_1` results in `glob` being converted to a floating type. If the value of `glob` contains more significant digits than supported by the floating type, the final result assigned to `loc` will not be the value expected. Using explicit casts, as in `CALC_2`, removes the problem caused by the macro argument having a floating type. However, as discussed elsewhere, other dependencies are introduced. Explicitly performing the cast, where the argument is passed, mimics the behavior of a function call and shows that the developer is aware of the type of the argument.

653 operand convert automatically

```
#define X_CONSTANT 123456789.0
#define Y_CONSTANT 2

#define CALC_1(a)  ((a) + (glob))
#define CALC_2(a)  ((long)(a) + (glob))
#define CALC_3(a)  ((a) + (glob))

extern long glob;

void f(void)
{
long loc;

loc = CALC_1(X_CONSTANT);
loc = CALC_1(Y_CONSTANT);

loc = CALC_2(X_CONSTANT);
loc = CALC_2(Y_CONSTANT);

loc = CALC_3((long)X_CONSTANT);
loc = CALC_3(Y_CONSTANT);
}
```

The previous discussion describes some of the unexpected behaviors that can occur when a floating constant is implicitly converted to an integer type. Some of the points raised also apply to objects having a floating type. The costs and benefits of relying on implicit conversions or using explicit casts are discussed, in general, elsewhere. That discussion did not reach a conclusion that resulted in a guideline recommendation being made. Literals differ from objects in that they are a single instance of a single value. As such developers have greater control over their use, on a case by case basis, and a guideline recommendation is considered to be more worthwhile. This guideline recommendation is similar to the one given for conversions of suffixed integer constants.

653 operand convert automatically

835.2 integer constant with suffix, not immediately converted

Cg 686.2 A floating constant shall not be implicitly converted to an integer type.

687 If the value of the integral part cannot be represented by the integer type, the behavior is undefined.[50)]

Commentary

The exponent part in a floating-point representation allows very large values to be created, these could significantly exceed the representable range supported by any integer type. The behavior specified by the standard reflects both the fact that there is no commonly seen processor behavior in this case and the execution-time overhead of performing some defined behavior.

Other Languages

Other languages vary in their definition of behavior. Like integer values that are not representable in the destination type, some languages require an exception to be raise while others specify undefined behavior. In this case Java uses a two step-process. It first converts the real value to the most negative, or largest positive (depending on the sign of the floating-point number) value representable in a **long** or an **int**. In the second step, if the converted integer type is not **long** or **int**; the narrowing conversions are applied to the result of the first step.

Common Implementations

Many processors have the option of raising an exception when the value cannot be represented in the integer type. Some allow these exceptions to be switched off, returning the least significant bytes of the value. The IEC 60559 Standard defines the behavior— raise invalid. Most current C99 implementations do not do this.

arithmetic saturated

In graphics applications saturated arithmetic is often required (see Figure 687.1). Some DSP processors[967] and the Intel MMX instructions[627] return the largest representable value (with the appropriate sign).

Coding Guidelines

A naive analysis would suggest there is a high probability that an object having a floating type will hold a value that cannot be represented in an integer type. However, in many programs the range of floating-point values actually used is relatively small. It is this application-specific knowledge that needs to be taken into account by developers.

exponent 334

Those translators that perform some kind of flow analysis on object values often limit themselves to tracking the values of integer and pointer types. Because of the potential graininess in the values they represent and their less common usage, objects having floating types may have their set/unset status tracked but their possible numeric value is rarely tracked.

It might appear that, in many ways, this case is the same as that for integer conversions where the value cannot be represented. However, a major difference is processor behavior. There is greater execution overhead required for translators to handle this case independently of how the existing instructions behave. Also, a larger number of processors are capable of raising an exception in this case.

integer value 684
not represented in signed integer

Given that instances of this undefined behavior are relatively rare and instances might be considered to be a fault, no guideline recommendation is made here.

---

integer conversion to floating

When a value of integer type is converted to a real floating type, if the value being converted can be represented exactly in the new type, it is unchanged. 688

Commentary

The value may be unchanged, but its representation is likely to be completely changed.

There are the same number of representable floating-point values between every power of two (when `FLT_RADIX` has a value of two, the most common case). As the power of two increases, the numeric distance between representable values increases (see Figure 368.1). The value of the `*_DIG` macros specify the number of digits in a decimal value that may be rounded into a floating-point number and back again without

FLT_RADIX 366
*_DIG 369
macros

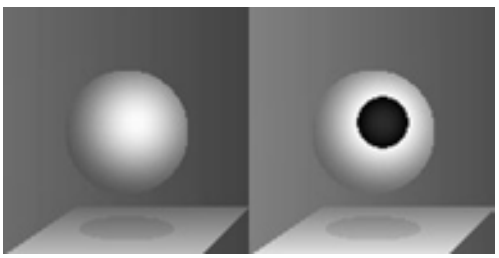

Figure 687.1: Illustration of the effect of integer addition wrapping rather than saturating. A value has been added to all of the pixels in the left image to increase the brightness, creating the image on the right. With permission from Jordán and Lotufo.[692]

change of value. In the case of the single-precision IEC 60559 representation FLT_DIG is six, which is less than the number of representable digits in an object having type **long** (or 32-bit **int**).

C++

An rvalue of an integer type or of an enumeration type can be converted to an rvalue of a floating point type. The result is exact if possible. 4.9p2

Who decides what is possible or if it can be represented exactly? A friendly reading suggests that the meaning is the same as C99.

Common Implementations

The Unisys A Series[1389] uses the same representation for integer and floating-point types (an integer was a single precision value whose exponent was zero).

Coding Guidelines

A common, incorrect belief held by developers is that because floating numbers can represent a much larger range of values than integers and include information on fractional parts, they must be able to exactly represent the complete range of values supported by any integer type. What is overlooked is that the support for an exponent value comes at the cost of graininess in the representation for large value (if objects of integer and floating type are represented in the same number of value bits).

The major conceptual difference between integer and floating types is that one is expected to hold an exact value and the other an approximate value. If developers are aware that approximations can begin at the point an integer value is converted, then it is possible for them to take this into account in designing algorithms. Developers who assume that inaccuracies don't occur until the floating value is operated on are in for a surprise.

Rev 688.1 Algorithms containing integer values that are converted to floating values shall be checked to ensure that any dependence on the accuracy of the conversion is documented and that any necessary execution-time checks against the *_DIG macros are made.

The rationale behind the guideline recommendations against converting floating constants to integer constants do not apply to conversions of integer constants to floating types. 686.2 floating constant implicitly converted

Example

```
#include <limits.h>
#include <stdio.h>

static float max_short = (float)SHRT_MAX;
static float max_int = (float)INT_MAX;
static float max_long = (float)LONG_MAX;

int main(void)
{
float max_short_m1,
      max_int_m1,
      max_long_m1;

for (int i_f=1; i_f < 3; i_f++)
   {
   max_short_m1 = (float)(SHRT_MAX - i_f);
   if (max_short == max_short_m1)
      printf("float cannot represent all representable shorts\n");
```

```
19      max_short=max_short_m1;
20      max_int_m1 = (float)(INT_MAX - i_f);
21      if (max_int == max_int_m1)
22         printf("float cannot represent all representable ints\n");
23      max_int=max_int_m1;
24      max_long_m1 = (float)(LONG_MAX - i_f);
25      if (max_long == max_long_m1)
26         printf("float cannot represent all representable longs\n");
27      max_long=max_long_m1;
28      }
29   }
```

---

int to float nearest representable value

If the value being converted is in the range of values that can be represented but cannot be represented exactly, the result is either the nearest higher or nearest lower representable value, chosen in an implementation-defined manner. 689

Commentary

There is no generally accepted behavior in this situation. The standard leaves it up to the implementation.

Other Languages

Most languages are silent on this issue.

Common Implementations

status flag 200 floating-point FLT_ROUNDS 352

Most processors contain a status flag that is used to control the rounding of all floating-point operations. Given that round-to-nearest is the most common rounding mode, the most likely implementation-defined behavior is round-to-nearest.

Coding Guidelines

A consequence of this behavior is that it is possible for two unequal integer values to be converted to the same floating-point value. Any algorithm that depends on the relationships between integer values being maintained after conversion to a floating type may not work as expected.

---

footnote 48

48) The integer promotions are applied only: as part of the usual arithmetic conversions, to certain argument expressions, to the operands of the unary +, -, and ~ operators, and to both operands of the shift operators, as specified by their respective subclauses. 690

Commentary

The certain argument expressions are function calls where there is no type information available. This happens for old-style function declarations and for prototype declarations where the ellipsis notation has been used and the argument corresponds to one of the parameters covered by this notation.

Another context where integer promotions are applied is the controlling expression in a **switch** statement. In all other cases the operand is being used in a context where its value is being operated on.

Contexts where the integer promotions are not applied are the expression specifying the number of elements in a VLA type definition (when there are no arithmetic or logical operators involved), function return values, the operands of the assignment operator, and arguments to a function where the parameter type is known. In the latter three cases the value is, potentially, implicitly cast directly to the destination type.

if statement 1744 operand compare against 0 iteration statement 1766 executed repeatedly

The standard does not specify that the implicit test against zero, in an **if** statement or iteration statement, will cause a single object (forming the complete controlling expression) to be promoted. A promotion would not affect the outcome in these contexts, and an implementation can use the as-if rule in selecting the best machine code to generate.

C++

In C++, integral promotions are applied also as part of the usual arithmetic conversions, the operands of the unary +, -, and ~ operators, and to both operands of the shift operators. C++ also performs integer promotions in contexts not mentioned here, as does C.

Coding Guidelines

There are a small number of cases where the integer promotions do not occur. Is anything to be gained by calling out these situations in coding guideline documents? Experience suggests that developers are more likely to forget that the integer promotions occur (or invent mythical special cases where they don't occur) rather than worry about additional conversions because of them. Coding guideline documents are no substitute for proper training.

---

691 49) The rules describe arithmetic on the mathematical value, not the value of a given type of expression. footnote 49

Commentary

This means that there are no representational issues involving intermediate results being within range of the type of the values. The abstract machine must act as if the operation were performed using infinite precision arithmetic.

C90

This observation was not made in the C90 Standard (but was deemed to be implicitly true).

C++

The C++ Standard does not make this observation.

---

692 50) The remaindering operation performed when a value of integer type is converted to unsigned type need not be performed when a value of real floating type is converted to unsigned type. footnote 50

Commentary

This permission reflects both differences in processor instruction behavior and the (in)ability to detect and catch those cases where the conversion might be performed in software. The behavior is essentially unspecified, although it is not explicitly specified as such (and it does not appear in the list of unspecified behaviors in Annex J.1).

C++

An rvalue of a floating point type can be converted to an rvalue of an integer type. The conversion truncates; that is, the fractional part is discarded. The behavior is undefined if the truncated value cannot be represented in the destination type. 4.9p1

The conversion behavior, when the result cannot be represented in the destination type is undefined in C++ and unspecified in C.

Common Implementations

The floating-point to integer conversion instructions on many processors are only capable of delivering signed integer results. An implementation may treat the value as a sequence of bits independent of whether a signed or unsigned value is expected. In this case the external behavior for two's complement notation is the same as if a remaindering operation had been performed. Converting values outside of the representable range of any integer type supported by an implementation requires that the processor conversion instruction either perform the remainder operation or raise some kind of range error signal that is caught by the implementation, which then performs the remainder operation in software.

Coding Guidelines

This is one area where developers' expectations may not mirror the behavior that an implementation is required to support.

Example

The following program may, or may not, output the values given in the comments.

```
#include <limits.h>
#include <stdio.h>

int main(void)
{
double d = UINT_MAX;
printf("%f, %u\n", d, (unsigned int)d); /* 4294967295.000000, 4294967295 */
d += 42;
printf("%f, %u\n", d, (unsigned int)d); /* 4294967337.000000, 41         */
d *= 20;
printf("%f, %u\n", d, (unsigned int)d); /* 85899346740.000000, 820       */
d = -1;
printf("%f, %u\n", d, (unsigned int)d); /* -1.000000, 4294967295         */
}
```

Thus, the range of portable real floating values is $(-1, \textit{Utype\_}\texttt{MAX} + 1)$. 693

Commentary

The round brackets are being used in the mathematical sense; the bounds represent excluded limits (i.e., -1 is not in the portable range). This statement only applies to unsigned integer types.

C++

The C++ Standard does not make this observation.

If the value being converted is outside the range of values that can be represented, the behavior is undefined. 694

Commentary

*_MAX_10_EXP[373]

An unsigned integer type represented in 123 bits, or more, could contain a value that would be outside the range of values representable in a minimum requirements **`float`** type (128 bits would be needed to exceed the range of the IEC 60559 single-precision).

C++

4.9p2 *Otherwise, it is an implementation-defined choice of either the next lower or higher representable value.*

The conversion behavior, when the result is outside the range of values that can be represented in the destination type, is implementation-defined in C++ and undefined in C.

Other Languages

Many other language standards were written in an age when floating-point types could always represent much larger values than could be represented in integer types and their specifications reflect this fact (by not mentioning this case). In Java values having integer type are always within the representable range of the floating-point types it defines.

Common Implementations

Processors that support 128-bit integer types, in hardware, are starting to appear.[27]

Coding Guidelines

Developers are likely to consider this issue to be similar to the year 2036 problem— address the issue when the course of history requires it to be addressed.

6.3.1.5 Real floating types

695 When a **float** is promoted to **double** or **long double**, or a **double** is promoted to **long double**, its value is unchanged (if the source value is represented in the precision and range of its type). float promoted to double or long double

Commentary

Although not worded as such, this is a requirement on the implementation. The type **double** must have at least the same precision in the significand and at least as much range in the exponent as the type **float**, similarly for the types **double** and **long double**.

A situation where the source value might not be represented in the precision and range of its type is when FLT_EVAL_METHOD has a non-zero value. For instance, if FLT_EVAL_METHOD has a value of 2, then the value `0.1f` is represented to the precision of **long double**, while the type remains as **float**. If a cast to **double** is performed<footnote, 87> the value may be different to that obtained when FLT_EVAL_METHOD was zero. [354] FLT_EVAL_ME

The wording was changed by the response to DR #318.

C++

*The type **double** provides at least as much precision as **float**, and the type **long double** provides at least as much precision as **double**. The set of values of the type **float** is a subset of the set of values of the type **double**; the set of values of the type **double** is a subset of the set of values of the type **long double**.* 3.9.1p8

This only gives a relative ordering on the available precision. It does not say anything about promotion leaving a value unchanged.

*An rvalue of type **float** can be converted to an rvalue of type **double**. The value is unchanged.* 4.6p1

There is no equivalent statement for type **double** to **long double** promotions. But there is a general statement about conversion of floating-point values:

An rvalue of floating point type can be converted to an rvalue of another floating point type. If the source value can be exactly represented in the destination type, the result of the conversion is that exact representation. 4.8p1

Given that (1) the set of values representable in a floating-point type is a subset of those supported by a wider floating-point type (3.9.1p8); and (2) when a value is converted to the wider type, the exact representation is required to be used (by 4.8p1)— the value must be unchanged.

Other Languages

Some languages specify one floating type, while others recognize that processors often support several different floating-point precisions and define mechanisms to allow developers to specify different floating types. While implementations that provide multiple floating-point types usually make use of the same processor hardware as that available to a C translator, other languages rarely contain this requirement.

Common Implementations

This requirement is supported by IEC 60559, where each representation is an extension of the previous ones holding less precision.

696 When a **double** is demoted to **float**, a **long double** is demoted to **double** or **float**, or a value being represented in greater precision and range than required by its semantic type (see 6.3.1.8) is explicitly converted <iso_delete>to its semantic type</iso_delete> (including to its own type), if the value being converted can be represented exactly in the new type, it is unchanged. double demoted to another floating type

Commentary

A simple calculation would suggest that unless an implementation uses the same representation for floating-point types, the statistically likelihood of a demoted value being exactly representable in the new type would be very low (an IEC 60559 double-precision type contains 2^{32} values that convert to the same single-precision value). However, measurements of floating-point values created during program execution show a surprisingly high percentage of value reuse (these results are discussed elsewhere).

binary * 1147 result
value 940
profiling
354 FLT_EVAL_METHOD
float 695 promoted to double or long double

A situation where a value might be represented in greater precision and range than required by its type is when FLT_EVAL_METHOD has a non-zero value.

The wording was changed by the response to DR #318.

C90

This case is not specified in the C90 Standard.

Coding Guidelines

equality 1214.1 operators not floating-point operands

Relying on the converted value being equal to the original value is simply a special case of comparing two floating-point values for equality.

Why is a floating-point value being demoted? If a developer is concerned about a floating-point value being represented to a greater precision than required by its semantic type, explicit conversions might be used simply as a way of ensuring known behavior in the steps in a calculation. Or perhaps a computed value is being assigned to an object. There are sometimes advantages to carrying out the intermediate steps in an expression evaluation in greater precision than the result that will be saved.

354 FLT_EVAL_METHOD
correctly 64 rounded result

If the value being converted is in the range of values that can be represented but cannot be represented exactly, the result is either the nearest higher or nearest lower representable value, chosen in an implementation-defined manner. 697

Commentary

352 FLT_ROUNDS

Although FLT_ROUNDS is only defined to characterize floating-point addition, its value is very likely to characterize the behavior in this case as well.

Other Languages

IEC 60559 29

Java specifies the IEEE-754 round-to-nearest mode.

Common Implementations

352 FLT_ROUNDS

Many implementations round-to-nearest. However, rounding to zero (ignoring the least significant bits) can have performance advantages. Changing the rounding mode of the hardware floating-point unit requires an instruction to be executed, which in itself is a fast instruction. However, but a common side effect is to require that the floating-point pipeline be flushed before another floating-point instruction can be issued— an expensive operation. Leaving the processor in round-to-zero mode may offer savings. The IBM S/360, when using its hexadecimal floating point representation, truncates a value when converting it to a representation having less precision.

Coding Guidelines

Like other operations on floating values, conversion can introduce a degree of uncertainty into the result. This is a characteristic of floating point; there are no specific guidelines for this situation.

---

floating value converted not representable

If the value being converted is outside the range of values that can be represented, the behavior is undefined. 698

Commentary

For very small values there is always a higher and lower value that bound them. The situation describes in the C sentence can only occur if the type being demoted from is capable of representing a greater range of exponent values than the destination type.

Other Languages

A value too small to be represented as a **`float`** *is converted to positive or negative zero; a value too large to be represented as a* **`float`** *is converted to a (positive or negative) infinity.* In Java

Common Implementations

On many processors the result of the conversion is controlled by the rounding mode. A common behavior is to return the largest representable value (with the appropriate sign) if rounding to zero is in force, and to infinity (with the appropriate sign) if rounding to nearest is in force. When rounding to positive or negative infinity, the result is either the largest representable value or infinity, depending on the sign of the result and the sign of the infinity being rounded to. Many processors also have the ability to raise some form of overflow exception in this situation, which can often be masked. [352] FLT_ROUNDS

In signal processing applications infinity is not a sensible value to round to, and processors used for these kinds of applications often saturate at the largest representable value.

Coding Guidelines

The issue of a value not being representable, in the destination type, applies to many floating-point operations other than conversion.

A result of infinity is the required behavior in some applications because it has known properties and its' effect on subsequent calculations might be intended to produce a result of infinity, or zero (for divide operations). Tests can be inserted into the source code to check for infinite results. In other applications, typically graphics or signal processing-oriented ones, a saturated value is required and developers would not expect to need to check for overflow.

Performance is often an important issue in code performing floating-point operations (adding code to do range checks can cause excessive performance penalties). Given the performance issue and the variety of possible application-desired behaviors and actual processor behaviors, there is no obvious guideline recommendation that can be made.

6.3.1.6 Complex types

699 When a value of complex type is converted to another complex type, both the real and imaginary parts follow the conversion rules for the corresponding real types.

Commentary

A complex type is the sum of its two parts in the Cartesian system. There is no requirement to minimize the difference between the modulus of the converted value and the modulus of the original value.

C90

Support for complex types is new in C99.

C++

The C++ Standard does not provide a specification for how the conversions are to be implemented.

Other Languages

The Fortran intrinsic function, `CMPLX` (whose behavior is mimicked on assignment), can take a complex parameter that specifies the type of conversion that should occur. If no `KIND` is specified, the intrinsic takes the value applicable to the default real type.

6.3.1.7 Real and complex

700 When a value of real type is converted to a complex type, the real part of the complex result value is determined by the rules of conversion to the corresponding real type and the imaginary part of the complex result value is a positive zero or an unsigned zero. real type converted to complex

Commentary

Prior to the conversion, the value has an arithmetic type and is in the real type domain. After the conversion the value has an arithmetic type and is in the complex type domain.

In mathematical terms all real numbers are part of the complex plane, with a zero imaginary part. It is only when a real type is converted to a complex type that a C implementation needs to start to associate an imaginary value with the complete value.

negative zero 615

The imaginary part is never a negative zero.

C90

Support for complex types is new in C99.

C++

The constructors for the complex specializations, 26.2.3, take two parameters, corresponding to the real and imaginary part, of the matching floating-point type. The default value for the imaginary part is specified as 0.0.

Other Languages

The Fortran intrinsic function `CMPLX` takes a parameter that specifies the type of conversion that should occur. If no `KIND` is specified, the intrinsic takes the value of the default real type. This intrinsic function also provides a default imaginary value of $0i$ (but does not say anything about the representation of zero).

Coding Guidelines

Support for complex types is new in C99 and there is no experience based on existing usage to draw on. Are there any parallels that can be made with other constructs (with a view to adapting guidelines that have been found to be useful for integer constants)? Some parallels are discussed next; however, no guideline recommendation is made because usage of complex types is not sufficiently great for there to be a likely worthwhile benefit.

Conversions between integer types and real floating types, and conversions between real floating to complex floating, both involve significant changes in developer conception and an implementation's internal representation. However, these parallels do not appear to suggest any worthwhile guideline recommendation.

A value of real type can also be converted to a complex type by adding an imaginary value of zero to it— for instance, `+0.0I` (assuming an implementation supports this form of constant). However, casts are strongly associated with conversion in developers' minds. The binary `+` operation may cause conversions, but this is not its primary association. The possibility that an implementation will not support this literal form of imaginary values might be considered in itself sufficient reason to prefer the use of casts, even without the developer associations.

```
1  #include <complex.h>
2
3  extern double _Complex glob;
4
5  void f(void)
6  {
7  glob = 1.0;                    /* Implicit conversion.      */
8  glob = (double _Complex)1.0;   /* Explicit conversion.      */
9  glob = 1.0 + 0.0I;             /* I might not be supported. */
10 }
```

Conversion of a value having a complex type, whose two components are both constants (the standard does not define the term *complex constant*), to a non-complex type is suspicious for the same reason as are other conversions of constant values.

floating-point 686
converted to integer

Are there any issues specifically associated with conversion to or from complex types that do not apply for conversions between other types? It is a change of type domain. At the time if writing there is insufficient experience available, with this new type, to know whether these issues are significant.

701 When a value of complex type is converted to a real type, the imaginary part of the complex value is discarded and the value of the real part is converted according to the conversion rules for the corresponding real type.

Commentary

This conversion simply extracts the real part from a complex value. It has the same effect as a call to the `creal` library function. A NaN value in the part being discarded does not affect the value of the result (rather than making the result value a NaN). There are no implicit conversions defined for converting to the type **`_Imaginary`**. The library function `cimag` has to be called explicitly.

1378 type specifier syntax

C++

In C++ the conversion has to be explicit. The member functions of the complex specializations (26.2.3) return a value that has the matching floating-point type.

Other Languages

Some languages support implicit conversions while others require an explicit call to a conversion function.

6.3.1.8 Usual arithmetic conversions

702 Many operators that expect operands of arithmetic type cause conversions and yield result types in a similar way.

operators cause conversions

Commentary

The operators cause the conversions in the sense that the standard specifies that they do. There is no intrinsic reason why they have to occur. The Committee could have omitted any mention of operators causing conversions, but would then have had to enumerate the behavior for all possible pairs of operand types. The usual arithmetic conversions are the lesser of two evils (reducing the number of different arithmetic types did not get a look in).

The operators referred to here could be either unary or binary operators. In the case of the unary operators the standard specifies no conversion if the operand has a floating type (although the implementation may perform one, as indicated by the value of the `FLT_EVAL_METHOD` macro). However, there is a conversion (the integer promotions) if the operand has an integer type.

354 FLT_EVAL_ME

Other Languages

Numeric promotion is applied to the operands of an arithmetic operator. Java

All languages that support more than one type need to specify the behavior when an operator is given operands whose types are not the same. Invariably the type that can represent the widest range of values tends to be chosen.

Coding Guidelines

Readers needing to comprehend the evaluation of an expression in detail, need to work out which conversions, if any, are carried out as a result of the usual arithmetic conversions (and the integer promotions). This evaluation requires readers to apply a set of rules. Most developers are not exposed on a regular basis to a broad combination of operand type pairs. Without practice, developers' skill in deducing the result of the usual arithmetic conversions on the less commonly encountered combinations of types will fade away (training can only provide a temporary respite). The consequences of this restricted practice is that developers never progress past the stage of remembering a few specific cases.

If a single integer type were used, the need for developers to deduce the result of the usual arithmetic conversions would be removed. This is one of the primary rationales behind the guideline recommendation that only a single integer type be used.

480.1 object int type only
653 operand convert automatically

As with the integer promotions, there is a commonly seen, incorrect assumption made about the usual

arithmetic conversions. This incorrect assumption is that they do not apply to objects defined using typedef names. In fact a typedef name is nothing more than a synonym. How an object is defined makes no difference to how the usual arithmetic conversions are applied. Pointing out this during developer training may help prevent developers from making this assumption.

typedef 1633 is synonym

---

common real type The purpose is to determine a *common real type* for the operands and result. 703

Commentary

This defines the term *common real type*. The basic idea is that both types are converted to the real type capable of holding the largest range of values (mixed signed/unsigned types are the fly in the ointment). In the case of integer types, the type with the largest rank is chosen. For types with the same rank, the conversions are unsigned preserving.

Many processor instructions operate on values that have the same type (or at least are treated as if they did). C recognizes this fact and specifies how the operands are to be converted. This process also removes the need to enumerate the behavior for all possible permutations of operand type pairs.

C90

The term *common real type* is new in C99; the equivalent C90 term was *common type*.

Other Languages

The need to convert the operands to the same type is common to languages that have a large number of different arithmetic types. There are simply too many permutations of different operand type pairs to want to enumerate, or expect developers to remember, the behavior for all cases. Some languages (e.g., PL/1) try very hard to implicitly convert the operands to the same type, without the developer having to specify any explicit conversions. Other languages (e.g., Pascal) enumerate a small number of implicit conversions and require the developer to explicitly specify how any other conversions are to be performed (by making it a constraint violation to mix operands having other type pairs).

Common Implementations

On some processors arithmetic operations can produce a result that is wider than the original operands—for instance multiplying two 16-bit values to give a 32-bit result. In these cases C requires that the result be converted back to the same width as the original operands. Such processor instructions also offer the potential optimization of not performing the widening to 32 bits before carrying out the multiplication. Other operand/result sizes include 8/16 bits.

Coding Guidelines

The C90 term *common type* is sometimes used by developers. Given that few developers will ever use complex types it is unlikely that there will be a general shift in terminology usage to the new C90 term.

Some developers make the incorrect assumption that if the two operands already have a common type, the usual arithmetic conversions are not applied. They forget about the integer promotions. For instance, two operands of type **short** are both promoted to **int** before the usual arithmetic conversions are applied.

Pointing out to developers that the integer promotions are always performed is a training issue (explicitly pointing out this case may help prevent developers from making this assumption). Following the guideline on using a single integer type ensures that incorrect developer assumptions about this promotion do not affect the intended behavior.

object 480.1 int type only

Example

```
1  unsigned char c1, c2, c3;
2
3  int f(void)
4  {
5  /*
6   * Experience shows that many developers expect the following additional and
```

```
7    * relational operations to be performed on character types, rather than int.
8    */
9   if ((c1 + c2) > c3)
10     c1 = 3;
11  }
```

704 For the specified operands, each operand is converted, without change of type domain, to a type whose corresponding real type is the common real type.

arithmetic conversions type domain unchanged

Commentary

This requirement means that the usual arithmetic conversions leave operands that have complex types as complex types and operands that have real types remain real types for the purposes of performing the operation. As well as saving the execution-time overhead on the conversion and additional work for the operator, this behavior helps prevent some unexpected results from occurring. The following example first shows the effects of a multiplication using the C99 rules:

500 complex types

520 real types

$$2.0 * (3.0 + \infty i) \Rightarrow 2.0 * 3.0 + 2.0 * \infty i \quad (704.1)$$

$$\Rightarrow 6.0 + \infty i \quad (704.2)$$

The result, $6.0 + \infty i$, is what the developer probably expected. Now assume that the usual arithmetic conversions were defined to change the type domain of the operands, a real type having $0.0i$ added to it when converting to a complex type. In this case, we get:

$$2.0 * (3.0 + \infty i) \Rightarrow (2.0 + 0.0i) * (3.0 - \infty i) \quad (704.3)$$

$$(2.0 * 3.0 - 0.0 * \infty) + (2.0 * \infty + 0.0 * 3.0)i \Rightarrow NaN + \infty i \quad (704.4)$$

The result, $NaN + \infty i$, is probably a surprise to the developer. For imaginary types:

$$2.0i * (\infty + 3.0i) \quad (704.5)$$

leads to $NaN + \infty i$ in one case and $-6.0 + \infty i$ in the C99 case.

C90

Support for type domains is new in C99.

C++

The term *type domain* is new in C99 and is not defined in the C++ Standard.

The template class `complex` contain constructors that can be used to implicitly convert to the matching complex type. The operators defined in these templates all return the appropriate complex type.

C++ converts all operands to a complex type before performing the operation. In the above example the C result is $6.0 + \infty i$, while the C++ result is $NaN + \infty i$.

Other Languages

Fortran converts the operand having the real type to a complex type before performing any operations.

Coding Guidelines

Support for complex types is new in C99, and at the time of this writing there is very little practical experience available on the sort of mistakes that developers make with it. An obvious potential misunderstanding would to be assume that if one operand has a complex type then the other operand will also be converted to the corresponding complex type. This thinking fits the pattern of the other conversions, but would be incorrect. Based on the same rationale as that given in the previous two sentences, the solution is training, not a guideline recommendation.

arithmetic conversions result type

Unless explicitly stated otherwise, the common real type is also the corresponding real type of the result, whose type domain is the type domain of the operands if they are the same, and complex otherwise. 705

Commentary

The only place where the standard *explicitly stated otherwise* is in the discussion of imaginary types in annex G. Support for such types, by an implementation, is optional. When one operand has a complex type and the other operand does not, the latter operand is not converted to a different type domain (although its real type may be changed by a conversion), so there is no common arithmetic type, only a common real type.

footnote 719 51

C++

The `complex` specializations (26.2.3) define conversions for **`float`**, **`double`** and **`long double`** to complex classes. A number of the constructors are defined as explicit, which means they do not happen implicitly, they can only be used explicitly. The effect is to create a different result type in some cases.

In C++, if the one operand does not have a complex type, it is converted to the corresponding complex type, and the result type is the same as the other operand having complex type. See footnote 51.

footnote 719 51

Other Languages

The result type being the same as the final type of the operands is true in most languages.

usual arithmetic conversions

This pattern is called the *usual arithmetic conversions*: 706

Commentary

This defines the term *usual arithmetic conversions*. There are variations on this term used by developers; however, *arithmetic conversions* is probably the most commonly heard.

Other Languages

The equivalent operations in Java are known as the *Binary Numeric Promotion*.

Common Implementations

In some cases the standard may specify two conversions— an integer promotion followed by an arithmetic conversion. An implementation need not perform two conversions. The as-if rule can be used to perform a single conversion (if the target processor has such an instruction available to it) provided the final result is the same.

Coding Guidelines

The concept of usual arithmetic conversions is very important in any source that has operands of different types occurring together in the same expression. The guideline recommendation specifying use of a single integer type is an attempt to prevent this from occurring. The general issue of whether any operand that is converted should be explicitly cast, rather than implicitly converted, is discussed elsewhere.

object 480.1 int type only
operand 653 convert automatically

arithmetic conversions long double

First, if the corresponding real type of either operand is **`long double`**, the other operand is converted, without change of type domain, to a type whose corresponding real type is **`long double`**. 707

Commentary

If the other operand has an integer type, the integer promotions are not first applied to it.

integer promotions 675

Other Languages

The operands having floating types takes precedence over those having integer types in all languages known to your author.

Common Implementations

Processors often support an instruction for converting a value having a particular integer type to a floating representation. Implementations have to effectively promote integer values to this type before they can be converted to a floating type. Since the integer type is usually the widest one available, there is rarely an externally noticeable difference.

Coding Guidelines

If both operands have a floating type, there is no loss of precision on the conversion.

When an integer is converted to a real type, there may be some loss of precision. The specific case of integer-to-floating conversion might be considered different from integer-to-integer and floating-to-floating conversions for a number of reasons:

- There is a significant change of representation.
- The mixing of operands having an integer and floating type is not common (the implication being that more information will be conveyed by an explicit cast in this context than in other contexts).
- The decision to declare an object to have a floating type is a much bigger one than giving it an integer type (experience suggests that, once this decision is made, it is much less likely to change than had an integer type has been chosen, for which there are many choices; so the maintenance issue of keeping explicit conversions up to date might be a smaller one than for integer conversions).

695 float promoted to double or long double
688 integer conversion to floating
688 integer conversion to floating

---

708 Otherwise, if the corresponding real type of either operand is **double**, the other operand is converted, without change of type domain, to a type whose corresponding real type is **double**.

arithmetic conversions double

Commentary

The operand may already be represented during expression evaluation to a greater precision than the type **double** (perhaps even type **long double**). However, from the point of view of type compatibility and other semantic rules, its type is still **double**.

354 FLT_EVAL_ME

Coding Guidelines

The issues associated with the operands being represented to a greater precision than denoted by their type are discussed elsewhere.

If the other operand has an integer type and is very large there is a possibility that it will not be exactly represented in type **double**, particularly if this type only occupies 32 bits (a single-precision IEC representation, the minimum required by the C Standard). The issues associated with of exact representation are discussed elsewhere.

354 FLT_EVAL_ME
688 integer conversion to floating

---

709 Otherwise, if the corresponding real type of either operand is **float**, the other operand is converted, without change of type domain, to a type whose corresponding real type is **float**.[51)]

arithmetic conversions float

Commentary

As was pointed out in the previous sentence, when one of the operands has type **double**, the operand may be represented to a greater precision during expression evaluation.

708 arithmetic conversions double

Common Implementations

Many implementations perform operations on floating-point operands using the type **double** (either because the instruction that loads the value from storage converts them to this form, or because the translator generates an instruction to implicitly convert them). The Intel x86 processor[627] implicitly converts values to an internal 80-bit form when they are loaded from storage.

---

710 Otherwise, the integer promotions are performed on both operands.

arithmetic conversions integer promotions

Commentary

At this point the usual arithmetic conversions become a two-stage process. Whether an implementation actually performs two conversions, or can merge everything into a single conversion, is an optimization issue that is not of concern to the developer. Performing the integer promotions reduces the number of permutations of operand types that the standard needs to specify behavior for.

675 integer promotions

Other Languages

Most languages have a small number of arithmetic types, and it is practical to fully enumerate the behavior in all cases, making it unnecessary to define an intermediate step.

Coding Guidelines

integer promotions 675
operand same type 712
no further conversion
object int type only 480.1

Developers sometimes forget about this step (i.e., they overlook the fact that the integer promotions are performed). The rule they jump to is often the one specifying that there need be no further conversions if the types are the same. There is no obvious guideline recommendation that can render this oversight (or lack of knowledge on the part of developers) harmless. If the guideline recommendation specifying use of a single integer type is followed these promotions will have no effect.

Usage

Usage information on integer promotions is given elsewhere (see Table 675.1).

---

arithmetic conversions integer types

Then the following rules are applied to the promoted operands: 711

Commentary

The C90 Standard enumerated each case based on type. Now the that concept of rank has been introduced, it is possible to specify rules in a more generalized form. This generalization also handles any extended integer types that an implementation may provide.

C++

The rules in the C++ Standard appear in a bulleted list of types with an implied sequential application order.

Common Implementations

In those implementations where the two types have the same representation no machine code, to perform the conversion at execution time, need be generated.

While the standard may specify a two-stage conversion process, some processors support instructions that enable some of the usual arithmetic conversions to be performed in a single instruction.

Coding Guidelines

standard integer types 493
conversion rank 659

Developers have a lot of experience in dealing with the promotion and conversion of the standard integer types. In the C90 Standard the rules for these conversions were expressed using the names of the types, while C99 uses the newly created concept of rank. Not only is the existing use of extended integer types rare (and so developers are unlikely to be practiced in their use), but conversions involving them use rules based on their rank (which developers will have to deduce). At the time of this writing there is insufficient experience available with extended integer types to be able to estimate the extent to which the use of operands having some extended type will result in developers incorrectly deducing the result type. For this reason these coding guidelines sections say nothing more about the issue (although if the guideline recommendation specifying use of a single integer type is followed the promotion of extended integer types does not become an issue).

object int type only 480.1

For one of the operands, these conversions can cause either its rank to be increased, its sign changed, or both of these things. An increase in rank is unlikely to have a surprising affect (unless performance is an issue, there can also be cascading consequences in that the result may need to be converted to a lesser rank later). A change of sign is more likely to cause a surprising result to be generated (i.e., a dramatic change in the magnitude of the value, or the reversal of its signedness). While 50% of the possible values an object can hold may produce a surprising result when it is converted between signed and unsigned, in practice the values that occur are often small and positive (see Table 940.4).

Experience has shown that mixing operands having signed and unsigned types in expressions has a benefit. Despite a great deal of effort, by a large number of people, no guideline recommendation having a cost less than that incurred by the occasional surprising results caused by the arithmetic conversions has been found.

Usage

Usage information on implicit conversions is given elsewhere (see Table 653.1).

712 If both operands have the same type, then no further conversion is needed.

operand same type no further conversion

Commentary

Both operands can have the same type because they were declared to have that type, the integer promotions converted them to that type, or because they were explicitly cast to those types.

C90

For language lawyers only: A subtle difference in requirements exists between the C90 and C99 Standard (which in practice would have been optimized away by implementations). The rules in the C90 wording were ordered such that when two operands had the same type, except when both were type **int**, a conversion was required. So the type **unsigned long** needed to be converted to an **unsigned long**, or a **long** to a **long**, or an **unsigned int** to an **unsigned int**.

Coding Guidelines

Many developers incorrectly assume this statement is true for all integer types, even those types whose rank is less than that of type **int**. They forget, or were never aware, that the integer promotions are always performed. The guideline recommendation dealing with a single integer type aims to ensure that both operands always have the same type.

675 integer promotions
480.1 object int type only

713 Otherwise, if both operands have signed integer types or both have unsigned integer types, the operand with the type of lesser integer conversion rank is converted to the type of the operand with greater rank.

Commentary

If the operands are both signed, or both unsigned, it is guaranteed that their value can be represented in the integer type of greater rank. This rule preserves the operand value and its signedness.

494 rank relative ranges

Other Languages

Those languages that support different size integer types invariably also convert the *smaller* integer type to the *larger* integer type.

Common Implementations

This conversion is usually implemented by sign-extending the more significant bits of the value for a signed operand, and by zero-filling for an unsigned operand. Many processors have instructions that will sign-extend or zero-fill a byte, or half word value, when it is loaded from storage into a register. Some processors have instructions that take operands of different widths; for instance, multiplying a 16-bit value by an 8-bit value. In these cases it may be possible to optimize away the conversion and to use specific instructions that return the expected result.

714 Otherwise, if the operand that has unsigned integer type has rank greater or equal to the rank of the type of the other operand, then the operand with signed integer type is converted to the type of the operand with unsigned integer type.

signed integer converted to unsigned

Commentary

This rule could be said to be unsigned preserving. The behavior for conversion to an unsigned type is completely specified by the standard, while the conversion to a signed type is not.

683 unsigned integer conversion to
684 integer value not represented in signed integer

Other Languages

Languages that have an unsigned type either follow the same rules as C in this situation, or require an explicit conversion to be specified (e.g., Modula-2).

Coding Guidelines

A signed operand having a negative value will be converted to a large unsigned value, which could be a surprising result. A guideline recommending against operands having negative values, in this case, might be considered equivalent to one recommending against faults— i.e., pointless. The real issue is one of operands of different signed'ness appearing together within an expression. This issue is discussed elsewhere.

683 unsigned integer conversion to
486 signed integer corresponding unsigned integer

Example

width 626
integer type

The width of the integer types is irrelevant. The conversion is based on rank only. The unsigned type has greater rank and the matching rule has to be applied.

```
1  signed int si;
2  unsigned long ul;
3
4  void f(void)
5  {
6  /* ... */ si + ul;
7  }
```

---

signed integer represent all unsigned integer values

Otherwise, if the type of the operand with signed integer type can represent all of the values of the type of the operand with unsigned integer type, then the operand with unsigned integer type is converted to the type of the operand with signed integer type. 715

Commentary

This rule is worded in terms of representable values, not rank. It preserves the value of the operand, but not its signedness. While a greater range of representable values does map to greater rank, the reverse is not true. It is possible for types that differ in their rank to have the same range of representable values. The case of same representation is covered in the following rule.

Other Languages

Most languages have a single integer type. Those that support an unsigned type usually only have one of them. A rule like this one is very unlikely to be needed.

Common Implementations

In this case an implementation need not generate any machine code. The translator can simply regard the value as having the appropriate signed integer type.

Example

In the following addition two possible combinations of representation yield the conversions:

1. 16-bit unsigned int plus 32-bit long $\Rightarrow$ 32-bit long
2. 32-bit unsigned int plus 32-bit long $\Rightarrow$ this rule not matched

```
1  unsigned int ui;
2  signed long sl;
3
4  void f(void)
5  {
6  /* ... */ ui + sl;
7  }
```

Otherwise, both operands are converted to the unsigned integer type corresponding to the type of the operand with signed integer type. 716

Commentary

This rule is only reached when one operand is an unsigned integer type whose precision is greater than or equal to the precision of a signed type having a greater rank. This can occur when two standard types have the same representation, or when the unsigned type is an extended unsigned integer type (which must have a

lesser rank than any standard integer type having the same precision). In this rule the result type is different from the type of either of the operands. The unsignedness is taken from one operand and the rank from another to create the final result type. This rule is the value-driven equivalent of the rank-driven rule specified previously.

714 signed integer converted to unsigned

Coding Guidelines

This result type of this rule is likely to come as a surprise to many developers, particularly since it is dependent on the width and precision of the operands (because of the previous rule). Depending on the representation of integer types used, the previous rule may match on one implementation and this rule match on another. The result of the usual arithmetic conversions, in some cases, is thus dependent on the representation of integer types.

A previous rule dealt with operands being converted from a signed to an unsigned type. For the rule specified here, there is the added uncertainty of the behavior depending on the integer representations used by an implementation.

714 signed integer converted to unsigned

Example

```
1  #include <stdint.h>
2
3  uint_fast32_t fast_ui;
4  signed long sl;
5  unsigned int ui;
6
7  void f(void)
8  {
9  /*
10  * 16-bit unsigned int + 32-bit signed long -> 32-bit signed long
11  * 32-bit unsigned int + 32-bit signed long -> 32-bit unsigned long
12  */
13 ui + sl;
14
15 fast_ui + sl; /* unsigned long result. */
16 }
```

---

717 The values of floating operands and of the results of floating expressions may be represented in greater precision and range than that required by the type;

Commentary

This issue is discussed under the FLT_EVAL_METHOD macro.

354 FLT_EVAL_ME

Other Languages

Most languages do not get involved in specifying this level of detail (although Ada explicitly requires the precision to be as defined by the types of the operands).

Coding Guidelines

Additional precision does not necessarily make for more accurate results, or more consistent behavior (in fact often the reverse). The issues involved are discussed in more detail under the FLT_EVAL_METHOD macro.

354 FLT_EVAL_ME

---

718 the types are not changed thereby.[52)]

Commentary

Any extra precision that might be held by the implementation does not affect the semantic type of the result.

---

719 51) For example, addition of a **double _Complex** and a **float** entails just the conversion of the **float** operand to **double** (and yields a **double _Complex** result).

footnote 51

Commentary

Similarly, the addition of operands having types **float _Complex** and **double** entails conversion of the complex operand to **double _Complex**.

C90

Support for complex types is new in C99

C++

arithmetic conversions 709
float

The conversion sequence is different in C++. In C++ the operand having type **float** will be converted to `complexfloat` prior to the addition operation.

```
1  #include <complex.h> // the equivalent C++ header
2
3  float complex fc; // std::complex<float> fc;  this is the equivalent C++ declaration
4  double d;
5
6  void f(void)
7  {
8  fc + d   /* Result has type double complex. */
9           // Result has type complex<float>.
10       ;
11 }
```

footnote 52

52) The cast and assignment operators are still required to perform their specified conversions as described in 6.3.1.4 and 6.3.1.5. 720

Commentary

To be exact an implementation is required to generate code that behaves as if the specified conversions were performed. An implementation can optimize away any conversion if it knows that the current value representation is exactly the same as the type converted to (implicitly or explicitly). When an implementation carries out floating-point operations to a greater precision than required by the semantic type, the cast operator is guaranteed to return a result that contains only the precision required by the type converted to. An explicit cast provides a filter through which any additional precision cannot pass.

The assignment operator copies a value into an object. The object will have been allocated sufficient storage to be able to hold any value representable in its declared type. An implementation therefore has to scrape off any additional precision which may be being held in the value (i.e., if the register holding it has more precision), prior to storing a value into an object.

Passing an argument in a function call, where a visible prototype specifies a parameter type of less floating-point precision, is also required to perform these conversions.

Other Languages

A universal feature of strongly typed languages is that the assignment operator is only able to store a value into an object that is representable in an object's declared type. Many of these languages do not get involved in representation details. They discuss the cast operator, if one is available, in terms of change of type and tend to say nothing about representation issues.

In some languages the type of the value being assigned becomes the type of the object assigned to. For such language objects are simply labels for values and have no identity of their own, apart from their name (and they may not even have that).

6.3.2 Other operands

6.3.2.1 Lvalues, arrays, and function designators

lvalue

An *lvalue* is an expression with an object type or an incomplete type other than **void**;[53] 721

Commentary

This defines the term *lvalue*, pronounced *ell-value*. It is an important concept and this term is used by the more sophisticated developers. An lvalue can have its address taken.

The difference between evaluating, for instance, the expression `a[i]` as a value and as an lvalue is that in the former case the result is the value, while in the latter it is the address of the i'th element of the array `a`.

```

> Tom Payne
This is true.  To clean up the history a bit: The 1967 BCPL manual I
have uses the words "lvalue" and "rvalue" liberally; my copy does not
have a consolidated grammar, but the section about Simple Assignment
Commands describes the syntactical possibilities for things on the
left of := , namely an identifier (not a manifest constant), a vector
application, or an rv expression (equivalent to C *, or later BCPL
!).  However, "lvalue" in the text does indeed seem to be a semantic
notion, namely a bit pattern that refers to a cell in the abstract
machine.
The Richards and Whitbey-Strevens book (my printing seems post-1985,
but it's a reprint of the 1980 edition) does not seem to use the
terms lvalue or rvalue.  On the other hand, it does make even more
explicit syntactically (in its grammar) what can appear on the LHS of
the := of an assignment-command, namely an <lhse> or left-hand-side
expression. This is the syntactic lvalue.
On yet another hand, it only indirectly and by annotation says that
the operand of the address-of operator is restricted.  Nevertheless,
the textual description seems identical to the consolidated grammar's
<lhse>.
In any event, my observation that K&R 1 used syntactic means as the
underlying basis for answering the question "what can go on the left
of = or as the operand of ++, &, ...?" seems true.  In C89 and C99
there are no syntactical restrictions; the many that exist are
semantic, for better or worse.
Dennis
```

C90

> *An lvalue is an expression (with an object type or an incomplete type other than* **void***) that designates an object.31)*

assignment operator 1289
modifiable lvalue

The C90 Standard required that an lvalue designate an object. An implication of this requirement was that some constraint requirements could only be enforced during program execution (e.g., the left operand of an assignment operator must be an lvalue). The Committee intended that constraint requirements be enforceable during translation.

Technically this is a change of behavior between C99 and C90. But since few implementations enforced this requirement during program execution, the difference is unlikely to be noticed.

C++

3.10p2 *An lvalue refers to an object or function.*

object types 475

Incomplete types, other than **void**, are object types in C++, so all C lvalues are also C++ lvalues.

The C++ support for a function lvalue involves the use of some syntax that is not supported in C.

3.10p3 *As another example, the function*

```
int& f();
```

yields an lvalue, so the call `f()` *is an lvalue expression.*

Other Languages

While not being generic to programming languages, the concept of lvalue is very commonly seen in the specification of other languages.

---

if an lvalue does not designate an object when it is evaluated, the behavior is undefined. 722

Commentary

This can occur if a dereferenced pointer does not refer to an object, or perhaps it refers to an object whose lifetime has ended.

lifetime of object 451

C90

In the C90 Standard the definition of the term *lvalue* required that it designate an object. An expression could not be an lvalue unless it designated an object.

C++

In C++ the behavior is not always undefined:

3.8p6 *Similarly, before the lifetime of an object has started but after the storage which the object will occupy has been allocated or, after the lifetime of an object has ended and before the storage which the object occupied is reused or released, any lvalue which refers to the original object may be used but only in limited ways. Such an lvalue refers to allocated storage (3.7.3.2), and using the properties of the lvalue which do not depend on its value is well-defined.*

Coding Guidelines

A guideline recommending that an lvalue always denote an object when it is evaluated is equivalent to a guideline recommending that programs not contain defects.

Example

```
1  extern int *p;
2
3  void f(void)
4  {
5  p[3]=3; /* Does p designate an object? */
6  }
```

---

723 When an object is said to have a particular type, the type is specified by the lvalue used to designate the object. particular type

Commentary

This is not a definition of the term *particular type*, which is only used in two other places in the standard. In the case of objects with static and automatic storage duration, it is usually the declared type of the object. For objects with allocated storage duration, almost any type can be used. The term *effective type* was introduced in C99 to provide a more precise specification of an object's type. 948 effective type

C++

The situation in C++ is rather more complex:

> *The constructs in a C++ program create, destroy, refer to, access, and manipulate objects. An object is a region of storage. [Note: A function is not an object, regardless of whether or not it occupies storage in the way that objects do.] An* `object` *is created by a* `definition` *(3.1), by a* `new-expression` *(5.3.4) or by the implementation (12.2) when needed. The properties of an object are determined when the object is created. An object can have a* `name` *(clause 3). An object has a* `storage duration` *(3.7) which influences its* `lifetime` *(3.8). An object has a* `type` *(3.9). The term* `object type` *refers to the type with which the object is created. Some objects are* `polymorphic` *(10.3); the implementation generates information associated with each such object that makes it possible to determine that object's type during program execution. For other objects, the interpretation of the values found therein is determined by the type of the* `expressions` *(clause 5) used to access them.* 1.8p1

Example

```
1  extern int ei;
2  extern void *pv;
3
4  void f(void)
5  {
6  ei = 2;
7  *(char *)pv = 'x';
8  }
```

---

724 A *modifiable lvalue* is an lvalue that does not have array type, does not have an incomplete type, does not have a const-qualified type, and if it is a structure or union, does not have any member (including, recursively, any member or element of all contained aggregates or unions) with a const-qualified type. modifiable lvalue

Commentary

This defines the term *modifiable lvalue*; which is not commonly used by developers. Since most lvalues are modifiable, the term *lvalue* tends to be commonly used to denote those that are modifiable. There are

a variety of different terms used to describe lvalues that are not modifiable lvalues, usually involving the phrase *const-qualified*. As the name suggests, a modifiable lvalue can be modified during program execution. All of the types listed in the C sentence are types whose lvalues are not intended to be modified, or for which there is insufficient information available to be able to modify them (an incomplete type).

footnote 1131 85 The result of a cast is not an lvalue, so it is not possible to cast away a const-qualification. However, it is possible to cast away constness via a pointer type:

```
1  struct {
2          const int m1;
3          /*
4           * The const qualifier applies to the array
5           * element, not to the array a_mem.
6           */
7          const int a_mem[3];
8          } glob;
9
10 const int * cp = &glob.m1;
11
12 void f(void)
13 {
14 *(int *)cp=2;
15 }
```

The term member applies to structure and union types, while element refers to array types.

C++

The term *modifiable lvalue* is used by the C++ Standard, but understanding what this term might mean requires joining together the definitions of the terms *lvalue* and *modifiable*:

3.10p10 *An lvalue for an object is necessary in order to modify the object except that an rvalue of class type can also be used to modify its referent under certain circumstances.*

3.10p14 *If an expression can be used to modify the object to which it refers, the expression is called modifiable.*

There does not appear to be any mechanism for modifying objects having an incomplete type.

8.3.4p5 *Objects of array types cannot be modified, see 3.10.*

This is a case where an object of a given type cannot be modified and follows the C requirement.

7.1.5.1p3 *. . . ; a const-qualified access path cannot be used to modify an object even if the object referenced is a non-const object and can be modified through some other access path.*

The C++ wording is based on access paths rather than the C method of enumerating the various cases. However, the final effect is the same.

Other Languages

Many languages only provide a single way of modifying an object through assignment. In these cases a general term describing modifiability is not required; the requirements can all be specified under assignment. Languages that support operators that can modify the value of an object, other than by assignment, sometimes define a term that serves a purpose similar to modifiable lvalue.

---

lvalue converted to value

Except when it is the operand of the **sizeof** operator, the unary **&** operator, the **++** operator, the **--** operator, or the left operand of the **.** operator or an assignment operator, an lvalue that does not have array type is converted to the value stored in the designated object (and is no longer an lvalue). 725

Commentary

The exceptions called out here apply either because information on the storage for an object is used or are situations where there is a possibility for the lvalue to be modified (in the case of the **&** and **.** operators this may occur in a subsequent operation). In the case of an array type, in most contexts, a reference to an object having this type is converted to a pointer to its first element (and so is always an lvalue). This converted lvalue is sometimes called an *rvalue*.

729 array converted to pointer

736 rvalue

C++

Quite a long chain of deduction is needed to show that this requirement also applies in C++. The C++ Standard uses the term *rvalue* to refer to the particular value that an lvalue is converted into.

> *Whenever an lvalue appears in a context where an rvalue is expected, the lvalue is converted to an rvalue;* 3.10p7

> *Whenever an lvalue expression appears as an operand of an operator that expects an rvalue for that operand, the lvalue-to-rvalue (4.1), . . . standard conversions are applied to convert the expression to an rvalue.* 5p8

The C wording specifies that lvalues are converted unless they occur in specified contexts. The C++ wording specifies that lvalues are converted in a context where an rvalue is expected. Enumerating the cases where C++ expects an rvalue we find:

> *The lvalue-to-rvalue (4.1), . . . standard conversions are not applied to the operand of* ***sizeof****.* 5.3.4p4

What is the behavior for the unary **&** operator?

> *There are some contexts where certain conversions are suppressed. For example, the lvalue-to-rvalue conversion is not done on the operand of the unary* ***&*** *operator.* 4p5

However, this is a *Note:* and has no normative status. There is no mention of any conversions in 5.3.1p2-5, which deals with the unary **&** operator.

In the case of the postfix **++** and **--** operators we have:

> *The operand shall be a modifiable lvalue. . . . The result is an rvalue.* 5.2.6p1

In the case of the prefix **++** and **--** operators we have:

> *The operand shall be a modifiable lvalue. . . . The value is the new value of the operand; it is an lvalue.* 5.3.2p1

So for the postfix case, there is an lvalue-to-rvalue conversion, although this is never explicitly stated and in the prefix case there is no conversion.

The C case is more restrictive than C++, which requires a conforming implementation to successfully translate:

```
1  extern int i;
2
3  void f(void)
4  {
5  ++i = 4; // Well-formed
6           /* Constraint violation */
7  }
```

For the left operand of the **.** operator we have:

5.2.5p4

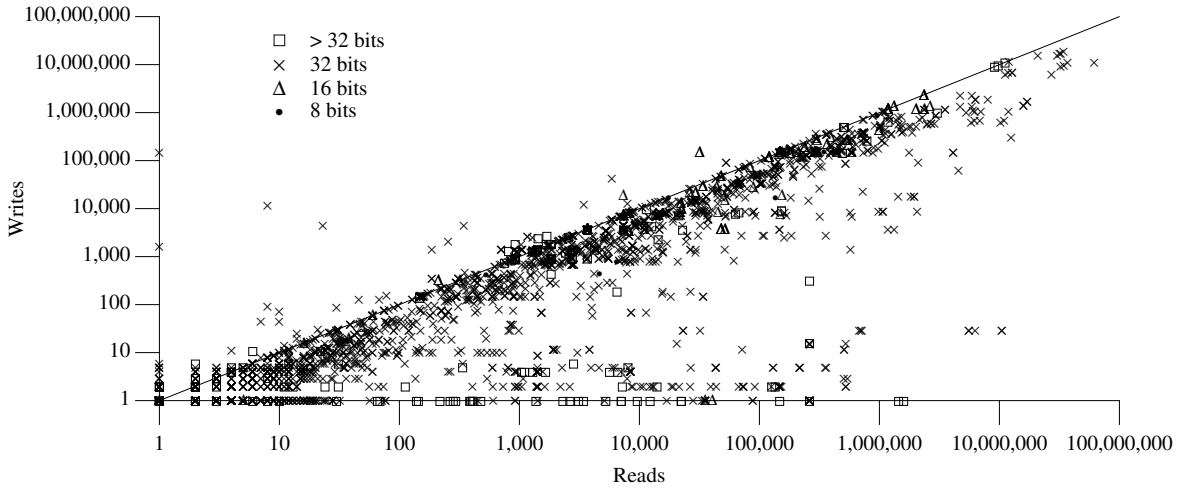

Figure 725.1: Execution-time counts of the number of reads and writes of the same object (declared in block or file scope, i.e., not allocated storage) for a subset of the MediaBench benchmarks; items above the diagonal indicate more writes than reads. Data kindly supplied by Caspi, based on his research.[207]

If `E1` *is an lvalue, then* `E1.E2` *is an lvalue.*

The left operand is not converted to an rvalue. For the left operand of an assignment operator we have:

5.17p1 *All require a modifiable lvalue as their left operand, . . . ; the result is an lvalue.*

The left operand is not converted to an rvalue. And finally for the array type:

4.1p1 *An lvalue (3.10) of a non-function, non-array type* `T` *can be converted to an rvalue.*

An lvalue having an array type cannot be converted to an rvalue (i.e., the C++ Standard contains no other wording specifying that an array can be converted to an rvalue).

In two cases the C++ Standard specifies that lvalue-to-rvalue conversions are not applied: Clause 5.18p1 left operand of the comma operator and Clause 6.2p1 the expression in an expression statement. In C the values would be discarded in both of these cases, so there is no change in behavior. In the following cases C++ performs a lvalue-to-rvalue conversion (however, the language construct is not relevant to C): Clause 8.2.8p3 Type identification; 5.2.9p4 static cast; 8.5.3p5 References.

Other Languages

The value that the lvalue is converted into is sometimes called an *rvalue* in other languages.

Coding Guidelines

The distinction between lvalue and rvalue and the circumstances in which the former is converted into the latter is something that people learning to write software for the first time often have problems with. But once the underlying concepts are understood, developers know how to distinguish the two contexts. The confusion that developers often get themselves into with pointers is the *pointer* or the *pointed-to object* being accessed is a separate issue and is discussed under the indirection operator.

unary * 1095
indirection

Usage

Usage information on the number of translation time references, in the source code, is given elsewhere (see Figure 1821.5, Figure 1821.6).

---

lvalue
value is unqualified

If the lvalue has qualified type, the value has the unqualified version of the type of the lvalue; 726

Commentary

Type qualification only applies to objects, not to values. A pointer value can refer to an object having a qualified type. In this case it is not the pointer value that is qualified.

```
1  extern int glob;
2  extern const int *p_1;
3  extern       int * const p_2 = &glob; /* The value of p_2 cannot be modified. */
4
5  void f(void)
6  {
7  const int loc = 2;
8
9  p_1 = &loc; /* The value of p_1 can be modified. */
10 }
```

C++

The value being referred to in C is what C++ calls an *rvalue*.

If T is a non-class type, the type of the rvalue is the cv-unqualified version of T. Otherwise, the type of the rvalue is T.[49)] 4.1p1

49) In C++ class rvalues can have cv-qualified types (because they are objects). This differs from ISO C, in which non-lvalues never have cv-qualified types. Footnote 49

Class rvalues are objects having a structure or union type in C.

Other Languages

Some languages give string literals their equivalent of a **const** qualifier, thus making it possible for values to be qualified, as well as have a type.

---

727 otherwise, the value has the type of the lvalue.

Commentary

Accessing an lvalues value does not change its type, even if there are more bits in the object representation than in the value representation. Those values that have an integer type whose rank is less than that of **int** may be promoted to **int** or some other type as a result of being the operand of some operator. But values start off with the type of the lvalue from which they were obtained.

574 object representation
595 value representation
675 integer promotions

Other Languages

This statement is probably generic to all languages.

---

728 If the lvalue has an incomplete type and does not have array type, the behavior is undefined.

Commentary

In the case of array types the element type is known, which is the only information needed by a translator (to calculate the offset of the indexed element, given any index value).

As the standard points out elsewhere, an incomplete type may only be used when the size of an object of that type is not needed.

1465 footnote 109

C++

4.1p1

An lvalue (3.10) of a non-function, non-array type T can be converted to an rvalue. If T is an incomplete type, a program that necessitates this conversion is ill-formed.

4.2p1 *An lvalue or rvalue of type "array of N T" or "array of unknown bound of T" can be converted to an rvalue of type "pointer to T."*

The C behavior in this case is undefined; in C++ the conversion is ill-formed and a diagnostic is required.

Common Implementations

It is very likely that an occurrence of this undefined behavior will be diagnosed by an implementation.

Coding Guidelines

It may surprise developers to find this case is not a constraint violation, but undefined behavior. While the standard specifies that the behavior is undefined, in this case, it is difficult to see how a translator could do anything other than issue a diagnostic and fail to translate (there are no meaningful semantics to give to such a construct). This is not to say that a low-quality translator will accept a program containing such a construct without issuing a diagnostic. Given the likely translator behavior, no guideline is recommended here.

Example

incomplete array indexing

A reference to an array degenerates into a pointer to its first element:

```
1  int ar[];
2
3  void f(void)
4  {
5  ar[2] = 3;
6  }
```

even though `ar` is incomplete at the time it is indexed. Below is a pointer to an incomplete type:

```
1  struct T *pt, *qt;
2
3  void g(void)
4  {
5  *pt=*qt;
6  }
```

Information on the members of the structure T is not needed when dealing with pointers to that structure.

---

array converted to pointer

Except when it is the operand of the **`sizeof`** operator or the unary **`&`** operator, or is a string literal used to initialize an array, an expression that has type "array of *type*" is converted to an expression with type "pointer to *type*" that points to the initial element of the array object and is not an lvalue. 729

Commentary

If arrays were converted to a pointer to their first element when appearing as the operand of the **`sizeof`** operator, it would be impossible to obtain their sizes.

array type 1598 adjust to pointer to

A similar conversion occurs in the declaration of parameters having an array type. Almost at the drop of a hat objects having an array type are converted into a pointer to their first element. Thus, complete arrays, unlike structures, cannot be assigned or passed as parameters because an occurrence of the identifier, denoting the array object, is converted to a pointer to the first element of that object.

wide string 905 literal type of

String literals have type array of **`char`**, or array of `wchar_t`.

In many contexts applying the unary **`&`** operator to an operand that is an array index is redundant (rather like using the unary **`+`** operator). However, support for such usage can simplify the automatic generation of C source (by allowing objects having an array type to be treated like any other object type).

```
int a[10];

&a;    /* Type pointer to array of int */
&a[3]; /* Type pointer to int */
a[3];  /* Type int */
```

This sentence in the C99 Standard has relaxed some of the restrictions that were in the C90 Standard:

```
#include <stdio.h>

struct S {
         int a[2];
         };

struct S WG14_N813(void)
{
struct S x;

x.a[0] = x.a[1] = 1;
return x;
}

int main(void)
{
/*
 * The following would have been a constraint violation in C90
 * since the expression WG14_N813(a).a is not an lvalue (in C90 the
 * member selection operator is only an lvalue if its left operand
 * is an lvalue, and a function call is not an lvalue).
 */
printf("Answer is %d\n", WG14_N813().a[0]);
}
```

C90

Except when it is the operand of the **`sizeof`** *operator or the unary* **`&`** *operator, or is a character string literal used to initialize an array of character type, or is a wide string literal used to initialize an array with element type compatible with* `wchar_t`*, an lvalue that has type "array of type" is converted to an expression that has type "pointer to type" that points to the initial element of the array object and is not an lvalue.*

The C90 Standard says " . . . , an lvalue that has type "array of type" is converted . . . ", while the C99 Standard says " . . . , an expression that has type . . . ". It is possible to create a non-lvalue array. In these cases the behavior has changed. In C99 the expression `(g?x:y).m1[1]` is no longer a constraint violation (C90 footnote 50, "A conditional expression does not yield an lvalue").

In the following, C90 requires that the size of the pointer type be output, while C99 requires that the size of the array be output.

```
#include <stdio.h>

struct {
       int m1[2];
       } x, y;
int g;

int main(void)
{
printf("size=%ld\n", sizeof((g?x:y).m1));
}
```

C++

5.3.3p4 *The . . . , array-to-pointer (4.2), . . . standard conversions are not applied to the operand of* ***sizeof****.*

4.2p1 *An lvalue or rvalue of type "array of N T" or "array of unknown bound of T" can be converted to an rvalue of type "pointer to T." The result is a pointer to the first element of the array.*

4.2p2 *A string literal . . . can be converted . . . This conversion is considered only when there is an explicit appropriate pointer target type, and not when there is a general need to convert from an lvalue to an rvalue.*

When is there an explicit appropriate pointer target type? Clause 5.2.1 Subscripting, requires that one of the operands have type *pointer to T*. A character string literal would thus be converted in this context.

5.17p3 *If the left operand is not of class type, the expression is implicitly converted (clause 4) to the cv-unqualified type of the left operand.*

8.3.5p3 *After determining the type of each parameter, any parameter of type "array of T" or "function returning T" is adjusted to be "pointer to T" or "pointer to function returning T," respectively.*

Clause 5.3.1p2 does not say anything about the conversion of the operand of the unary **&** operator. Given that this operator requires its operand to be an lvalue not converting an lvalue array to an rvalue in this context would be the expected behavior.

There may be other conversions, or lack of, that are specific to C++ constructs that are not supported in C.

Other Languages

Implicitly converting an array to a pointer to its first element is unique to C (and C++).

Common Implementations

Most implementations still follow the C90 behavior. `gcc`'s support for `(g?x:y).m1[1]` is a known extension to C90 that is not an extension in C99.

Coding Guidelines

The implicit conversion of array objects to a pointer to their first element is a great inconvenience in trying to formulate stronger type checking for arrays in C.

Inexperienced, in the C language, developers sometimes equate arrays and pointers much more closely than permitted by this requirement (which applies to uses in expressions, not declarations). For instance, in:

file_1.c
```
1 extern int *a;
```

file_2.c
```
1 extern int a[10];
```

the two declarations of `a` are sometimes incorrectly assumed by developers to be compatible. It is difficult to see what guideline recommendation would overcome incorrect developer assumptions (or poor training). If the guideline recommendation specifying a single point of declaration is followed, this problem will not occur.

identifier declared in one file 422.1

function designator converted to type 732

Unlike the function designator usage, developers are familiar with the fact that objects having an array type are implicitly converted to a pointer to their first element. Whether applying a unary **&** operator to an operand having an array type provides readers with a helpful visual cue or causes them to wonder about the intent of the author ("what is that redundant operator doing there?") is not known.

Example

```
1   static double a[5];
2
3   void f(double b[5])
4   {
5   double (*p)[5] = &a;
6   double **q = &b;    /* This looks suspicious, */
7
8   p = &b;             /* and so does this.      */
9   q = &a;
10  }
```

730 If the array object has register storage class, the behavior is undefined.

array object register storage class

Commentary

The conversion specified in the previous sentence is implicitly returning the address of the array object. This statement is making it clear what the behavior is in this case (no diagnostic is required). It is a constraint violation to explicitly take the address, using the **&** operator, of an object declared with the **register** storage class (even although in this case there is no explicit address-of operator).

1088 unary & operand constraints

1074 footnote 83

C90

This behavior was not explicitly specified in the C90 Standard.

C++

*A **register** specifier has the same semantics as an **auto** specifier together with a hint to the implementation that the object so declared will be heavily used.*

7.1.1p3

Source developed using a C++ translator may contain declarations of array objects that include the **register** storage class. The behavior of programs containing such declarations will be undefined if processed by a C translator.

Coding Guidelines

Given that all but one uses of an array object defined with register storage class, result in undefined behavior (its appearance as the operand of the **sizeof** operator is defined), there appears to be no reason for specifying this storage class in a declaration. However, the usage is very rare and no guideline recommendation is made.

731 A *function designator* is an expression that has function type.

function designator

Commentary

This defines the term *function designator*, a term that is not commonly used in developer discussions. The phrase *designates a function* is sometimes used.

C++

This terminology is not used in the C++ Standard.

Other Languages

Many languages do not treat functions as types. When they occur in an expression, it is because the name of the function is needed in a function call. A few languages do support function types and allow an expression to evaluate to a function type. These languages usually define some technical terminology to describe the occurrence.

function designator converted to type

Except when it is the operand of the **sizeof** operator[54] or the unary **&** operator, a function designator with type "function returning *type*" is converted to an expression that has type "pointer to function returning *type*". 732

Commentary

Using the unary **&** operator with function types is redundant (as it also is for array types), but supporting such usage makes the automatic generation of C source code simpler (by allowing objects having pointer-to function type to be treated like any other object type). In:

```
1  extern void f(void);
2
3  void g(void)
4  {
5  void (*pf)(void) = f;
6
7  f();
8  pf();
9  }
```

the last two occurrences of `f` are converted to a pointer-to the function denoted by the declaration at file scope. In the first case this pointer is assigned to the object `pf`. In the second case the pointer value is operated on by the **()** operator, causing the pointed-to function to be called. The definition of `g` could, equivalently (and more obscurely), have been:

```
1  void g(void)
2  {
3  void (*pf)(void) = &f;
4
5  &f();
6  (*pf)();
7  }
```

C++

5.3.3p4 *The . . . , and function-to-pointer (4.3) standard conversions are not applied to the operand of* ***sizeof****.*

5.3.1p2 *The result of the unary* ***&*** *operator is a pointer to its operand. The operand shall be an lvalue or a* `qualified-id`*. In the first case, if the type of the expression is "T," the type of the result is "pointer to T."*

While this clause does not say anything about the conversion of the operand of the unary **&** operator, given that this operator returns a result whose type is "pointer to T", not converting it prior to the operator being applied would be the expected behavior. What are the function-to-pointer standard conversions?

4.3p1 *An lvalue of function type T can be converted to an rvalue of type "pointer to T."*

5p8 *Whenever an lvalue expression appears as an operand of an operator that expects an rvalue for that operand, . . . , or function-to-pointer (4.3) standard conversions are applied to convert the expression to an rvalue.*

In what contexts does an operator expect an rvalue that will cause a function-to-pointer standard conversion?

5.2.2p1

For an ordinary function call, the postfix expression shall be either an lvalue that refers to a function (in which case the function-to-pointer standard conversion (4.3) is suppressed on the postfix expression), or it shall have pointer to function type.

The suppression of the function-to-pointer conversion is a difference in specification from C, but the final behavior is the same.

If either the second or the third operand has type (possibly cv-qualified) **`void`***, then the . . . , and function-to-pointer (4.3) standard conversions are performed on the second and third operands,* 5.16p2

If the left operand is not of class type, the expression is implicitly converted (clause 4) to the cv-unqualified type of the left operand. 5.17p3

After determining the type of each parameter, any parameter of type "array of T" or "function returning T" is adjusted to be "pointer to T" or "pointer to function returning T," respectively. 8.3.5p3

This appears to cover all cases.

Other Languages

Those languages that support function types provide a variety of different mechanisms for indicating that the address of a function is being taken. Many of them do not contain an address-of operator, but do have an implicit conversion based on the types of the operands in the assignment.

Common Implementations

Most implementations generate code to call the function directly (an operation almost universally supported by host processors), not to load its address and indirectly call it.

Coding Guidelines

The fact that a function designator is implicitly converted to a pointer-to function type is not well-known to developers. From the practical point of view, this level of detail is unlikely to be of interest to them. Using the unary **&** operator allows developers to make their intentions explicit. The address is being taken and the parentheses have not been omitted by accident. Use of this operator may be redundant from the translators point of view, but from the readers point of view, it can be a useful cue to intent. In:

```
1  int f(void)
2  { /* ... */ }
3
4  void g(void)
5  {
6  if (f)  /* Very suspicious. */
7     ;
8  if (f())
9     ;
10 if (&f) /* Odd, but the intent is clear. */
11    ;
12 }
```

Cg 732.1 When the address of a function is assigned or compared against another value, the address-of operator shall be applied to the function designator.

Example

In the following, all the function calls are equivalent:

```
1   void f(void);
2
3   void g(void)
4   {
5   f();
6   (f)();
7   (*f)();
8   (**f)();
9   (**********f)();
10  (&f)();
11  }
```

they all cause the function `f` to be called.

Forward references: address and indirection operators (6.5.3.2), assignment operators (6.5.16), common definitions **<stddef.h>** (7.17), initialization (6.7.8), postfix increment and decrement operators (6.5.2.4), prefix increment and decrement operators (6.5.3.1), the **sizeof** operator (6.5.3.4), structure and union members (6.5.2.3). 733

---

footnote 53

53) The name "lvalue" comes originally from the assignment expression **E1 = E2**, in which the left operand **E1** is required to be a (modifiable) lvalue. 734

Commentary

Or *left value* of assignment. The *right value* being called the rvalue. This is translator writers' terminology that the C Standard committee has adopted.

C++

The C++ Standard does not provide a rationale for the origin of the term *lvalue*.

Other Languages

Many languages have terms denoting the concept of lvalue and rvalue. Some use these exact terms.

It is perhaps better considered as representing an object "locator value". 735

Commentary

Many languages only allow an object to be modified through assignment. C is much more flexible, allowing objects to be modified by operators other than assignment (in the case of the prefix increment/decrement operators the object being modified appears on the right). Happily, the term *locator* starts with the letter *l* and can be interpreted to have a meaning close to that required.

Coding Guidelines

This term is not in common usage by any C related groups or bodies. The term *lvalue* is best used. It is defined by the C Standard and is also used in other languages.

---

rvalue

What is sometimes called "rvalue" is in this International Standard described as the "value of an expression". 736

Commentary

The term *rvalue* only appears in this footnote. It is not generally used by C developers, while the term *value of expression* is often heard.

C++

The C++ Standard uses the term *rvalue* extensively, but the origin of the term is never explained.

3.10p1

Every expression is either an lvalue or an rvalue.

Other Languages

The term *rvalue* is used in other languages.

Coding Guidelines

The term *value of an expression* is generally used by developers. While the term *rvalue* is defined in the C++ Standard, its usage by developers in that language does not appear to be any greater than in C. There does not seem to be any benefit in trying to change this commonly used terminology.

---

737 An obvious example of an lvalue is an identifier of an object.

Commentary

A nonobvious lvalue is a string literal. An obvious example of an rvalue is an integer constant.

903 string literal static storage duration

---

738 As a further example, if **E** is a unary expression that is a pointer to an object, ***E** is an lvalue that designates the object to which **E** points.

Commentary

And it may, or may not also be a modifiable lvalue.

---

739 54) Because this conversion does not occur, the operand of the **sizeof** operator remains a function designator and violates the constraint in 6.5.3.4.

footnote 54

Commentary

The committee could have specified a behavior that did not cause this constraint to be violated. However, the size of a function definition is open to several interpretations. Is it the amount of space occupied in the function image, or the number of bytes of machine code generated from the statements contained within the function definition? What about housekeeping information that might need to be kept on the stack during program execution? Whichever definition is chosen, it would require a translator to locate the translated source file containing the function definition. Such an operation is something that not only does not fit into C's separate compilation model, but could be impossible to implement (e.g., if the function definition had not yet been written). The Committee could have specified that the size need not be known until translation phase 8 (i.e., link-time) but did not see sufficient utility in supporting this functionality.

1118 sizeof constraints

139 translation phase 8

C++

The C++ Standard does not specify that use of such a usage renders a program ill-formed:

*The **sizeof** operator shall not be applied to an expression that has function or incomplete type, or to an enumeration type before all its enumerators have been declared, or to the parenthesized name of such types, or to an lvalue that designates a bit-field.* 5.3.3p1

6.3.2.2 void

---

740 The (nonexistent) value of a *void expression* (an expression that has type **void**) shall not be used in any way, and implicit or explicit conversions (except to **void**) shall not be applied to such an expression.

void expression

Commentary

This defines the term *void expression*. It makes no sense to take an expression having a type that cannot represent any values and cast it to a type that can represent a range of values. As specified here, these requirements do not require a diagnostic to be issued. However, constraint requirements in the definition of the cast operator do require a translator to issue a diagnostic, if a violation occurs.

1134 cast scalar or void type

C++

3.9.1p9 *An expression of type* **void** *shall be used only as an expression statement (6.2), as an operand of a comma expression (5.18), as a second or third operand of* **?:** *(5.16), as the operand of* **typeid**, *or as the expression in a return statement (6.6.3) for a function with the return type* **void**.

The C++ Standard explicitly enumerates the contexts in which a void expression can appear. The effect is to disallow the value of a void expression being used, or explicitly converted, as per the C wording.
The C++ Standard explicitly permits the use of a void expression in a context that is not supported in C:

```
1  extern void g(void);
2
3  void f(void)
4  {
5  return g(); /* Constraint violation. */
6  }
```

5.2.9p4 *Any expression can be explicitly converted to type "cv* **void***."*

Thus, C++ supports the **void** casts allowed in C.

Other Languages

In many languages the assignment token is not an operator; it is a token that appears in an assignment statement. Casting away the result of an assignment is not possible because it does not have one. Also there is often a requirement that functions returning a value (those that don't return a value are often called procedures or subroutines) must have that value used.

Coding Guidelines

It is possible for a program to accidentally make use of a *void value*; for instance, if a function is defined with a **void** return type, but at the point of call in a different translation unit, it is declared to return a scalar type. The behavior in this case is undefined because of the mismatch between definition and declaration at the point of call. If the guideline recommendations on having a single point of declaration is followed this situation will not occur.

function call not compatible with definition 1024
identifier declared in one file 422.1

If an expression of any other type is evaluated as a void expression, its value or designator is discarded. 741

Commentary

A void expression can occur in an expression statement and as the left operand of the comma operator. According to the definition of a void expression, it has type **void**. In the example below the expression statement `x = y` has type **int**, not **void**. But in this context its value is still discarded. In the following:

void expression 740

```
1  int x, y;
2
3  void f(void)
4  {
5  x = y;
6  (void)(x = y);
7
8  x = (y++, y+1);
9  x = ((void)y++, y+1);
10 }
```

all of the statements are expressions, whose value is discarded after the assignment to `x`.

C90

If an expression of any other type occurs in a context where a void expression is required, its value or designator is discarded.

The wording in the C90 Standard begs the question, "When is a void expression required"?

C++

There are a number of contexts in which an expression is evaluated as a void expression in C. In two of these cases the C++ Standard specifies that lvalue-to-rvalue conversions are not applied: Clauses 5.18p1 left operand of the comma operator, and 6.2p1 the expression in an expression statement. The other context is an explicit cast:

Any expression can be explicitly converted to type "`cv` ***`void`****." The expression value is discarded.* 5.2.9p4

So in C++ there is no value to discard in these contexts. No other standards wording is required.

Other Languages

Most languages require that the value of an expression be used in some way, but then such languages do not usually regard assignment as an operator (which returns a value) or have the equivalent of the comma operator. In many cases the syntax does not support the use of an expression in a context where its value would be discarded.

Common Implementations

For processors that use registers to hold intermediate results during expression evaluation, it is a simple matter of ignoring register contents when there is no further use for its contents. For stack-based architectures the value being discarded has to be explicitly popped from the evaluation stack at some point. (As an optimization, some implementations only reset the evaluation stack when a backward jump or function **`return`** statement is encountered.)

Coding Guidelines

1732 expression statement evaluated as void expression
1314 comma operator left operand

All expression statements return a value that is not subsequently used, as does the left operand of the comma operator. However, all of the information needed for readers to evaluate the usage is visible at the point the statement or operator appears in the source.

In the case of a function returning a value that is not used, the intent may not be immediately visible to readers. Perhaps the function had not originally returned a value and a later modification changed this behavior. One way of indicating, to readers, that the return value is being intentionally ignored, is to use an explicit cast (the exception for library functions is given because the specification of these functions' return type rarely changes).

Cg 741.1 If a function, that does not belong to a standard library, returning a non-void type is evaluated as a void expression its result shall be explicitly cast to **`void`**.

Example

```
1  extern int f(void);
2
3  void g(void)
4  {
5  (void)f();
6  }
```

(A void expression is evaluated for its side effects.) 742

Commentary

redundant code 190 A void expression is not required to have any side effects. The issue of redundant code is discussed elsewhere.

C++

This observation is not made in the C++ Standard.

Example

In the following:

```
1  int i,
2      j;
3
4  extern int f(void);
5
6  void g(void)
7  {
8  i+1;     /* expression 1 */
9  j=4;     /* expression 2 */
10 4+(i=3); /* expression 3 */
11 (void)f();
12 }
```

execution of *expression 1* will not change the state of the abstract machine. It contains no side effects. Execution of *expression 2* will change the state of the abstract machine, but it may not have any effect on subsequent calculations; or, if it does, those calculations may not have any effect on the output of the program, so is a redundant side effect. *expression 3* contains a side effect, but in a nested subexpression. The root operator in *expression 3* does not contain a side effect.

6.3.2.3 Pointers

pointer to void converted to/from

A pointer to **void** may be converted to or from a pointer to any incomplete or object type. 743

Commentary

generic pointer 523 Pointer to **void** is intended to implement the concept of a generic pointer (other terms include abstract pointer, anonymous pointer), which may point at an object having any type. Constraints on pointer conversions are discussed elsewhere.

pointer conversion constraints 1135

C++

5.2.9p10 *An rvalue of type "pointer to* `cv` ***void****" can be explicitly converted to a pointer to object type.*

object types 475 In C++ incomplete types, other than `cv` **void**, are included in the set of object types.

In C++ the conversion has to be explicit, while in C it can be implicit. C source code that relies on an implicit conversion being performed by a translator will not be accepted by a C++ translator.

The suggested resolution to SC22/WG21 DR #137 proposes changing the above sentence, from 5.2.9p10, to:

Proposed change to C++ *An rvalue of type "pointer to* `cv1` ***void****" can be converted to an rvalue of type "pointer to* `cv2` *T", where T is an object type and* `cv2` *is the same cv-qualification as, or greater cv-qualification than,* `cv1`*.*

If this proposal is adopted, a pointer-to qualified type will no longer, in C++, be implicitly converted unless the destination type is at least as well qualified.

Common Implementations

A pointer to **void** is required to have the same representation as a pointer to **char**. On existing processors where there is a difference between pointer representations, it is between pointer-to character types and pointers-to other types. So the above requirement is probably made possible by the previous representation requirement.

558 pointer to void same representation and alignment as
